Histone acetylation

ABSTRACT

Extracellular matrix (ECM) regulates cell morphology and gene expression in vivo; these relationships are maintained in three-dimensional (3D) cultures of mammary epithelial cells. In the presence of laminin-rich ECM (lrECM), mammary epithelial cells round up and undergo global histone deacetylation, a process critical for their functional differentiation. However, it remains unclear whether lrECM-dependent cell rounding and global histone deacetylation are indeed part of a common physical–biochemical pathway. Using 3D cultures as well as nonadhesive and micropatterned substrata, here we showed that the cell ‘rounding’ caused by lrECM was sufficient to induce deacetylation of histones H3 and H4 in the absence of biochemical cues. Microarray and confocal analysis demonstrated that this deacetylation in 3D culture is associated with a global increase in chromatin condensation and a reduction in gene expression. Whereas cells cultured on plastic substrata formed prominent stress fibers, cells grown in 3D lrECM or on micropatterns lacked these structures. Disruption of the actin cytoskeleton with cytochalasin D phenocopied the lrECM-induced cell rounding and histone deacetylation. These results reveal a novel link between ECM-controlled cell shape and chromatin structure and suggest that this link is mediated by changes in the actin cytoskeleton.

INTRODUCTION

Cell structure and function were postulated to be intimately connected in maintenance of tissue homeostasis [1]. Manipulating cellular and nuclear morphology in culture can induce a variety of functional changes, including glucose uptake and metabolism [2], proliferation [3–5], apoptosis [4], differentiation and gene expression [6–10]. These morphologically driven processes are controlled by the local microenvironment as exemplified in the mammary gland and mammary epithelial cells (for a review see [11]). Isolated mouse mammary epithelial cells can be induced to undergo structural and functional

differentiation in three-dimensional (3D) cultures. The acquisition of the functionally differentiated phenotype, i.e. expression of milk proteins, requires lactogenic hormones and the basement membrane protein laminin-111 (laminin-1) [12,13]. The latter induces dramatic morphological changes in that cells become rounded and actin becomes cortical. These morphological changes are necessary for expression of some milk proteins including β-casein [9]. Artificially pre-rounding the cells by plating on the nonadhesive substratum poly(2-hydroxyethyl methacrylate) (polyHEMA) poises them for responsiveness to prolactin and laminin-rich ECM (lrECM) [9], whereas preventing cell rounding by treatment with the phorbol ester 12-0-tetradecanoylphorbol 13-acetate (TPA) inhibits milk protein synthesis [14]. These previous findings strongly suggested that cell rounding, mediated by reorganization of actin filaments and other cytoskeletal components, may be an important physical signal conveyed by the ECM leading to changes in gene expression.

Cell fate and differentiated function are controlled by patterns of gene expression, which in turn are dictated by chromatin organization. The structure of chromatin is regulated by a number of post-translational modifications at the amino-terminal tails of nucleosomal histones, including acetylation/deacetylation, phosphorylation, methylation, and ADP ribosylation [15]. The acetylation status of chromatin is dynamic, balanced by the activities of histone acetyltransferases (HATs) and histone deacetylases (HDACs) [16]. Gene expression generally correlates with histone hyperacetylation at promoter regions and other regulatory cis-elements [17–19] whereas histone deacetylation represses transcription by promoting chromatin condensation into heterochromatin [20,21]. Histone deacetylation was shown to correlate with changes in gene expression in the developing brain in rats [22], and abrogating the deacetylation by treatment with an HDAC inhibitor resulted in impaired brain development and delayed expression of differentiation markers. Functional differentiation of many cell types is associated with activation of specific subsets of genes, silencing of other genes, and extensive formation of heterochromatin [23].

Acinar morphogenesis of a non-malignant human mammary epithelial cell line HMT3522-S1 is accompanied by rearrangements in chromatin structure and nuclear architecture [24–26]. These reorganizations appear to be important for establishing and maintaining the normal phenotype of cells in 3D [24,25,27]. We previously found that the global level of histone acetylation is critical for functional differentiation of mammary epithelial cells [24,28]. Altering chromatin structure by increasing histone acetylation with trichostatin A induces human mammary epithelial cells to alter their morphology, re-enter the cell cycle, and become disorganized [24]; overexpressing an HAT in mouse mammary epithelial cells inhibits production of endogenous β-casein in response to lrECM [28]. Conversely, treatment with lrECM induces global histone deacetylation in human and mouse mammary epithelial cells [25,28].

These previous studies showed that ECM has profound effects on cell shape and chromatin structure, particularly histone deacetylation, but it was not understood whether these effects were linked. In this report, we used several strategies to change cell shape, including 3D culture on different substrata with different adhesiveness and micropatterned substrata. We find that cell rounding per se induces global histone deacetylation and an increase in chromatin condensation and that these processes are associated with a global reduction of gene expression. These results reveal a process by which ECM integrates structure and function in mammary epithelial cells through a shape-dependent global histone deacetylation.

Materials and methods

Cell culture

HMT-3522-S1 and -T4-2 human mammary epithelial cells [29,30] were grown as two-dimensional (2D) monolayers on plastic or within 3D lr ECM (Matrigel, Collaborative Research) and maintained as previously described [31,32]. Cells were grown in 2D and 3D for 10 days before harvests. For culture on nonadhesive substrate, ~4000 cells/cm² were seeded on polyHEMA (Sigma)-coated plates prepared as previously described for mouse mammary epithelial cells [9].

Micropatterning

Micropatterned substrata consisting of collagen-coated islands were created as described [33]. Briefly, elastomeric stamps containing a relief of the desired pattern were coated with type I collagen (50 μg/mL in water; Vitrogen 100, Cohan Technologies, Palo Alto, CA) for 2 h, washed with water, and dried under a stream of nitrogen. Flat poly(dimethylsiloxane) (PDMS; Sylgard 184, Elsworthy Adhesives, Germantown, WI) elastomer-coated substrata were UV-oxidized for 7 min (UVO Cleaner, Jeffilco, Irvine, CA), stamped with collagen, blocked with 1% pluronic F108 (BASF Corp., Florham Park, NJ) in water for 1 h, and rinsed in PBS before seeding T4-2 cells. Cells were allowed to attach to the patterned islands for approximately 30 min before washing away the remaining floating cells. A flat block of PDMS was coated with collagen and stamped for the unpatterned substratum control. For measurements of projected cell area, phase contrast images of individual cells were outlined and processed with Scion Image software.

Global gene expression analysis

cDNA microarrays with ~8000 known genes spotted on poly-L-lysine-coated chips (custom arrayed at Lawrence Berkeley National Laboratory using Research Genetics 8k human clones) were used. mRNA samples of interest were directly compared to each other by co-hybridization to the same slide using dendrimer technology to label with red-Cy5 and green-Cy3 (Genisphere). Total RNA (1 μg) isolated with Qiagen RNeasy reagents was used for each sample hybridized. Cells in 3D lrECM were extracted using 5 mM EDTA in cold PBS to dissolve the Matrigel. For each comparison, 3 independent sets of cells cultured for 10 days were processed, and 4 slides were hybridized. This corresponded to 3 sets of RNA from independent culture sets plus a dye-swap experiment in which the red and green label was switched for the two samples in question to account for dye-specific effects. Arrays were scanned using a GenePix scanner (Axon). Raw data for each channel (red and green) were loaded onto GeneSpring (Silicon Genetics) for normalization and analysis. For each chip, per-spot and per-chip intensity-dependent Lowess
normalization was performed using 20% of data for smoothing at a cutoff value for a signal of 10. This was followed by normalization of each chip to the 50th percentile of the measurements taken from that chip, without extra background correction. Differential gene expression was determined at the $t$-test $p$-value of 0.01 or lower.

Immunofluorescence analysis

Samples were fixed in 2% paraformaldehyde in PBS, rinsed in 50 mM glycine in PBS, blocked in 10% goat serum, and stained with a 1:500 dilution of FITC-phalloidin (Molecular Probes) or with a 1:100 dilution of AcH4 antibody in PBS. Stained samples were imaged using a Spot RT camera attached to a Zeiss upright epifluorescence microscope or a Stanford Photonics XR/Mega-10 ICCD camera attached to a Zeiss spinning disk confocal microscope.

DNA was stained with DAPI and the corresponding fluorescence was measured by acquiring confocal sections separated by 0.16 μm using a spinning disk confocal microscope. Confocal images were corrected for background. To assess the nuclear volume, a common intensity threshold was established to define the edge of the nuclei in each confocal section and calculate the enclosed area. The total fluorescence intensity was divided by the nuclear volume to obtain the average dye spatial density, which correlates with the average chromatin packing ratio [36]. All image processing was performed using Image J software.

Western blotting

Total protein from S1 or T4-2 cells was extracted with lysis buffer [50 mM Tris (pH 7.4), 30 mM NaCl, 2% (w/v) SDS, and protease inhibitor cocktail]. After sonication, an equal amount of protein from each sample was subjected to SDS gel electrophoresis and then transferred to nitrocellulose membrane (Schleicher and Schuell). The membrane was subsequently blocked in TBST buffer [50 mM Tris (pH 8.0), 150 mM NaCl, 0.1% (v/v) Tween 20] containing 5% nonfat dried milk then incubated in blocking buffer containing primary antibody (AcH3 and AcH4 from Upstate; total H3 from Santa Cruz). All blots were further incubated in blocking buffer containing horseradish peroxidase-conjugated secondary antibodies and subjected to enhanced chemiluminescence (ECL) using the SuperSignal chemiluminescent substrate (Pierce, Rockford, IL). The results were quantified with AlphaEaseFC software, and Student’s $t$ test was performed using SigmaPlot.
Quantitative real-time PCR analysis

Total RNA was extracted from cells with Trizol reagent (Invitrogen). cDNA was synthesized using Superscript first strand synthesis kit (Invitrogen) from equal amounts of RNA. Quantitative real-time PCR analysis was performed with the Lightcycler System (Roche) using the Lightcycler FastStart DAN Master SYBR Green I kit (Roche). The following primers were used to amplify p21 and 18S sequences: forward primer of the p21 gene 5′-CTGGGGATGTTCCGTAAGAAC-3′ and reverse primer 5′-AGCGAGGCAACAA-3′; forward primer of the 18S gene: 5′-ACGACAGGAGGATAA-3′ and reverse primer 5′-GGAATCTCAAGGAC-3′. The following Lightcycler PCR amplification protocol was used: 95 °C for 10 min, and 45 amplification cycles (95 °C for 5 s, 60 °C for 10 s, 72 °C for 5 s). Amplification was followed by melting curve analysis to verify the presence of a single PCR product [34]; 18S was amplified as a reference gene using the same protocol.

Chromatin immunoprecipitation (ChIP) assay

ChIP assays were performed using a commercially available kit (ChIP kit; Upstate Biotechnology, Lake Placid, NY) as per manufacturer instructions. For 2D conditions, 1 × 10^7 S1 cells grown in a 100-mm dish were cross-linked with 1% formaldehyde at room temperature for 10 min. For 3D conditions, S1 cells were isolated from lrECM using PBS/EDTA and cross-linked as above. Cells were washed with PBS, resuspended, and lysed in ChIP lysis buffer (1% SDS, 10 mM EDTA, 50 mM Tris–HCl pH 8.0). Sonicated lysates were diluted with ChIP dilution buffer and bound to protein A–agarose beads. The precleared lysates were then immunoprecipitated with AcH3 or AcH4 antibodies (Upstate Biotechnology), collected with protein A–agarose beads, and washed sequentially with each of the following buffers: low salt wash buffer (0.1% SDS, 1% Triton X-100, 2 mM EDTA, 20 mM Tris–HCl pH 8.0, 150 mM NaCl); high salt wash buffer (0.1% SDS, 1% Triton X-100, 2 mM EDTA, 20 mM Tris–HCl pH 8.0, 500 mM NaCl); LiCl buffer (0.25 M LiCl, 1% NP-40, 1% SDC, 1 mM EDTA, 10 mM Tris–HCl pH 8.0); TE buffer (20 mM Tris–HCl pH 8.0, 1 mM EDTA pH 8.0). The remaining bound p21 promoter DNA was PCR-amplified using the following primers: forward primer 5′-GGTAGTGCTAGTGCTCAGAC-3′ and reverse primer 5′-GGAAGCTACCAGAC-3′.

Results

Culturing cells in 3D lrECM induces alterations in cellular morphology and global histone deacetylation

Culturing non-malignant breast epithelial S1 cells in 3D within lrECM allows the cells to form spherical polarized structures that resemble mammary acini in vivo (Fig. 1A), whereas the cells form monolayers when they are cultured in 2D.
Immunofluorescence and western blot analysis showed that levels of both acetylated histones H3 and H4 were reduced in 3D cultures (Figs. 1A–C). Histone deacetylation is associated with chromatin condensation, and hypoacetylation of histones is commonly used as a marker of heterochromatin [35]. Here we used the average 4′,6-diamidino-2-phenylindole (DAPI) spatial density to assess global changes in chromatin condensation because the density of DAPI staining in nuclei increases with the chromatin packing ratio [36,37]. We found that S1 cells in 3D IrECM had higher DAPI density than cells cultured in 2D (Fig. 1D). These data indicate that the histone deacetylation in 3D cultures is associated with increased chromatin compaction. In addition, the tissue-like morphogenesis observed in 3D was accompanied by a significant decrease in nuclear diameter (Fig. 1E).

T4-2, the tumorigenic derivative of S1 cells, form large non-polarized and disorganized colonies in 3D IrECM reminiscent of tumors in vivo, but they still respond to IrECM by changing cell shape (Supplemental Fig. A). To determine whether global histone deacetylation was the result of acinar morphogenesis, we measured the levels of acetylated histones H3 and H4 in T4-2 cells which form disorganized structures in IrECM. Histone acetylation was decreased in 3D culture, whether or not the cells were polarized (Figs. 1B, C), indicating that the reduction in histone deacetylation is a response either to ECM-induced cell rounding or to ECM-induced signaling.

Cell rounding induces global histone deacetylation

To test whether changes in cell morphology could alter histone acetylation, we compared cells cultured on plastic with those cultured on the nonadhesive substratum polyHEMA, which prevents cell attachment and spreading and allows examination of the role of cellular shape independently of ECM signaling [3,9]. Both S1 (Fig. 2A) and T4-2 (data not shown) cells adopted a rounded morphology when cultured on polyHEMA. Culturing cells on polyHEMA for 4 days also caused them to cluster together (Fig. 2A). Immunofluorescence and western blot analysis of acetylated histones H3 and H4 demonstrated that cultivation on polyHEMA leads to histone deacetylation in both S1 and T4-2 cells (Figs. 2A–C). Additionally, histone deacetylation in cells on polyHEMA is associated with chromatin condensation and a decrease in nuclear size (Figs. 2D, E). Adding IrECM to cells cultured on polyHEMA did not decrease histone acetylation.
levels further (data not shown), indicating that histone deacetylation induced by lrECM is due specifically to an effect of cell rounding or cell clustering and that ECM ligand-induced signaling does not potentiate this effect.

To delineate the effects of cell rounding from those of cell clustering, we used a micropatterning approach to maintain single attached cells in a rounded morphology. Cells were cultured on micropatterned substrata that contained micrometer-sized islands of collagen surrounded by nonadhesive regions. Cells plated on these substrata could only attach to the collagen-coated islands; individual cells cultured on small islands were prevented from spreading. We compared unpatterned and freely spread T4-2 cells with those patterned on 25-μm square islands (Fig. 3A). T4-2 cells plated on micropatterned substrata remained rounded compared to those plated on unpatterned collagen-coated substrata (Fig. 3A). Whereas control cells formed stress fibers, patterned cells exhibited mainly cortical actin (Fig. 3A). The mean projected area of individual cells plated on the micropatterned substrata was significantly reduced when compared to cells plated on tissue culture plastic (Supplemental Fig. B). Western blot analysis showed that levels of acetylated histones H3 and H4 were reduced in patterned cells compared to unpatterned cells (Figs. 3B, C). Quantification of DAPI staining demonstrated that patterned cells had more compacted chromatin than unpatterned cells (Fig. 3D), accompanied by a reduction in nuclear size in the patterned cells (Fig. 3E). These data show that ECM-induced cell rounding directly controls histone deacetylation and chromatin condensation in mammary epithelial cells. It further indicates that even malignant T4-2 cells remain sensitive to shape-induced changes in their microenvironment.

Cell shape is largely governed by the actin cytoskeleton [38]. Shape dependence therefore implies a requirement for a particular actin organization. Indeed, one of the striking differences we noticed between cells spread on plastic and those rounded in 3D lrECM or on micropatterned substrata was the organization of the actin cytoskeleton. Both S1 and T4-2 cells cultured in 2D exhibited prominent stress fibers as well as cortical actin when stained with fluorescently tagged phalloidin (Fig. 4A). In contrast, even though the gross architectures of the colonies formed by these cells differed substantially, individual S1 and T4-2 cells appeared similarly rounded in 3D (Fig. 1A and Supplemental Fig. A) with mainly cortical actin (Fig. 4A). Cells rounded by culture on micropatterned substrata also showed prominent cortical actin (Fig. 3A). To address the involvement of shape and actin organization in regulation of histone acetylation,
global histone deacetylation, we performed microarray analysis. In 3D lrECM induced a reduction in gene expression in addition to all genes with p to levels of 18S in the same samples. (**)p (green). (B) Quantitative RT/PCR analysis for p21 normalized mRNA levels in 3D (red); 162 genes have lower levels in 3D deacetylation. Changes associated with cell rounding induce global histone H3 and H4 (Figs. 4C, D). Importantly, removal of the drug increase in histone acetylation (Fig. 4D). Therefore, cytoskeletal reversed cell morphology (data not shown) and induced an rounding (Fig. 4B), and reduced the levels of acetylated histones with this drug disrupted actin microfilaments, induced cell histone deacetylation in 3D culture regulates gene expression. (A) Ratio of global mRNA levels for S1 cells cultured in 2D and 3D lrECM. The x-axis shows mean ratio of 3D/2D for four experiments; all genes with p<0.01 are displayed: 91 genes have higher mRNA levels in 3D (red); 162 genes have lower levels in 3D (green). (B) Quantitative RT/PCR analysis for p21 normalized to levels of 18S in the same samples. (**) p<0.01; (C) ChIP assay measuring levels of AcH3 and AcH4 in the p21 promoter for S1 cells cultured in 2D and 3D.

S1 cells grown on tissue culture plastic were treated with the actin polymerization inhibitor cytochalasin D (5 μM). Treatment with this drug disrupted actin microfilaments, induced cell rounding (Fig. 4B), and reduced the levels of acetylated histones H3 and H4 (Figs. 4C, D). Importantly, removal of the drug reversed cell morphology (data not shown) and induced an increase in histone acetylation (Fig. 4D). Therefore, cytoskeletal changes associated with cell rounding induce global histone deacetylation.

Culture in 3D lrECM induces a global reduction in gene expression

One question that arises from these observations is whether the histone deacetylation in 3D culture regulates gene expression. Indeed, broad acetylation of histones H3 and H4 was shown to lead to chromatin decondensation and a structure permissive for transcription (reviewed in [39]), whereas histone deacetylation correlated with the repressed state of chromatin and alterations in patterns of gene expression [40]. To determine whether culture in 3D lrECM induced a reduction in gene expression in addition to global histone deacetylation, we performed microarray analysis. mRNA samples from S1 cells cultured on plastic or in 3D lrECM were fluorescently tagged and co-hybridized to cDNA microarrays, and the intensity of hybridizations was compared. Genes expressed differentially between the two conditions were selected for analysis. We found that cells cultured in 3D lrECM showed an appreciable reduction in gene expression as compared to cells cultured on plastic (Fig. 5A; Supplemental Table 1). Of the differentially expressed genes, 162 genes were expressed at lower levels in 3D, compared to 91 expressed at higher levels. This decrease in gene expression is consistent with the global histone deacetylation observed in 3D cultures.

Acetylation of histones in the promoter regions and other regulatory cis-elements clearly affects transcription of a large number of genes [17,18,41]. To address the question of whether the lrECM-dependent global deacetylation could specifically affect the promoter of a functionally relevant gene, we focused our attention on the cell cycle inhibitor p21. It was previously shown that the expression of the p21 gene is controlled by the acetylation status of histones associated with its promoter [42,43]. Indeed, from our array data, the transcript level of p21 in S1 cells in 3D was reduced to 76% of that in cells in 2D after 10 days of culture (Supplemental Table 1). Quantitative real-time RT/PCR confirmed that p21 mRNA levels were reduced in 3D compared to 2D (Fig. 5B). To determine whether this reduction in expression is correlated with reduced acetylation at the promoter region of the p21 gene, we performed chromatin immunoprecipitation (ChIP) experiments. Lysates from S1 cells cultured in 2D or 3D were immunoprecipitated for acetylated histones H3 or H4, and the remaining associated DNA was PCR-amplified using primers specific for the p21 promoter. Culturing the cells in 3D lrECM induced a dramatic reduction of histone acetylation in the p21 promoter (Fig. 5C). This result is consistent with the reduced expression of p21 observed by microarray analysis and RT/PCR. These data indicate that lrECM-induced histone deacetylation is associated with a functional reduction of gene expression.

Discussion

The interactions between a cell and its local microenvironment have profound effects on cell shape, cytoskeletal and nuclear matrix organization, chromatin structure, and gene expression [24,44–46]. In this study, we found that culture of human mammary epithelial cells within 3D lrECM induced cell rounding and global histone deacetylation. Histone deacetylation correlates with chromatin condensation and reduced gene expression. These data are corroborated by previous studies demonstrating that lrECM-induced morphogenesis correlates with reduced histone acetylation and increased histone methylation [24,25,28,44]. Cells receive at least two types of signals from laminin-rich ECM gels: biochemical signals from the engagement of cell surface receptors, and biophysical signals from the change in their morphology [9]. Altering cellular shape has been shown to regulate nuclear morphology and chromatin structure [37]. Using non-adhesive and micropatterned substrata as well as inhibitors of actin polymerization, we determined that cell rounding is a sufficient stimulus to induce histone deacetylation and chromatin condensation in the absence of
biochemical signals transduced from the ECM; notably, adding ECM to pre-rounded cells did not potentiate the shape-induced histone deacetylation.

There is increasing evidence that cell rounding inhibits cell proliferation [3,4] and that histone acetylation levels correlate with cell cycle status [47]. We found that culturing cells on plastic and in 3D lrECM led to a similar percentage of growth-arrested cells (Supplemental Fig. C). Furthermore, global histone deacetylation was detected in T4–2 cells cultured in 3D, although these cells failed to growth arrest (data not shown). Therefore, the ECM-induced reduction in histone acetylation does not correlate with decreased proliferation in this system. S1 cells undergo growth arrest after 10 days of culture in both 2D and 3D. However, transcription levels of the p21 gene were lower in 3D than in 2D culture, suggesting that the growth arrest in 3D may be regulated by other proteins or signaling pathways. Consistent with this possibility, we previously reported that cell cycle arrest in 3D culture was accompanied by progressive hypophosphorylation of the retinoblastoma (Rb) gene and induction of the cyclin-dependent kinase (CDK) inhibitor p27kip1 [48].

Results over the past two decades appear to support the hypothesis that the ECM is dynamically coupled to the nucleus through the cytoskeleton and the nuclear matrix [1,49–51]. One attractive potential mechanism to regulate chromatin structure involves signaling from the cytoskeleton. We found that cell rounding (either in 3D lrECM or on micropatterned substrata) altered the actin cytoskeleton and prevented the formation of stress fibers and that blocking actin polymerization/depolymerization with cytochalasin D led to histone deacetylation. Disrupting microtubules also causes cell rounding [52] and has been shown to induce histone deacetylation [53]. These results suggest a role for low intracellular tension generated by cytoskeletal organization in the control of histone acetylation. It has been shown that disrupting actomyosin tension generation by inhibiting myosin light chain kinase, RhoA, or Rho-kinase leads to global histone deacetylation, and conversely, increasing actomyosin contractility enhances histone acetylation levels in gastric carcinoma cells [41]. Increasing tension by application of shear stress leads to histone acetylation, chromatin remodeling, and changes in gene expression in endothelial and embryonic stem cells [54,55]. In agreement, experimental and theoretical evidence supports a specific role for the actin cytoskeleton in physically connecting sites of cell adhesion to ECM with the nucleus [51] as well as integrating changes in cell and nuclear shape [56,57]. In this scenario it is thought that tension developed by actin bundles in spread cells deforms the nucleus to increase its projected area, while a decrease in tension (as occurs in round cells) would have the opposite effects. In support of this model we observed a systematic reduction in nuclear diameter in round cells compared to control cells. Based on the collective data described, it is tempting to speculate that cell shape regulates histone acetylation through mechanical transmission of actin/ cytoskeletal tension to the nucleus.

Histone acetylation and deacetylation are catalyzed by HATs and HDACs; therefore cell rounding could regulate histone acetylation by altering the total cellular levels or activities of these enzymes, changing their levels in the nucleus, or their association with the nuclear matrix. Cell rounding reduces the caliber of nuclear pore complexes and reduces the rate of nucleocytoplasmic transport [58,59], which could directly affect the shuttling of HATs and HDACs and their relative levels within the nucleus. Biochemically, HAT and HDACshuttling is regulated by phosphorylation which changes their binding affinity to chaperone proteins that usher them into or out of the nucleus [60]. Indeed, during skeletal muscle differentiation Ca2+/calmodulin-dependent protein kinase (CaMK) activity regulates class II HDAC phosphorylation, binding to 14–3–3 protein chaperone, and subsequent nuclear shuttling [61]. Additionally, some HDACs have been found to bind to actin filaments and microtubules in the cytoplasm, potentially sequestering them away from the nuclear compartment [62]. Depolymerizing portions of the cytoskeleton may release HDACs and allow them to shuttle from the cytoplasm into the nucleus, tipping the balance in favor of histone deacetylation. In general, regulation of HDAC and HAT activities is a large field of study which is opening an ever greater array of possible mechanisms by which cell shape might regulate histone acetylation.

Despite the fact that ECM-induced cell rounding leads to global histone deacetylation and that the deacetylation is associated with a reduction in overall gene expression in 3D cultures, histones associated with genes specifically upregulated during differentiation are most probably acetylated locally. For example, histone H4 acetylation is increased in the promoter region of the α-casein milk protein gene in mammary epithelial cells in the presence of collagen [63], and histone H3 and H4 acetylation is increased in the promoter region of the β-casein gene during differentiation [64,65]. It will be interesting to determine how cell shape affects the acetylation status of these and other differentiation-associated genes. Although global histone deacetylation is observed during functional differentiation of mammary epithelial cells [24,28] and is regulated by cell rounding, the latter per se may not explain all the effects of ECM on functional differentiation; indeed, the assembly of a basement membrane is required in addition to cell rounding for the reorganization of the nuclear protein NuMA and tissue-specific functions [24], and biochemical signals transmitted through integrin and non-integrin laminin receptors are required for functional differentiation and β-casein expression [9,12,66,67].

We have provided strong evidence for a link between ECM-regulated cell shape, chromatin structure, and gene expression. Since ECM influences morphology and gene expression in a wide variety of tissues [reviewed in [68–72]], it is most likely that cell shape-induced changes in global histone acetylation and chromatin structure are a common mechanism in regulation of tissue- and context-specific gene expression in many organs.
