The Snowflake Divertor (SD) control and detachment control to manage the heat flux at the divertor are successfully demonstrated at DIII-D. Results of the development and implementation of these two heat flux reduction control methods are presented.

1. Snowflake Divertor control

The present vision of the tokamak plasma–material interface is an axisymmetric magnetic X-point divertor. One approach to handling the high heat exhaust per unit area on the PFCs is to use alternative magnetic configurations. Examples of these advanced divertors are the snowflake divertor (SD), X-divertor, super X-divertor, and X-point target divertor. These configurations require active and precise control of the magnetic configuration in order to regulate the particle and heat flow.

Recent research at DIII-D focused on the SD configuration, which uses a second-order poloidal field null created by merging, or bringing close to each other, two first-order poloidal field null points (X-points) of a standard divertor configuration [1]. A poloidal cross-section of the obtained magnetic flux surfaces with a hexagonal null-point has the appearance of a snowflake. The SD geometry results in high poloidal flux expansion and a large plasma-wetted area compared to the standard divertor, which reduces peak heat flux. Also, SD has four strike points which help share the divertor power load, compared to the two-strike-point configuration.

The exact second-order null configuration is topologically unstable to variations in coil currents, which destroy the perfect alignment. This splits the double null into two first-order null X-points, and two variants of the exact configuration called snowflake-plus and snowflake-minus are often realized in steady-state, as shown in Figure 1.
Figure 1. Three plasma equilibria in DIII-D showing the exact snowflake configuration with a double null; the snowflake-minus configuration with the secondary X-point in the private flux region; and the snowflake-plus configuration with the secondary X-point in the Scrap-Off Layer (SOL).

We implemented the world’s first real-time SD detection and control system on DIII-D in order to stabilize this configuration. This control employs a fast real-time snowflake identification algorithm, which accurately calculates two X-points (magnetic nulls) by locally expanding the Grad-Shafranov equation in toroidal coordinates. We assume that the plasma in the divertor region has a low beta, and the magnetic field there can be considered curl-free. Then, the equation in toroidal coordinates around the divertor is given as

\[ r \frac{\partial}{\partial r} \left( \frac{1}{r} \frac{\partial \Psi}{\partial r} \right) + \frac{\partial^2 \Psi}{\partial z^2} = 0. \]

This equation is normalized and \( \Psi \), the magnetic flux, is expanded around the snowflake center in radial, \( \delta r \), and vertical, \( \delta z \), coordinates up to the third order to achieve

\[ \Psi_{\text{exp}} = \Psi(c_{\text{exp}}, \delta r, \delta z), \]

where \( c_{\text{exp}} \) are the expansion coefficients. Solving the first two orders of the expanded Grad-Shafranov (G-S) equation yields six unknown expansion coefficients. These unknowns are solved by first choosing three points around the snowflake center and then evaluating the components of the magnetic field given as

\[ B_r = \frac{1}{r} \frac{\partial \Psi_{\text{exp}}}{\partial \delta z}, \quad B_z = \frac{1}{r} \frac{\partial \Psi_{\text{exp}}}{\partial \delta x}, \]

from the real-time equilibrium reconstruction (rt-EFIT). This gives us six linear equations for the six unknown expansion coefficients. These equations are solved using Gaussian elimination. Finally, the magnetic field nulls are solved by setting \( B_r = 0, B_z = 0 \). This results in the location of the two X-points: \( \delta r_{X_1}(c_{\text{exp}}), \delta z_{X_1}(c_{\text{exp}}) \), \( \delta r_{X_2}(c_{\text{exp}}), \delta z_{X_2}(c_{\text{exp}}) \). The resulting algorithm is a one-step (no-iteration) fast algorithm (<<1ms) with reasonable accuracy, which has been implemented in the DIII-D Plasma Control System (PCS).
Once the locations of the two X-points are obtained, poloidal field (PF) coils are used to control the relative locations to obtain the desired SD (exact, minus, plus). At DIII-D, the F4B, F5B, F8B are the PF coils closest to the diverter and they have therefore been used to control the SD. F9B is also effective in the SD manipulation. However, in order to avoid damage to the unprotected surfaces inside the cryopump, the strike point must be prevented from entering the cryopump gap under any possible circumstances. To satisfy this constraint without inducing any hardware or software protection, the F9B coil is set to be zero current.

The SD control algorithm calculates the distance and angle (defined in Figure 2.a) components of the relative positions of the two X-points in addition to the coordinates of the snowflake centroid, $r_c$ and $z_c$. The values are compared to the user-requested values and the differences are filtered and fed to the control algorithm. For precise control, the effect of the change in PF coil currents, $\delta I_{PF}$, on the X-point locations is calculated. This is achieved by applying the chain rule on the snowflake parameters:

$$\frac{\partial \delta r_{x_i}}{\partial I_{PF}} = \frac{\partial \delta r_{x_i}}{\partial c_{exp}} \left( \frac{\partial c_{exp}}{\partial B_r} \frac{\partial B_r}{\partial I_{PF}} + \frac{\partial c_{exp}}{\partial B_z} \frac{\partial B_z}{\partial I_{PF}} \right).$$

Here, the first two terms, $\frac{\partial \delta r_{x_i}}{\partial c_{exp}}$ and $\frac{\partial c_{exp}}{\partial B_r}$, are obtained through the manipulation of the G-S expansion, as explained above. $\frac{\partial B_z}{\partial I_{PF}}$ is found from the Green’s Function of the G-S problem. This enables us to write the variation of the snowflake geometric parameter in terms of the PF coil currents as

$$\begin{bmatrix}
\delta \theta \\
\delta \rho \\
\delta r_c \\
\delta z_c
\end{bmatrix} = A \begin{bmatrix}
\delta I_{F4B} \\
\delta I_{F5B} \\
\delta I_{F8B}
\end{bmatrix}.$$ 

Then, the control needed to achieve the requested snowflake configuration is obtained by taking the pseudo-inverse of this equation and multiplying it by a weighting function, $W$,

$$\begin{bmatrix}
\delta I_{F4B} \\
\delta I_{F5B} \\
\delta I_{F8B}
\end{bmatrix} = (A^T A)^{-1} A^T W \begin{bmatrix}
\delta \theta \\
\delta \rho \\
\delta r_c \\
\delta z_c
\end{bmatrix}.$$ 

Since there are three actuators and four control parameters, the weighing function is used to define the importance of the parameters that we wish to control. Then, a Proportional-Integral-Derivative control is used to obtain the PF-coil voltage requests to the power supplies.
An example of an almost exact SD obtained with the snowflake control is shown in Figure 2, where the SD control is turned on at 3 seconds (shown with the red line) and $\rho$ is controlled to a few cm until the end of the shot. Note that this is within the grid resolution of the rt-EFIT. As the perfect SD is approached, broadening of the heat flux profile at the outer strike point is observed, as shown in Figure 2.b.

**Figure 2.** (a) PF coils used in SD control and the definition of the SD configuration parameters. (b) Plasma controlled to almost exact SD. The SD control starts at 3000 ms. The lower panel shows the heat flux at the outer strike point (#155478).

This control enabled SD minus, SD plus, and exact SD formations with varying $\sigma$, the distance between the X-points normalized to the minor radius, ranging from 0.08 to 0.5 in various scenarios. SD was successfully integrated to an advanced tokamak (AT) scenario with $\beta_N = 3.0$ and $H98(y,2) \cong 1.35$. The flux profile for AT scenario with the standard divertor and SD is shown in Figure 3. We achieved a 2.5 times increase in the flux expansion and a 2.5 reduction in peak heat flux for many energy confinement times (2-3 s) without any adverse effects to the core plasma, such as confinement. The maximum allowable heat flux on plasma-facing tiles stipulate that SD will operate under radiative conditions for fusion reactors. The radiative SD regime was explored with the gas seeding. SD control was shown to be robust under partial and full detachment conditions.
2. Detachment control

Divertor “detachment”, where the particle flux at the target plates drops by more than an order of magnitude, is achieved by increasing the density close to the divertor. The ITER tokamak and future fusion reactors will require detached divertor plasmas to achieve acceptable divertor target heat loads. However, it is difficult to stabilize this effect when plasmas become fully detached. The influx of impurities into the confined plasma cause high radiation levels from this region, which may result in the thermal instability of the whole plasma, known as MARFE (Multi-faceted Asymmetric Radiation From the Edge). Thus, ITER needs to operate in a state called partial-detachment under active feedback control in order to balance the need for acceptable divertor target heat loads and core stability.

We developed a new feedback control system on DIII-D to regulate and study the physics of divertor detachment. The system uses real-time electron temperature measurements from Thomson scattering, along with impurity line ratio measurement, to compute the location of the detachment front, while monitoring the core and divertor radiation measured by the bolometer diagnostic. We employed the new system to test the feasibility of envisioned ITER partial-detachment operation, using divertor Thomson measurements on DIII-D. (ITER will have a divertor Thomson with the diagnostic capability to measure as low as 1 eV [2].) This control regulates the detachment front while minimizing the effect of the detachment on the core by fixing the core density independent of the detachment control. This is achieved by a feedback control system that uses two gas valves, as shown in Figure 4. The valve close to the strike point regulates both deuterium fuel and impurity gas injection rates to maintain the detachment front (where the plasma temperature drops to less than a few eV) at a pre-set distance from the divertor target using the real-time electron temperature measurements, and

Figure 3. The heat flux profile at the inner and outer strike point for (a) the standard divertor double null AT and (b) the SD (-) double null AT.

Figure 4. Sketch of the partial-detachment control system
the far-away valve keeps the core density stationary by using the interferometry measurements.

The comparison of the core and divertor density of two DIII-D L-mode shots with and without detachment control is shown in Figure 5. The feedback algorithm increases the density at the divertor by a factor of \(~5\), which leads to detachment, while keeping the core density constant.

![2D Projected divertor Thomson temperature measurements for DIII-D.](image)

**Figure 6.** 2D Projected divertor Thomson temperature measurements for DIII-D: (a) shot without detachment control (#153814) shows no detachment, (b) shot with partial-detachment control (#153816) achieves detached cold front region, shown in purple and blue.
The control stabilized the detachment front fixed at the mid-distance between the strike point and the X-point throughout the shot, as shown in the 2D Thomson projection in Figure 6. This partial detachment reduces the radiation peak from the strike point and spreads it across the detached area, as shown in Figure 7. The new system allows the systematic study of the physics of plasma detachment and plasma-surface interactions under constant, reproducible conditions. The data from these experiments are used to test 2D models of the scrape-off-layer and divertor plasma as well as to interpret surface erosion and material migration measurements.

Figure 7. Radiation profile for DIII-D: (a) shot without detachment control (#153814) shows peaked radiation from the strike point, (b) shot with partial-detachment control (#153816) spreads the radiation across the detached area.
