Submitted to Proceedings of the National Academy of Sciences of the United States of America

Recursive utility models that feature investor concerns about the intertemporal composition of risk are used extensively in applied research in macroeconomics and asset pricing. These models represent preferences as the solution to a nonlinear forward-looking difference equation with a terminal condition. In this paper we study infinite horizon specifications of this difference equation in the context of a Markov environment. We establish a connection between the solution to this equation and an arguably simpler Perron-Frobenius eigenvalue equation of the type that occurs in the study of large deviations for Markov processes. By exploiting this connection, we establish existence and uniqueness results. Moreover, we explore a substantive link between large deviation bounds for tail events for stochastic consumption growth and preferences induced by recursive utility.

intertemporal composition of risk are used extensively in applied research in macroeconomics and asset pricing. These models represent preferences as the solution to a nonlinear forward-looking difference equation with a terminal condition. In this paper we study infinite horizon specifications of this difference equation in the context of a Markov environment. We establish a connection between the solution to this equation and an arguably simpler Perron-Frobenius eigenvalue problem. We use the latter problem to feature the process 

Recursive utility models of the type suggested by [1] and featured in the asset pricing literature by [2] and others represent preferences as the solution to a nonlinear forward-looking difference equation with a terminal condition. Such preferences are used in economic dynamics because seemingly simple parametric versions provide a convenient device to change risk aversion while maintaining the same intertemporal elasticity of intertemporal substitution. In this paper we explore infinite horizon specifications in the context of a Markov environment. Even under the Markov specification, establishing the existence of a solution to this forward-looking recursion used to depict preferences can be challenging. In this paper we establish a connection between the solution to this equation and an arguably simpler eigenvalue equation of the type that occurs in the study of large deviations for Markov processes, see [4], [5] and [6].

The remainder of the paper is organized as follows. First, we state formally the recursive utility problem and a related Perron-Frobenius eigenvalue problem. We use the latter problem to construct a change in probability that plays a central role in our analysis. Under this change of measure, we establish several inequalities leading up to our main analytical result. We conclude the paper by expanding on some of the ramifications of our analysis and linking our results to the study of large deviations applied to a Markov process.

Two related problems

Consider a discrete-time specification of recursive preferences of the type suggested by [1] and [2]. We use the homogeneous-of-degree-one aggregator specified in terms of current period consumption \( C_t \) and the continuation value \( V_t \):

\[
V_t = \left( \left( C_t \right)^{-\rho} - \exp(-\delta) \mathbb{E}_t (V_{t+1}) \right)^{1-\rho} \left( 1 + \rho \right). \tag{1}
\]

where

\[
\mathbb{E}_t (V_{t+1}) = \left( E \left( (V_{t+1})^{1-\gamma} | \mathcal{F}_t \right) \right)^{\frac{1}{1-\gamma}}
\]

adjusts the continuation value \( V_{t+1} \) for risk. With these preferences, \( \frac{1}{\rho} \) is the elasticity of intertemporal substitution and \( \delta \) is a subjective discount rate. The parameter \( \zeta \) does not alter preferences, but gives some additional flexibility, and we will select it in a judicious manner.

Next exploit the homogeneity-of-degree one specification of the aggregator [1] to obtain:

\[
\left( \frac{V_t}{C_t} \right)^{1-\rho} = \zeta^{1-\rho} + \exp(-\delta) \mathbb{E}_t \left( \frac{V_{t+1} C_{t+1}}{C_t} \right)^{1-\rho} \tag{2}
\]

Applying the aggregator requires a terminal condition for the continuation value. In what follows we will consider infinite-horizon limits. Thus we will explore the construction of the continuation value \( V_t \) as a function of \( C_t, C_{t+1}, C_{t+2}, \ldots \).

Consider now a Markov specification in discrete time. Let \( (X, Y) = \{(X_t, Y_t)\} \) be an underlying Markov process, and suppose that

Assumption 1. (a) The joint distribution of \((X_{t+1},Y_{t+1})\) conditioned on \((X_t,Y_t)\) depends only on \(X_t\).

(b) Consumption dynamics evolve as:

\[
\log C_{t+1} - \log C_t = \kappa(X_{t+1}, Y_{t+1}, X_t).
\]

In light of this restriction, we may view \( X \) alone as a Markov process and \( Y \) does not “cause” \( X \) in the sense of [7]. As suggested by a referee, the process \( Y \) can be viewed as an independent sequence conditioned on the entire process \( X \) where the conditional distribution of \( Y_t \) depends only on \( X_t \) and \( X_{t-1} \).

When the joint process \((X,Y)\) is stationary, the logarithm of consumption has stationary increments and the level process for consumption displays stochastic geometric growth. For convenience we normalize \( C_0 = 1 \). Given our assumed homogeneity in preference, it is straightforward to allow for more general initial conditions. This specification allows us to feature the the process \( X \) in our analysis while allowing for some additional flexibility. Generally, we may think of this as a convenient specification of consumption that could emerge from a model in which consumption is determined endogenously.

Reserved for Publication Footnotes

* See [3] for a recent thorough analysis of existence and uniqueness of continuation value processes, but the sufficient conditions given there impose restrictions that preclude some of the parametric models used in practice.

† The referee noted that an argument given on page 1616 of [8] may be extended to demonstrate this conditional independence and that we may view \((X_t, X_{t-1}, X_{t-2})\) as a “hidden state Markov chain” with hidden state \((X_{t-1}, X_{t-2})\). In our analysis \( X_t \) is treated as directly observable, and we defer the study of hidden states in this setting to future research.

‡ In the special case in which \( \kappa \) does not depend on \( Y_t \), the consumption process is what is called a multiplicative functional in the applied mathematics literature.
The eigenvalue equation of interest is:

\[ \frac{V_t}{C_t} \gamma_{t+1} = f(X_t), \quad f \geq 0. \]

Writing \( \alpha = \frac{1}{1 - \beta} \) and for \( f \geq 0 \), \( Uf = \zeta^{1-\rho} + \exp(-\delta) (E[f(X_{t+1})] \exp((1 - \gamma) \kappa(X_{t+1}, Y_{t+1}, X_t) | X_t = x]) \),
we can express equation \([2]\) as:

\[ f(x) = \mathbb{U} f(x) \] \([3]\)

Remarkably, the solution to the fixed point problem \([3]\) is closely related to a Perron-Frobenius eigenvalue equation of the type analyzed by \([9]\) in their study of risk-return relations and risk pricing over long-term investment horizons. The eigenvalue problem studied in \([9]\) is also closely related to an eigenvalue equation that occurs in the study of large-deviations. Consider the mapping:

\[ \mathbb{T} f(x) = E[(1 - \gamma) \kappa(X_{t+1}, Y_{t+1}, X_t)] f(X_{t+1}) | X_t = x. \]

The eigenvalue equation of interest is:

\[ T \phi(x) = \exp(\eta x) \phi(x). \] \([4]\)

for \( \eta > 0 \). In many specifications this equation has multiple positive solutions with eigenfunctions that are not equal up to a scale factor.

**Changing the probability measure**

We use a Perron-Frobenius eigenfunction to change the probability measure. Associated with each such eigenfunction is a positive random variable

\[ M_{t+1} = \frac{\exp((1 - \gamma) \kappa(X_{t+1}, Y_{t+1}, X_t)) e(X_{t+1})}{e(X_t)} \exp(-\eta), \]

which has conditional expectation equal to unity. We use this to define a change of measure for the transition probability of the Markov process, via:

\[ \mathbb{E} \{ \phi(X_{t+1}, Y_{t+1}) | X_t = x, Y_{t+1} = y \} = E \{ M_{t+1} \phi(X_{t+1}, Y_{t+1}) | X_t = x \} \]

for any Borel measurable function \( \phi \) with the appropriate domain. This change in the transition probability preserves the Markov property and the restrictions imposed by Assumption 1. Only one of the eigenfunctions induces a change of measure that is stochastically stable in the sense that

**Assumption 2.** Under the change of probability measure,

\[ \lim_{t \to \infty} \mathbb{E} \{ \phi(X_t, Y_t) | X_0 = x \} = \mathbb{E} \{ \phi(X_t, Y_t) \} \]

for any bounded Borel measurable function \( \phi \). The expectation on the right-hand side uses a stationary distribution implied by the change in the transition distribution. We require that the convergence applies for almost all Markov states \( x \) under this stationary distribution.

There is an extensive literature that gives sufficient conditions for stochastic stability.

To apply this change in measure, we use a multiplicative scaling of functions:

\[ g(x) = f(x) e^{-\frac{\eta}{2}}. \]

The transformed counterpart to equation \([3]\) is:

\[ \tilde{g}(x) = \mathbb{U} \tilde{g}(x) \]

where:

\[ \tilde{U} g(x) = \zeta^{1-\rho} e(x)^{\frac{1}{2}} + \exp(-\xi) \mathbb{E} \{ [g(X_{t+1})]^{\alpha} | X_t = x \}^{\frac{1}{\alpha}}. \]

and \( \xi = \delta - \frac{\eta}{2} \). Notice that this altered recursion uses the change of measure to absorb the stochastic component to growth. Moreover,

\[ \tilde{V} h(x) \geq \zeta^{1-\rho} e(x)^{\frac{1}{2}}. \] \([5]\)

We will also consider an alternative recursion defined via an operator \( \tilde{V} \) defined on non-negative functions \( h \) given by

\[ \tilde{V} h = [\tilde{V} (h \frac{1}{2})]^{\alpha}. \]

That is,

\[ \tilde{V} h(x) = \zeta^{1-\rho} e(x)^{-\frac{1}{2}} + \exp(-\xi) \mathbb{E} \{ [h(X_{t+1})]^{\alpha} | X_t = x \}^{\frac{1}{\alpha}}. \]

In particular there is a one-to-one correspondence between fixed points of \( \tilde{U} \) and fixed points of \( \tilde{V} \) and inequality \([5]\) implies that \( \tilde{V} h(x) \geq \zeta^{1-\gamma} e(x)^{-1} \) if \( \alpha > 0 \).

To maintain discounting in the presence of stochastic growth, we assume:

**Assumption 3.** \( \xi > 0 \).

In terms of the initial parameters, Assumption 3 implies:

\[ \delta > \frac{1 - \rho}{1 - \gamma} \eta \] \([6]\)

For typical parameterizations, \( \eta < 0 \). Thus when \( \gamma > 1 \), this bound on \( \delta \) is positive for \( \rho < 1 \) and negative when \( \rho > 1 \).

**Some Useful Inequalities**

In this section we establish inequalities that we will use to show the existence of fixed points to \( \tilde{U} \) and \( \tilde{V} \). We will consider alternative operators with fixed points that are easier to characterize. These alternative fixed points provide bounds for the fixed points that interest us. Starting from these bounds we will construct monotone sequences that converge to candidate fixed points of \( \tilde{U} \) and \( \tilde{V} \). We also show when the two constructed fixed-points coincide. Recall that we have the flexibility to set \( \zeta \geq 0 \) in an arbitrary fashion. We exploit this convenience by setting \( \zeta = [1 - \exp(-\xi)]^{\frac{1}{1-\gamma}} \).

---

\(^{1}\) Uniqueness is established in \([9]\) for a continuous-time Markov specification, but their result has a direct counterpart for discrete-time.

\(^{2}\) \([3]\) construct \( L^{\infty} \) spaces weighted by scale factors that depend on time, including factors with geometric decay as a featured case. The \( L^{\infty} \) structure preserves processes with bounded support, although the support can increase over time because of the scale factors that they introduce. In contrast, we exploit heavily a Markov structure and use the Perron-Frobenius eigenvalue embedded in our change of probability measure to accommodate geometric growth and other convenient forms of stochastic growth in consumption. The recursion, \( \bar{U} \), maps into special case of the recursions in \([3]\) for \( \alpha < 0 \) and \( 1 < \alpha \leq 1 \); and the recursion, \( \bar{V} \), maps into a special case when \( \alpha > 0 \) except that we feature \( L^{1} \) spaces instead of \( L^{\infty} \) spaces.

\(^{3}\) It is possible that \( \eta \) is positive, which alters the parameter restrictions.
Inequalities for $\tilde{U}$. Suppose that $\alpha < 0$ and apply Jensen’s inequality to obtain

$$E \left[ g \left( X_{t+1} \right)^\alpha | X_t = x \right] \geq \left( E \left[ g \left( X_{t+1} \right) | X_t = x \right] \right)^\alpha.$$ \[7\]

Since $\frac{1}{\alpha} < 0$,

$$\left( E \left[ g \left( X_{t+1} \right)^\alpha | X_t = x \right] \right)^{\frac{1}{\alpha}} \leq E \left[ g \left( X_{t+1} \right) | X_t = x \right].$$ \[8\]

When $0 < \alpha < 1$, relation \[7\] holds with the reverse inequality and raising both sides to the $\frac{1}{\alpha}$ power preserves inequality \[8\]. When $\alpha \geq 1$, relation \[7\] holds and raising both side to the power $\frac{1}{\alpha}$ gives us inequality \[8\] with the reverse sign. Thus we have

$$\tilde{U}g(x) \leq \tilde{U}g(x), \quad \alpha < 0$$
$$\tilde{U}g(x) \leq \tilde{U}g(x), \quad 0 < \alpha < 1$$
$$\tilde{U}g(x) \geq \tilde{U}g(x), \quad \alpha \geq 1$$

where

$$\tilde{U}g(x) = \left[ 1 - \exp(-\xi) \right] e(x)^{-\frac{1}{\alpha}} + \exp(-\xi) \bar{E} \left[ g \left( X_{t+1} \right) | X_t = x \right].$$

A sufficient condition to obtain a fixed point for $\tilde{U}$ is:

**Assumption 4.** $\bar{E} \left[ e(x)^{-\frac{1}{\alpha}} \right] < \infty$.

In this case

$$\tilde{g}(x) = \left[ 1 - \exp(-\xi) \right] \sum_{t=0}^{\infty} \exp(-t\xi) \bar{E} \left[ e(X_{t+1}) | X_t = x \right]$$

is in $L^1$ (using the $\gamma$ stationary distribution) and is a fixed point for $\tilde{U}$. In addition, under Assumption 4, if $\alpha \leq 1$, since inequality \[8\] holds, $\tilde{U}$ maps $L^\alpha_+$ into $L^\alpha_+$.

Inequalities for $\tilde{V}$. Suppose again that $\alpha < 0$ and apply Jensen’s inequality to obtain

$$\left[ 1 - \exp(-\xi) \right] e(x)^{-\frac{1}{\alpha}} + \exp(-\xi) \left( \bar{E} \left[ h \left( X_{t+1} \right) | X_t = x \right] \right)^{\frac{1}{\alpha}} \geq \left[ 1 - \exp(-\xi) \right] e(x)^{-1} + \exp(-\xi) \left( \bar{E} \left[ h \left( X_{t+1} \right) | X_t = x \right] \right)$$

Raising both sides to the power $\alpha$ reverses the inequality and thus

$$\left( \left[ 1 - \exp(-\xi) \right] e(x)^{-\frac{1}{\alpha}} + \exp(-\xi) \left( \bar{E} \left[ h \left( X_{t+1} \right) | X_t = x \right] \right)^{\frac{1}{\alpha}} \right)^\alpha \geq \left[ 1 - \exp(-\xi) \right] e(x)^{-1} + \exp(-\xi) \left( \bar{E} \left[ h \left( X_{t+1} \right) | X_t = x \right] \right).$$ \[9\]

For $0 < \alpha < 1$, the inequality in \[9\] remains the same and raising both sides to power $\alpha$ does not reverse this inequality. For $\alpha \geq 1$ the inequality \[9\] is reversed and raising both sides to the power $\alpha$ does not reverse the inequality. Thus

$$\tilde{V}h(x) \leq \tilde{V}h(x), \quad \alpha < 0$$
$$\tilde{V}h(x) \geq \tilde{V}h(x), \quad 0 < \alpha < 1$$
$$\tilde{V}h(x) \leq \tilde{V}h(x), \quad \alpha \geq 1$$

where

$$\tilde{V}h(x) = \left[ 1 - \exp(-\xi) \right] e(x)^{-1} + \exp(-\xi) \bar{E} \left[ h \left( X_{t+1} \right) | X_t = x \right].$$

A sufficient condition to obtain a fixed point for $\tilde{V}$ is:

**Assumption 5.** $\bar{E} \left[ e(x)^{-1} \right] < \infty$.

In this case,

$$\tilde{h}(x) = \left[ 1 - \exp(-\xi) \right] \sum_{t=0}^{\infty} \exp(-t\xi) \bar{E} \left[ e(X_{t+1})^{-1} | X_0 = x \right]$$ \[10\]

is a fixed point for $\tilde{V}$.

A consequence of Jensen’s inequality is that Assumption 4 implies Assumption 5 when $0 < \alpha < 1$ and conversely for $\alpha \geq 1$. For $\alpha < 0$, they are not comparable. We can apply Jensen’s inequality to rank fixed points of the operators:

$$\tilde{h}(x) \leq \tilde{g}(x), \quad \alpha < 0$$
$$\tilde{h}(x) \leq \tilde{g}(x), \quad 0 < \alpha < 1$$
$$\tilde{h}(x) \geq \tilde{g}(x), \quad \alpha \geq 1.$$

**Candidate fixed points for $\tilde{U}$ and $\tilde{V}$.** We use monotonicity to construct candidate fixed points for $\tilde{U}$ and $\tilde{V}$. We consider three cases associated with three different intervals for $\alpha$.

**$\alpha < 0$:** When Assumption 5 is satisfied, $\tilde{V}h(x) \leq \tilde{h}(x)$, and $\tilde{V}h(x)$ is a decreasing sequence of functions. This sequence converges pointwise to a function $\hat{h}$. We will establish below that this limit is a fixed-point for $\tilde{V}$.

When Assumption 4 is satisfied, we use $\tilde{g}$, the pointwise limit of the decreasing sequence $\left\{ \tilde{U}^j \tilde{g} \right\}$, as a candidate fixed point for $\tilde{U}$. Since $\tilde{h} \leq \tilde{g}$, $\left( \tilde{V}^j \tilde{h} \right) \leq \tilde{V}^j \tilde{g}$. Taking limits as $j$ tends to infinity, $\tilde{h} \leq \tilde{g}$ when Assumptions 4 and 5 are both satisfied.

**$0 < \alpha < 1$:** In this case we impose the more restrictive Assumption 4 and use $\tilde{U}$ to construct a fixed point. Notice that

$$\tilde{V}h \leq \tilde{U} \left( \tilde{h} \right)^{\alpha} = \tilde{g}^\alpha.$$

Applying $\tilde{V}$ to both sides,

$$\tilde{V}^2 \tilde{h} \leq \tilde{V} \left[ \tilde{U} \left( \tilde{h} \right)^{\alpha} \right] = \tilde{V} \left[ \tilde{U} \left( \tilde{h} \right)^\alpha \right] \leq \tilde{V} \left[ \tilde{U} \tilde{g} \right]^\alpha = \tilde{g}^\alpha.$$

Repeating this argument, we see that $\tilde{V}^n \tilde{h} \leq \tilde{g}^\alpha$.

Since $\tilde{V} h \geq \tilde{h}$, $\left\{ \tilde{V}^j \tilde{h} \right\}$ a bounded from above increasing sequence of functions. This sequence converges pointwise to a function $\hat{h}$.

Since $\tilde{h} \leq \tilde{g}$, $\left( \tilde{V}^j \tilde{h} \right) \leq \tilde{U} \tilde{g}$. Taking limits as $j$ tends to infinity $\tilde{h} \leq \tilde{g}$.

**$\alpha \geq 1$:** In this case we impose the more restrictive Assumption 5 and use $\tilde{V}$ to construct a decreasing sequence bounded below by a strictly positive function and thus converging pointwise to a positive function $\tilde{g}$. We use $\tilde{U}$ to construct an increasing sequence that is bounded from above by a positive function. This sequence converges to a function $\hat{h}$ with $\hat{h} \geq \tilde{g}$.

**Extending the domain of convergence.** We constructed fixed points by iterating operators starting from a specific function, say $\tilde{g}$, and converging to a limit point, say $\tilde{g}$ where $\tilde{g} \leq \tilde{g}$. Consider a function $g$ such that $\tilde{g} \leq g \leq \tilde{g}$. Then $\tilde{g} = \tilde{U}^j \tilde{g} \leq \tilde{U}^j g \leq \tilde{U}^j \tilde{g}$. Since $\left\{ \tilde{U}^j \right\}$ converges to $\tilde{g}$, $\left\{ \tilde{U}^j g \right\}$ also converges to $\tilde{g}$. At least in this specific sense, the candidate fixed points are “stable”.
Main result

We now state and prove a result on the existence of recursive utilities in a Markov setting. The proposition collects intermediate results proved earlier, shows that the candidate fixed points are actual fixed points and that they coincide if $\alpha > 0$.

**Proposition 6.** Suppose a) $(X, Y)$ is a Markov process satisfying Assumption 1; b) $e$ is a solution to the Perron-Frobenius equation (4) satisfying Assumption 2 with $\exp(\eta)$ the associated eigenvalue; and c) the subjective rate of discount satisfies $\delta > \tilde{\gamma}$ (Assumption 3). Then for alternative ranges of $\alpha$ we have the following results:

i) If $\alpha < 0$, $\tilde{h}^\frac{1}{2}$ is a fixed point of $\tilde{U}$ provided that Assumption 5 is satisfied, and $\tilde{g}$ is a fixed point of $\tilde{U}$ provided that Assumption 4 is satisfied. When both assumptions are satisfied, $\tilde{h}^\frac{1}{2} \leq \tilde{g}$.

ii) If $0 < \alpha < 1$, $\tilde{h}^\frac{1}{2} = \tilde{g}$ is a fixed point of $\tilde{U}$ provided that Assumption 5 is satisfied.

iii) If $\alpha \geq 1$, $\tilde{h}^\frac{1}{2} = \tilde{g}$ is a fixed point of $\tilde{U}$ when Assumption 4 is satisfied. Moreover, $\tilde{g}$ is the unique fixed point with a finite $\alpha$ moment under the $\tilde{\gamma}$ stationary distribution.

While the proposition features $\tilde{U}$, fixed points of $\tilde{V}$ are obtained by raising the fixed points of $\tilde{U}$ to power $\alpha$. Solutions for $\tilde{g}$ are given by multiplying fixed points of $\tilde{U}$ by the eigenfunction $e^\frac{1}{2}$ and raising the product to the power $\frac{1}{1-\alpha}$.

We first show that the limits we constructed above are actually fixed points.

**Existence of fixed points.** To prove existence, we again treat three cases, depending on the magnitude of $\alpha$.

1. $\alpha < 0$: If Assumption 5 holds, then $\tilde{h} \in L^1_+$ and $\tilde{V}^{\frac{1}{2}} \tilde{h}$ is a dominated sequence of $L^1_+$ functions converging pointwise to $\tilde{h}$. The Dominated Convergence theorem guarantees that,

$$\lim_{i \to \infty} E[\tilde{V}^{\frac{1}{2}} h(X_{t+1}) | X_t = x] = E[\tilde{h}(X_{t+1}) | X_t = x],$$

with $\tilde{\gamma}$ measure one. Hence $\tilde{h}$ is a fixed point of $\tilde{V}$.

If Assumption 4 holds, then, as we showed above, $\tilde{g} \in L^1_+$ and $\tilde{U}$ maps $L^1_+$ into $L^1_+$. Since $[1 - \exp(-\xi) \eta(x)]^{\frac{1}{2}} \tilde{V} \leq \tilde{g}(x)$, where the first inequality follows from bound [5], the dominated convergence theorem assures us that $\tilde{g} \in L^1_+$ and is the strictly positive (with probability one) $L^1_+$ limit of $\tilde{U}^{\frac{1}{2}} \tilde{g}$. From inequality (8) it follows that for each $j$, 

$$E \left\{ \tilde{U}^{\frac{1}{2}} \tilde{g}(X_{t+1}) | X_t = x \right\} < \infty.$$

Since $\alpha < 0$, $(\tilde{U}^{\frac{1}{2}} \tilde{g})^\alpha \geq (\tilde{U}^{\frac{1}{2}} \tilde{g})^\alpha$. Beppo Levi’s Monotone Convergence theorem thus implies that for $x \in A$, 

$$E \left\{ \tilde{U}^{\frac{1}{2}} \tilde{g}(X_{t+1}) | X_t = x \right\} \to E \left\{ \tilde{g}(X_{t+1}) | X_t = x \right\},$$

as a consequence $\tilde{g}(x) = \lim_{i \to \infty} \tilde{U}^{\frac{1}{2}} \tilde{g}(x) = \tilde{U} \tilde{g}(x)$, for $x \in A$. If $x \notin A$ then, 

$$E \left\{ \tilde{U}^{\frac{1}{2}} \tilde{g}(X_{t+1}) | X_t = x \right\} \to \infty,$$

and $\tilde{g}(x) = [1 - \exp(-\xi) \eta(x)]^{\frac{1}{2}} \tilde{U} \tilde{g}(x)$. Since $\tilde{g} \leq \tilde{U} \tilde{g}$ and $\tilde{U}$ is monotone, $\tilde{U} \tilde{g} \leq \tilde{g}$, and thus for $x \notin A$, we also have $\tilde{U} \tilde{g}(x) = \tilde{g}(x)$.

2. $0 < \alpha < 1$: If Assumption 4 holds, $\tilde{g} \in L^1_+$ and $\tilde{V}^{\frac{1}{2}} \tilde{h}$ is a sequence of $L^1_+$ functions dominated by $\tilde{g}$.

3. $\alpha > 1$: If Assumption 5 holds, the proof for $\alpha < 0$ applies.

We next show that when $\alpha > 0$ the constructed fixed points are actually the same. Again we treat separately the cases $0 < \alpha < 1$ and $\alpha \geq 1$.

Consider first the case in which $0 < \alpha < 1$. For $s > 0$ the function $\psi(r) = [s + \exp(-\xi) \eta(r)]^{\frac{1}{2}}$ is convex for $r > 0$. Consequently for each fixed $x$, $\tilde{V}$ is a convex function of $h > 0$. A subgradient for this convex function at $h_1$ is the linear map that maps a $k \in L^1_+$ into $d(x) \tilde{V}[k(X_{t+1}) | X_t = x]$ and a simple calculation shows that $0 < \tilde{V}_h(x) < 1$. Thus if $h_1 \geq h_2$ are non-negative fixed points of $\tilde{V}$,

$$h_2(x) - h_1(x) = \tilde{V} h_2(x) - \tilde{V} h_1(x) \geq \tilde{V}_h(x)(h_1(X_{t+1}) - h_2(X_{t+1})).$$

By the Law of Iterated Expectations,

$$E[h_2(X_{t+1}) - h_1(X_{t+1})] \geq \tilde{E} \tilde{V}_h(X_t)(h_2 - h_1)(X_{t+1}).$$

Since $0 < \tilde{V}_h(x) < 1$, $h_1$ and $h_2$ coincide in a set with $\tilde{\gamma}$ measure one. In particular $\tilde{g}^\alpha = \tilde{h}$.

Next consider the case in which $\alpha \geq 1$. We view

$$E[g(X_{t+1}) \alpha | X_t = x]$$

as a conditional norm. As a consequence, if $g_1 \geq 0$ and $g_2 \geq 0$ are fixed points of $\tilde{U}$,

$$|g_1(x) - g_2(x)| = \tilde{U} g_1(x) - \tilde{U} g_2(x) \leq \exp(-\xi) \left[ E (g_1(X_{t+1}) - g_2(X_{t+1})) | X_t = x \right]^{\frac{1}{2}}$$

where the last inequality follows from (the reverse) Triangle Inequality. Next raise both sides to the power $\alpha$ and then integrate with respect to the $\tilde{\gamma}$ stationary distribution. By the Law of Iterated Expectations, $E [(g_1(X_{t+1}) - g_2(X_{t+1}))^\alpha] \leq \exp(-\xi) E [(g_1(X_{t+1}) - g_2(X_{t+1}))^\alpha]$ provided that $g_1$ and $g_2$ have finite $\alpha$ moments under the $\tilde{\gamma}$ stationary distribution. Thus $g_1$ and $g_2$ must be equal with $\tilde{\gamma}$ probability one.

Since $\tilde{g}^\alpha \leq \tilde{h} \leq \tilde{g}$, under Assumption 5 $\tilde{g}$ and $\tilde{h}$ have finite $\alpha$ moments under the $\tilde{\gamma}$ stationary distribution. Therefore $\tilde{g}$ and $\tilde{h}$ coincide. In addition, $\tilde{g}$ is the unique fixed point of $\tilde{U}$ with a finite $\alpha$ moment under the $\tilde{\gamma}$ stationary distribution.

**Three interesting extensions**

**A limiting version of asset valuation.** [10] characterizes asset pricing implications in the limiting case $\xi \approx 0$ by interpreting the eigenvalue problem as the limit of a utility recursion. As is well known in the asset pricing literature, one-period stochastic discount factors provide a convenient way to depict the “shadow prices” of one-period claims that would clear hypothetical competitive markets. See, for instance, [11] or [12]. The valuation of multi-period claims can then be obtained by repeatedly applying the formula for valuation of one-period claims. The stochastic discount factor $S$ for the recursive utility model satisfies:

$$S_t^{t+1} = \exp(-\delta) \left[ \frac{C_{t+1}}{C_t} \right]^{\gamma} \frac{V_{t+1}/C_{t+1}}{R_k (V_{t+1}/C_t)^{\gamma}}. \tag{11}$$

Using the implied one-period stochastic discount factor, the date $t$ valuation of a claim that pays $f(X_{t+1})$ at $t+1$ is:

$$\mathbb{P} f(x) = E \left[ \frac{S_{t+1}}{S_t} f(X_{t+1}) \right] | X_t = x. \tag{4}$$

Iterating the $\mathbb{P}$ operator extends pricing to claims with a longer payoff horizon.**

---

**Footnote: Stochastic growth may be introduced into this valuation while preserving the same mathematical structure as in (9)**

---

**Footnote Author**
The formula for the stochastic discount factor remains well defined in the limiting case. The limit operator \( \overline{V} \) is given by \( \overline{V}h(x) = \overline{E} [h(X_{t+1})|X_t = x] \). Any positive constant is a fixed point of \( \overline{V} \). One such constant is given by the limit solution to \([10]\) as \( \xi \) tends to zero, \( \hat{h} = \overline{E} [e(x)^{-1}] \). This corresponds to \( \left( \frac{C_t}{C_0} \right)^{1-\gamma} = e(X_t)\overline{E} [e(x)^{1-\gamma}] \). Setting \( \delta \) to its limit value given in \([6]\) or equivalently \( \xi = 0 \), and normalizing \( S_0 = 1 \),
\[
S_t = \exp(-\eta t) \left( \frac{C_t}{C_0} \right)^{1-\gamma} \exp \left[ \gamma \left( e(X_t)/e(x) \right) \right] \overline{E} \frac{e(X_t)}{e(x)}.
\]
When the process \( X \) is stationary, the long-term decay of this stochastic discount factor is dominated by \( S_t = \exp(-\eta t) \left( \frac{C_t}{C_0} \right)^{1-\gamma} \), which is the stochastic discount factor for a model in which preferences are depicted by a time-separable power utility function with power \( 1 - \gamma \). An equivalent depiction of the power utility specification is achieved by setting \( \rho = \gamma \). The extra contribution of recursive utility is captured by the Perron-Frobenius eigenfunction \( e \), via the term: \( S_t = \left[ \frac{e(X_t)}{e(x)} \right] \overline{E} \). Applying methods developed in \([9]\), \([10]\) uses such representations to characterize permanent and transitory contributions to asset valuation and to make formal comparisons of recursive utility to power utility models of consumer preferences.

A unitary elasticity of substitution. So far we have abstracted from the case \( \rho = 1 \). When \( \rho = 1 \), we may use the recursion:
\[
\hat{U} g(x) = \frac{\eta \exp(-\delta)}{1-\gamma} \left[ e(X_t)/e(x) \right] - [1 - \exp(-\delta)] \log e(x) + \exp(-\delta) \overline{E} \left[ (1-\gamma)g(X_{t+1}) \right] |X_t = x
\]
where we no longer restrict \( g \) to be positive. This recursion is a special case of the so-called “risk sensitive recursion” studied by \([14]\) and \([15]\) where discounting is included in the manner suggested by \([16]\). Let
\[
\hat{U} g(x) = \frac{\eta \exp(-\delta)}{1-\gamma} \left[ e(X_t)/e(x) \right] - [1 - \exp(-\delta)] \log e(x) + \exp(-\delta) \overline{E} [g(X_{t+1})|X_t = x].
\]
Then \( \hat{U} \hat{g} \leq \hat{U} g \) and \( \hat{U} \) has a fixed point \( \hat{g} \) if \( \overline{E} [\log e(X_t)] \) is finite. We may use our previous arguments to show that \( \{U_t^{\hat{g}}\} \) is a decreasing sequence, but we do not have an obvious lower bound on these iterations. When they converge to a finite valued function \( \hat{g} \), this function is a fixed point of \( \hat{U} \).

A different starting point. Our analysis takes as given the consumption dynamics in contrast to stochastic growth economies such as those studied by \([17]\). The change of probability measure we use is determined by the multiplicative martingale component for consumption raised to a power as discussed in \([9]\) and \([10]\). Some stochastic growth economies with production have a balanced growth path relative to some stochastically growing technology. In such economies, the value of \( \gamma \) and the change of measure may be deduced prior to solving the model. In particular we may check the restriction \( \delta > -\frac{1}{\gamma} \eta \) by solving for \( \eta \) using the exogenously specified technology and the balanced-growth restriction. This restriction on \( \delta \) may be viewed as an extension of \([18]\)’s analysis of subjective discount rates in stochastic growth economies for models with power utility \( \gamma = \rho \). The eigenfunction \( e \), which is also restricted in our analysis, will depend on a conjectured equilibrium solution for consumption, however.

Relation to large deviations

\([4]\) and others use principal eigenvalue problems as a device for computing large deviation bounds. While their analysis allows for the construction of large deviation bounds for a large class of events, we consider bounding a rather simple set of tail events.

Following the work of \([19]\), we explore the probabilities that consumption growth will be below some growth threshold at a given date. Consider the following threshold probability:
\[
Pr \{ \log C_t - \log C_0 \leq -rt|X_0 = x \} =
Pr \{ - \log C_t + \log C_0 - rt \geq 0|X_0 = x \}
\]
This probability is the “value at risk” that the growth rate of consumption will be less than \( r \). As we will eventually make the time horizon \( t \) tend to infinity, adding a constant to the threshold in \([12]\) will be inconsequential. This computation is similar to but distinct from calculations for a class of ruin problems initiated by Cramer and Lundberg. See \([20]\) for a more refined use than what we describe here of large deviation theory to compute asymptotic ruin probabilities.

To bound the probability in \([12]\), we follow the usual approach to large deviations by constructing a family of functions that dominate the indicator function
\[
x \theta \geq 1 (\log x \geq 0)
\]
for any \( \theta \geq 0 \). An implication of this domination expressed in terms of logarithms of probabilities scaled by \( \frac{1}{t} \) is:
\[
-\theta r + \frac{1}{t} \log E \left[ \frac{C_0}{C_t} \right] \left| X_0 = x \right.
\geq \frac{1}{t} \log Pr \{ \log C_t - \log C_0 + rt \leq 0|X_0 = x \}
\]
where we scaled by \( t \). This bound holds for all \( \theta > 0 \), which leads us to minimize the left-hand side with respect to \( \theta \). We will study the limiting result as the time horizon becomes large. The optimized \( \theta \) depends on the growth rate \( r \) used in constructing the threshold of interest. We will link the choice of \( \theta \) to the preference parameter \( \gamma > 1 \), and as a consequence, the inverse problem will be of interest to us. Given \( \theta \), for what value of the growth rate \( r \) will this \( \theta \) be the best choice for constructing a large-deviation bound?

The large \( t \) approximation to the left-hand side is:
\[
-\theta r + \eta(\theta).
\]
where \( \eta(\theta) \) is the Perron-Frobenius eigenvalue obtained by solving:
\[
E \left( \exp[\theta \kappa(X_{t+1}, Y_{t+1}, X_t)]e(X_{t+1})|X_1 = x \right) = \exp[\eta(\theta)]e(x).
\]
To construct the best possible asymptotic bound we minimize \([13]\) with respect to \( \theta \geq 0 \), or equivalently:
\[
\xi(r) = \sup_{\theta \geq 0} \theta r - \eta(\theta).
\]

PNAS | Issue Date | Volume | Issue Number | 5
which is a Legendre transform. The function $\eta$ can be shown to be convex in $\theta$ as is the Legendre transform $\xi$. With this construction, the decay rate in the probabilities for threshold $r$ is $\xi(r)$. The first-order conditions are:

$$r = \eta'(\theta) = -\mathbb{E}[\kappa(X_{t+1}, Y_{t+1}, X_t)]$$

provided that $\eta$ is differentiable and the distorted distribution is evaluated at the optimized value of $\theta$. This same change in probability distribution is commonly used to verify that the upper bound just computed is also the best possible bound.

So far we have taken $r$ to be specified and we solve for $\theta$. To build a connection to our earlier analysis of intertemporal utility functions, we now consider the inverse problem by computing a threshold $r$ that solves the optimization problem for a given $\theta$. Suppose that $\gamma > 1$ and let $\theta = \gamma - 1$. For each such value of $\gamma$, we compute a threshold for which the power specification for terminal consumption gives the best probability bound.

We illustrate these calculations using a specification from [21] of a "long-run risk" model for consumption dynamics featured by [22]. [22] use historical data from the United States to motivate their choice of parameters. Their model includes predictability in both conditional means and in conditional volatility. We use the continuous-time specification from [21] because the resulting model of stochastic volatility is more tractable. Our analysis assumes a discrete-time model. Since a continuous-time Markov process

$$X_t$$

observed

$$C_t$$

because the resulting model of stochastic volatility is more tractable. Our analysis assumes a discrete-time model. Since a continuous-time Markov process $X$ observed at interval points in time remains a Markov process in discrete time, we use the implied discrete-time specification to construct preferences and analyze implications. In so doing we exploit the continuous-time quasi analytical formulas given by [10] for $\eta(\theta)$ as an important input into our calculations.

We explore the consequences of changes in $\theta$ and implicitly for $\gamma$ in Figure 1. This figure depicts two curves. One curve plots the threshold $r$ for which the value of $\theta$ on the horizontal axis is optimal. The threshold is computed as $r(\theta) = \eta'(\theta)$. The unconditional mean of $\log C_{t+1} - \log C_t$ is .0015, and this is equal to $-r(\theta)$. We expect this outcome because the distribution of the growth rate (in logarithms) of consumption, after adjusting for mean growth rate and scaling by $\frac{1}{\sqrt{T}}$, obeys a Central Limit Theorem. Positive values of $\theta$, imply larger values of $r$, which corresponds to movements to the left tail of the distribution of $\log C_t - \log C_0$. Figure 1 also plots the implied decay rates in the probabilities of consumption over an horizon $t$ exceeding the threshold $-r(\theta)t$. This decay rate increases in $\theta$ since the implied threshold $r$ is getting larger. For instance when $r(\theta) = -0.0075$, the decay rate is .0104 per annum and when $r(\theta) = 0$, the decay rate is .0408 per annum. The zero threshold $r(\theta) = 0$ occurs when $\theta = 4.51$ or equivalently $\gamma = 5.51$.

In summary, the same Perron-Frobenius problem that we use as device to analyze the infinite-horizon recursive valuation also gives an explicit link between the preference parameter $\gamma$ and large-deviation bounds for the tail behavior of the growth rate in consumption.

Conclusions

We use Perron-Frobenius theory applied to valuation operators to i) establish existence of the infinite-horizon value function for specifications of recursive utility that are commonly used in the study of economic dynamics; ii) provide a limiting characterization of asset valuation that features the beliefs of economic agents about macroeconomic growth and uncertainty; iii) illustrate a connection between our analysis and research on large-deviation bounds for Markov processes.
