Games with Imperfectly Observable Actions in Continuous Time.

Yuliy Sannikov

September 22, 2006

Abstract

This paper investigates a new class of 2-player games in continuous time, in which the players’ observations of each other’s actions are distorted by Brownian motions. These games are analogous to repeated games with imperfect monitoring in which the players take actions frequently. Using a differential equation we find the set $E(r)$ of payoff pairs achievable by all public perfect equilibria of the continuous-time game, where $r$ is the discount rate. The same differential equation allows us to find public perfect equilibria that achieve any value pair on the boundary of the set $E(r)$. These public perfect equilibria are based on a pair of continuation values as a state variable, which moves along the boundary of $E(r)$ during the course of the game. In order to give players incentives to take actions that are not static best responses, the pair of continuation values is stochastically driven by the players’ observations of each other’s actions along the boundary of the set $E(r)$.\footnote{I would like to thank especially Bob Wilson, Andy Skrzypacz, Peter DeMarzo, Paul Milgrom, Dilip Abreu, Manuel Amador, Darrell Duffie, Drew Fudenberg, Mike Harrison, Eddie Lazear, George Mailath, Ennio Stacchetti, Ivan Werning, Ruth Williams, David Ahn, Anthony Chung, Willie Fuchs, Vitaly Kalesnik, Patricia Lassus, Deishin Lee, Day Manoli, Gustavo Manso, David Miller, William Minozzi, Dan Quint, Korok Ray, Alexei Tchistyi and all seminar participants at Stanford, Berkeley, Harvard, Princeton, Northwestern, NYU, MIT, the University of Chicago, Yale, the University of Minnesota, UCSD, Humboldt, Oxford, the Minnesota Workshop in Macroeconomic Theory, Rochester, the University of Pennsylvania and the University of Michigan for very valuable feedback on this paper. Also, I would like to thank the editor, Andrew Postlewaite, and two anonymous referees for very thoughtful comments.}
1 Introduction.

This paper analyzes a new class of two-player games in continuous time that are related to repeated games with imperfect monitoring (i.e. imperfectly observable actions). In these continuous-time games players do not see each other’s actions directly; they only see signals that are distorted by Brownian motions. We are interested in the set of payoff pairs that can be achieved in an equilibrium of the entire game. The benefit of modeling dynamic interactions as continuous-time games lies in the clarity with which the set of equilibrium payoffs can be characterized. The continuous-time approach also allows for a simple description of equilibrium strategies that achieve the extreme points of the set of equilibrium payoffs.

We study public perfect equilibria (PPE) and the set of payoff pairs that can be achieved by PPE in a game with imperfectly observable actions. This set of payoff pairs is denoted by $E(r)$ for a discount rate $r$. A PPE is a pair of strategies that depend only on the commonly observable public outcomes such that each player’s strategy is a best response after all public histories. The purpose of this paper is not to prove a Folk Theorem for this class of games, but to precisely characterize the set $E(r)$ as well as public perfect equilibria.

We show that the boundary of the set $E(r)$ can be found using an ordinary differential equation, which we call the optimality equation. The optimality equation also allows us to construct equilibria that achieve any payoff pair on the boundary of the set $E(r)$. The dynamics of such equilibria are based on a pair of continuation values as a state variable, which moves along the boundary of the set $E(r)$ during the course of the game. At any moment of time, a player’s continuation value is his future expected payoff in the remaining game. The current continuation values determine the players’ actions and the impact of observed signals on motion of continuation payoffs.

The optimality equation relates incentives, the equilibrium motion of continuation values, and the geometry of the set $E(r)$. In equilibrium, a player’s incentives stem from the influence of the signal about his actions on his future continuation values. An action of a player is optimal when it maximizes his instantaneous payoff flow plus the expected rate of change of his continuation value. Because signals are stochastic, so is the motion of continuation values. The optimality equation, shown informally on the third panel of Figure 1, ties together four measures:

1. inefficiency, how much continuation values $v$ fall behind the flow of payoffs $g(a)$
2. incentives, the sensitivity of continuation values to public signals
3. the amount of noise in signals
4. the curvature of the set $\mathcal{E}(r)$.

We see that noise, curvature, and the necessity to provide incentives contribute positively to inefficiency. In equilibrium, as continuation values move on the boundary of the set $\mathcal{E}(r)$, the tangent line gives the ratio at which players can instantaneously transfer future equilibrium payoffs in order to create incentives. Because of the curvature of the set $\mathcal{E}(r)$ players cannot transfer utility between each other indefinitely at the same constant rate. Curvature, together with the magnitude of noise in the public signal, quantifies the informational inefficiency. The greater the curvature, the more costly it is to provide incentives and the greater should be the difference between the continuation values and the flow of payoffs.

The optimality equation also assigns an equilibrium action pair $a$ to each point $v$ on the boundary of the set $\mathcal{E}(r)$. That action pair optimally resolves the trade-off between inefficiency and incentives to stretch the boundaries of the set $\mathcal{E}(r)$ as far out as possible.

This paper contributes to the theory of repeated games with imperfect monitoring, which has been developed by Abreu, Pearce, and Stacchetti (1990), hereafter APS, and Fudenberg, Levine, and Maskin (1994), hereafter FLM. Specifically, continuous-time games illustrate the pattern of equilibrium dynamics in such games and clearly outline the trade-offs involved in the choice of equilibrium actions. The contributions of APS, FLM, and continuous-time games are illustrated in three panels of Figure 1, in which the horizontal and vertical axes represent the players’ payoffs.

APS investigate sequential equilibria of repeated games with imperfect monitoring. These games have a great multiplicity of equilibria. APS make the problem of finding equilibrium payoffs much more manageable. They show that any equilibrium payoff vector can be achieved by a recursive equilibrium, in which the players’ continuation values are state variables. In equilibrium continuation values change location after every observation of the public signal. The arrows in the left panel of Figure 1 illustrate the potential jumps of continuation values after different signals. The challenge behind our understanding of discrete-time games is that it is difficult to see a pattern behind these jumps and the

---

2 As noise increases, the variance of continuation values necessary to provide incentives increases. Because of the curvature of $\mathcal{E}(r)$, that increases inefficiency.

3 Also, see Fudenberg and Levine (1994) for complementary results to FLM when the Folk Theorem fails, and the book Mailath and Samuelson (2006) for an excellent general exposition of the current theory of discrete-time repeated games.
connection between the equilibrium dynamics and the shape of the set of equilibrium payoffs. Continuous-time games illuminate the connection between the equilibrium motion of continuation values, incentives, and the shape of the set $E(r)$. In particular, the optimality equation leads naturally to a simpler computational procedure in a continuous-time setting.

FLM show that under appropriate conditions the Folk Theorem holds for repeated games with imperfect information: any smooth convex payoff set $W$ inside the set $V^*$ of all feasible and individually rational payoffs can be achieved in equilibrium as long as the players are sufficiently patient. The key insight behind FLM’s proof of the Folk Theorem is to consider a specific pattern of the motion of continuation values. Specifically, any payoff pair $v$ on the boundary of $W$ is achievable if the future continuation values (denoted by $w$, $w'$ and $w''$ in the middle panel of Figure 1) are chosen on a translation of the tangent line. The continuous-time setting allows us to do more: for any discount rate $r$ we can characterize the optimal equilibrium motion of continuation values. It turns out that this motion stays on the boundary of the set of equilibrium payoffs $E(r)$, i.e. it is locally tangential.

One may be surprised that the informational problem persists in our continuous-time setting. After all, if players can change their actions fast, why can they not instantaneously punish all deviations? A critical feature of our model is that while the players can adjust their actions as quickly as they want, the faster they react, the less information they observe. This feature is in a sharp contrast with the model adopted in FLM, where as the duration of a period is shrunk to 0, the amount of information that the players learn per period nevertheless remains the same. This issue was addressed by Abreu, Milgrom and

\[ g(a) = \frac{2 \text{ inefficiency}}{r(\text{incentives})^2(\text{noise})^2} \]

Figure 1: Illustration of the methods of APS, FLM and this paper.
Brownian motion was first applied to the problem of dynamic incentive provision in Holmstrom and Milgrom (1987). Their paper is a good example that in some situations a continuous-time formulation allows us to better recognize patterns and prove clean results. The information flow in our paper is similar to Holmstrom and Milgrom (1987) in the sense that players learn about each other’s actions from a continuous process with i.i.d. increments.  

Simon and Stinchcombe (1989) illustrate many difficulties associated with the modeling of games in continuous time. For example, a simple description of a strategy in discrete time often has no equivalent in continuous time. These difficulties arise when the actions of one player instantaneously create information available to his opponent. This issue is not a problem in our framework. In our continuous-time games, information is defined exogenously in terms of all possible signals, and a strategy of a player simply defines a probability measure over all possible signals.

Recently, a number of authors have enriched the problem of optimal incentive provision in a dynamic setting using the mathematical tools of optimal control of diffusion processes. Sannikov (2004) and Williams (2004) both introduce a new method of analyzing the informational problem in a dynamic principal-agent relationship. In both models, the agent drives a stochastic state $X$ with his choice of controls, but the agent’s choice is not directly observable. Both papers analyze models with one-sided imperfect information, where only the agent takes hidden actions. This paper extends the continuous-time method to a two-sided setting, where both players take hidden actions.

This paper is organized as follows. Section 2 provides an example of a prisoners’ dilemma in continuous time. Section 3 formally describes the class of continuous-time games analyzed in this paper. Section 4 describes several standard game-theoretic concepts in our setting: the stage game, the minmax payoff and the sets of unconstrained payoffs and Nash equilibrium payoffs. Section 5 identifies incentive compatibility conditions, discusses the concept of a continuation value, and describes PPE in terms of the stochastic motion of

---

4Also, Kandori (1992) shows that the set of payoffs achieved in PPE increases in the accuracy of monitoring.

5We do not allow statistically meaningful jumps in the players’ observations, as in the Poisson model of Abreu, Milgrom and Pearce (1991). As a result, the noise has the form of a Brownian motion.

6Williams (2004) characterizes the optimal contract with a partial differential equation based on the following state variables: time, state $X$, the agent’s value, and possibly other variables in an enriched formulation. In Sannikov (2004) the optimal contract can be derived using an ordinary differential equation based on a single state variable, the agent’s continuation value.
continuation values. Section 6 interprets this description of PPE as a stochastic control problem and characterizes the set $\mathcal{E}(r)$ as well as PPE that achieve its extreme points. Section 7 summarizes the main results and provides an intuitive discussion of public perfect equilibria. Section 8 presents computational techniques and an additional example of duopoly with differentiated products. Section 9 concludes the paper.

2 An Example.

This section presents an example, a dynamic partnership game in continuous time. Two players participate in a joint venture. They continuously take actions from the sets $\mathcal{A}_1 = \mathcal{A}_2 = \{0, 1\}$ at each moment of time $t \in [0, \infty)$, where action 0 means “no effort” and 1 means “effort.” Players do not directly observe each other’s past actions. Instead, they get imperfect information about each others’ actions through publicly observable random processes

$$X^1_t = \int_0^t A^1_s ds + Z^1_t, \quad X^2_t = \int_0^t A^2_s ds + Z^2_t,$$

where $Z^1$ and $Z^2$ are independent standard Brownian motions and $A^i_t$ is the action of player $i$ at time $t$. A public strategy for player $i$ a stochastic process $\{A^i_t\}_{t \geq 0}$ progressively measurable with respect to the history of public information that contains $X^1$ and $X^2$ (to be defined later).

![Figure 2: Matrix of Static Payoffs and Set $\mathcal{E}(r)$ in Partnership.](image)

The increments of the process $X^i$ reflect how much the actions of player $i$ contribute to
the success of the joint venture. Players enjoy their joint success, but dislike effort. The actual payoffs of players 1 and 2 are given by

\[ r \int_0^\infty e^{-rt}(2dX_1^1 + 2dX_2^1 - 3A_1^1) dt \quad \text{and} \quad r \int_0^\infty e^{-rt}(2dX_1^2 + 2dX_2^2 - 3A_1^2) dt. \]

Note that the instantaneous payoff of player \( i \) depends on \( A_i^1, dX_1^i \) and \( dX_2^i \). The expected payoffs can be written as

\[ E \left[ r \int_0^\infty e^{-rt}g_1(A_1^1, A_2^2) dt \right] \quad \text{and} \quad E \left[ r \int_0^\infty e^{-rt}g_2(A_1^1, A_2^2) dt \right], \]

where

\[ g_1(a_1, a_2) = 2a_2 - a_1 \quad \text{and} \quad g_2(a_1, a_2) = 2a_1 - a_2. \]

Static payoff functions \( g_1 \) and \( g_2 \) give the expectation of the rates at which the players receive their payoffs for any pair of actions. The matrix of expected payoffs of the stage game, shown in Figure 2, is that of a prisoners’ dilemma.

To give a taste of our results, Figure 2 also shows a computed set \( \mathcal{E}(r) \) for \( r = 0.2 \). In the figure players can achieve payoffs much better than those of a static Nash equilibrium, but cannot achieve full efficiency due to noise.

Let us describe the equilibrium that achieves the largest sum of payoffs, corresponding to point \( C \) on the boundary of the set \( \mathcal{E}(r) \). During the equilibrium play, the pair of continuation values follows a diffusion process on the boundary of \( \mathcal{E}(r) \), driven by the realizations of \( X \). The pair of continuation values has a drift and a volatility. The tangential component of the drift is shown in Figure 2: it is directed away from points \( A, C \) and \( E \), towards points \( B, D \), and the origin. Players choose their effort levels depending on the current pair of continuation values as shown in Figure 2. Both players put effort on the thick portion of the boundary of \( \mathcal{E}(r) \).

Figure 3 gives three sample paths of the players’ continuation values in the equilibrium that achieves payoff pair \( C \). The vertical axis represents the boundary of \( \mathcal{E}(r) \), denoted by \( \partial \mathcal{E}(r) \), with points \( A, B, C, D \) and \( E \) clearly marked.

In Figure 3, the drift of continuation values is directed away from the dashed horizontal lines, towards the solid lines. The solid lines represent the boundaries, where one of the players switches from effort to no effort. Because of the drift pattern, players typically spend considerable amounts of time in “unequal” regimes between the dashed lines, where one player puts effort and the other alternates between effort and no effort.
The realizations of $X$ cause players to switch from one unequal regime to another, until they become absorbed in the static Nash equilibrium, in which players stop putting effort. We see from Figure 3 that the collapse into Nash equilibrium is fast because the drift towards the Nash equilibrium point becomes stronger as the continuation values approach that point.

The partnership game belongs to a simple subclass of repeated games with two separate one-dimensional signals, whose drifts equal the actions of the two players. These games have a product structure (see footnote 11) and are a useful starting point to understand continuous-time games in general. The provision of incentives in these games is especially simple, as discussed in Subsection 7.1. In Section 8, where we mostly discuss computation, we present another example of a continuous-time game from this class, a duopoly with differentiated products.

Figure 3: Sample Paths of Continuation Values.
3 The Setting.

Two players participate in a repeated game with imperfect monitoring in continuous time. At each moment of time $t \in [0, \infty)$, player $i$ takes an action $A^i_t$ from a finite set $A^i$. Players do not see each others’ actions $A_t = (A^1_t, A^2_t)$ directly, but only observe $d$-dimensional public signals

$$X_t = \int_0^t \mu(A_s) \, ds + Z_t,$$

where $Z$ is a $d$-dimensional Brownian motion and $\mu : A^1 \times A^2 \to \mathbb{R}^d$ is a drift function.\(^\text{7}\) The arrival public information is captured by the filtration $\{\mathcal{F}_t\}$. It can be strictly bigger than the filtration generated by $X$ to allow for public randomization (by both continuous and discontinuous processes). A pure public strategy of player $i$ is a stochastic process $A^i_t$ with values in $A^i$, which is progressively measurable with respect to $\{\mathcal{F}_t\}$.

Formally, the game takes place on a probability space $(\Omega, \mathcal{F}, P)$ with filtration $\{\mathcal{F}_t\}$. The state space $\Omega$ of all possible paths of $X$ and outcomes of public randomization, as well as the filtration $\{\mathcal{F}_t\}$ with $\mathcal{F}_\infty = \mathcal{F}$, are fixed for the game. However, the probability measure $P$ is determined by the players’ actions in such a way that (1) holds.\(^\text{8}\)

Player $i$’s random total discounted payoff for a profile of public strategies $A$ is\(^\text{9}\)

$$r \int_0^\infty e^{-rt} c_i(A^i_t) \, dt + b_i(A^i_t) \, dX_t = r \int_0^\infty e^{-rt} (c_i(A^i_t) + b_i(A^i_t) \mu(A_t)) \, dt + r \int_0^\infty e^{-rt} b_i(A^i_t) \, dZ_t,$$

for some functions $c_i : A^i \to \mathbb{R}$ and $b_i : A^i \to \mathbb{R}^d$, where $r > 0$ denotes the common discount.

\(^\text{7}\)Throughout the paper, $d$-dimensional vectors $X$, $Z$ and $\mu$ are column vectors, $b$, $\beta$, $\phi$, $\psi$ and $\chi$ are row vectors, 2-dimensional vectors $g$, $v$, $w$, and $W$ are column vectors, and $T$ and $N$ are unit row vectors.

\(^\text{8}\) If players deviate from a pair of strategies $A = (A^1, A^2)$ to a pair of strategies $\hat{A}$, then the probability measure over signals becomes altered by the relative density process $\xi$ defined by $\xi_0 = 1$ and $d\xi_t = \xi_t (\mu(A_2) - \mu(A_1))^	op \, dX_t$. The value of $\xi_t$ captures the relative likelihood that a path $\{X_s, s \in [0, t]\}$ of the public signals becomes realized from strategies $\hat{A}$ in comparison with $A$. Note that the players’ actions affect only signals $X$ and nothing else, as the relative density process depends only on the players’ actions and the realizations of $X$.

\(^\text{9}\) The proper way of writing the payoff of player $i$ is

$$r \int_0^\infty e^{-rt} c_i(A^i_t) \, dt + r \int_0^\infty e^{-rt} b_i(A^i_t) \, dX_t,$$

where the Lebesgue integral and the stochastic integral are separated. Throughout the paper we put them under one integral sign to shorten notation, recognizing that we are mixing two types of integrals, but believing that this cannot cause confusion.
rate of the two players. Let

\[ g_i(A_t) = c_i(A^i_t) + b_i(A^i_t) \mu(A_t) \]

be player i’s expected payoff flow at time t.

**Definition.** A profile of public strategies \( A = (A^1, A^2) \) is a *perfect public equilibrium* (PPE) if for \( i = 1, 2 \), \( A^i \) maximizes the expected discounted payoff of player \( i \) given the strategy \( A^j \) of his opponent after all public histories.

Formally, the expected discounted payoff (a.k.a. continuation value) of player \( i \) after a public history at time \( t \) is

\[
W^i_t(A) = E_t \left[ r \int_t^{\infty} e^{-r(s-t)}(c_i(A^i_s) + b_i(A^i_s) \mu(X_s)) \right. \left. ds \mid A_s, s \in [t, \infty) \right] = E_t \left[ r \int_t^{\infty} e^{-r(s-t)}g_i(A_s) \right. \left. ds \mid A_s, s \in [t, \infty) \right].
\]

This expectation, conditioned on the public information at time \( t \), makes explicit the fact that actions affect payoffs directly through \( g_i(A_s) \) and indirectly because \( \{A_s; s \in [t, \infty)\} \) determines the probability distribution over the future paths of \( X \). Denote \( W_t(A) = (W^1_t(A), W^2_t(A))^\top \) and \( g(a) = (g_1(a), g_2(a))^\top \).

Starting with Section 6, we make two assumptions about payoffs and signals:\(^{10}\)

**Assumption 1.** All action profiles \((a_1, a_2) \in A_1 \times A_2\) of the stage game are *pairwise identifiable*, i.e. the spans of the \( d \times (|A^1| - 1) \) matrix \( M_1(a) \) with columns \( \mu(a'_1, a_2) - \mu(a), a'_1 \neq a_1 \) and the \( d \times (|A^2| - 1) \) matrix \( M_2(a) \) with columns \( \mu(a_1, a'_2) - \mu(a), a'_2 \neq a_2 \) intersect only at the origin.

Pairwise identifiability, adapted to our continuous-time setting from FLM, implies that deviations of different players can be statistically distinguished. Note that we do not require *individual full rank*, i.e. independence of the columns of \( M_i(a) \).

**Assumption 2.** Either

(i) For all \( i = 1, 2 \) and \( a_i \in A^i \), the static best response to \( a_i \) is unique or

\(^{10}\)These assumptions serve a technical role: they ensure that the *optimality equation* that characterizes the set \( \mathcal{E}(r) \) is Lipschitz-continuous. Lemma 1 in Appendix A uses Assumption 1, and Lemma 3 uses Assumption 2.
(ii) For all \( a \in A \), the spans of \( M_1(a) \) and \( M_2(a) \) are orthogonal\(^{11}\)

In the next sections we characterize the set \( \mathcal{E}(r) \) of payoff pairs achievable by all PPE and pay special attention to the PPE that achieve extreme value pairs of the set \( \mathcal{E}(r) \).\(^{12}\) We find that the equilibrium play in those PPE is determined essentially uniquely and it does not use public randomization.\(^{13}\) The equilibrium dynamics are described in terms of the stochastic motion of continuation values on the boundary of \( \mathcal{E}(r) \) driven by the public signals.

4 Important Sets.

Let us review several concepts that are familiar from the theory of repeated games. A stage game \( G \) has the set of players \( N = \{1, 2\} \), an action set of each player \( A_i \) and payoff functions \( g_i \).

\[
G = \{ N, (A_i)_{i \in N}, (g_i)_{i \in N} \}.
\]

Denote the set of all action profiles of the stage game \( G \) by \( A = A_1 \times A_2 \), and the set of pure strategy Nash equilibria, by \( A^N \subseteq A \). Let \( \mathcal{N} \) be the convex hull of all pure strategy Nash equilibrium payoff pairs of game \( G \), and \( \mathcal{V} \), the convex hull of all feasible payoff pairs:

\[
\mathcal{N} \equiv \text{co} \{ g(a) \mid a \in A^N \} \quad \mathcal{V} \equiv \text{co} \{ g(a) \mid a \in A \}.
\]

The pure strategy minmax payoff of player \( i \) is

\[
v_i \equiv \min_{a_j} \max_{a_i} g_i(a_i, a_j) \quad (3)
\]

\(^{11}\) For example, games with product structure, in which two separate independent signals reflect the actions of players 1 and 2, satisfy Assumption 2(ii).

\(^{12}\) In a game with public monitoring, any pure strategy is a public strategy. Therefore, under pure strategies the set of PPE payoffs coincides with the set of payoffs achievable by all sequential equilibria. This is not always the case for mixed strategies: as shown in Kandori and Obara (2003), players can sometimes get payoffs higher than those achievable in any mixed-strategy PPE by the use of private strategies, in which a player’s current action can depend not only on the public history of signals, but also the private history of his own past actions.

\(^{13}\) By allowing public randomization, we can conclude early in Section 4 that the set \( \mathcal{E}(r) \) is convex. This conclusion greatly simplifies the derivation of other properties of \( \mathcal{E}(r) \) on the way to our main result. In the end, public randomization becomes unnecessary, but it proves simplifying in the course of our derivation.
Player $i$ can guarantee himself his pure strategy minmax payoff for any strategy of the opponent. Define by

$$\mathcal{V}^* = \{v \in \mathcal{V} \mid v_i \geq v_i^a, \text{ for } i = 1, 2\},$$

the subset of $\mathcal{V}$ on which each player receives at least his minmax payoff.

![Diagram](image)

**Figure 4**: Sets $\mathcal{N}$, $\mathcal{E}(r)$, $\mathcal{V}^*$ and $\mathcal{V}$ for the Noisy Partnership with $r = 0.2$.

Due to the possibility of public randomization the set $\mathcal{E}(r)$ of payoff pairs achievable by all PPE is convex. Indeed, if $A$ and $\hat{A}$ are two PPE with expected values $W_0(A)$ and $W_0(\hat{A})$, a PPE with value $\lambda W_0(A) + (1 - \lambda)W_0(\hat{A})$ for some $\lambda \in (0, 1)$ can be achieved by selecting equilibrium $A$ or $\hat{A}$ according to the realization of a discrete random variable at time 0.\(^{14}\)

As in repeated games in discrete time, we have

$$\mathcal{N} \subseteq \mathcal{E}(r) \subseteq \mathcal{V}^* \subseteq \mathcal{V},$$

as illustrated in Figure 4.

\(^{14}\)Although we rely on public randomization and the convexity of $\mathcal{E}(r)$ during our analysis, we will learn from our main result that public randomization is, in fact, not required to achieve any payoff pair in $\mathcal{E}(r)$.  

12
5 Continuation Values, Incentives and PPE.

In this section, we characterize public perfect equilibria in terms of the stochastic properties of the continuation values $W^1_t(A)$ and $W^2_t(A)$. Our analysis proceeds as follows. We start with the definition of a continuation value: it is the future expected payoff of a player from a given pair of strategies after a given public history. As time passes and the history unfolds, the continuation values change. Their motion is determined by the public information: the signals $X_t$ and public randomization. Proposition 1 represents the relationship between public information and the motion of continuation values formally, and shows that this motion must satisfy a promise keeping condition. This condition relates a player’s current continuation value, his current payoff flow and the expected change of his continuation value under an arbitrary pair of strategies $A$.

Next, we explore conditions under which a pair of strategies $A$ is a PPE. We find that the players’ incentives are connected with the relationship between the public signals and the motion of continuation values. A player may have incentives to take an action different from a static best response because (a) actions affect public signals, and (b) public signals affect future continuation values. Proposition 2 proves that a strategy of player $i$ is optimal in response to the strategy of his opponent at all times if and only if the instantaneous incentive compatibility condition always holds. The analogue of Proposition 2 in discrete time is the one-shot deviation principle. The results of Propositions 1 and 2 are summarized in Theorem 1, which characterizes $\mathcal{E}(r)$ as the largest bounded self-generating set.

Recall that the continuation value of player $i$, the expected future payoff from a strategy profile $A$ after a given public history, is

$$W^i_t(A) = E_t \left[ r \int_t^\infty e^{-r(s-t)} g_i(A_s) \, ds \mid A_s, s \in [t, \infty) \right].$$

$$W^i_t(A)$$ has the following representation in terms of the public information in $\mathcal{F}_t$.

**Proposition 1. (Representation and Promise Keeping).** A stochastic process $W^i_t$ is the continuation value $W^i_t(A)$ of player $i$ under a strategy profile $A$ if and only if there exist processes $\beta^i = (\beta^i_1 \ldots \beta^i_d)$ in $\mathcal{L}^*$ and a martingale $\tilde{\epsilon}^i$ orthogonal to $X$ with $\tilde{\epsilon}^i_0 = 0$, such that for all $t \geq 0$, $W^i_t$ satisfies

$$W^i_t = W^i_0 + r \int_0^t (W^i_s - g_i(A_s)) \, ds + r \int_0^t \beta^i_s \, (dX_s - \mu(A_s)ds) + \tilde{\epsilon}^i_t.$$  

$^\text{15}$ $\mathcal{L}^*$ is the space of all progressively measurable processes $\delta$ such that $E[\int_0^T \delta^2_t dt] < \infty$ for all $T < \infty$.  

13
When the filtration $\{\mathcal{F}_t\}$ is generated by $X$, so that there is no public randomization, then a process $W^i_t$ is the continuation value of player $i$ if and only if (5) holds with $\tilde{e}^i = 0$.

The representation in Proposition 1 formalizes how the process $W^i_t(A)$ is determined by public information: signals $X$ and orthogonal information $\tilde{e}^i_t$, with $\tilde{e}^i_t = 0$ when there is no public randomization. There is a simple logic behind the representation (5), whose shorthand form

$$dW^i_t = r(W^i_t - g_i(A_t)) \, dt + r\beta^i_t (dX_t - \mu(A_t)dt) + d\tilde{e}^i_t$$

(6)

can be interpreted as an instantaneous projection of $dW^i_t$ onto a “constant” $dt$ and $dX_t - \mu(A_t) dt$. Clearly, the “residual” $d\tilde{e}^i_t$ has to be orthogonal to the constant, and thus a martingale. The residual is 0 when $\{\mathcal{F}_t\}$ is generated by $X$ as then 0 is the only martingale orthogonal to $X$.

Coecient $\beta^i_t$ denotes the exposure of player $i$’s continuation value to $dX_t$. The term $r(W^i_t - g_i(A_t))$ is the drift of continuation values $W^i_t(A)$ when the players are actually following strategies $A$ so that $dX_t = \mu(A_t) dt + dZ_t$. This drift condition under the pair of strategies $A$, which we can call the promise keeping condition, is simply a consequence of book-keeping. It has an analogue in discrete time: If a payoff vector $W_t$ is decomposable by an action vector $a$ and continuation promises $W_{t+1}(y_t)$ for different public signals $y_t$ in period $t$, then

$$W_t = (1 - \delta)g(A_t) + \delta E[W_{t+1}(y_t)|A_t] \Rightarrow E[W_{t+1}(y_t)|A_t] - W_t = \frac{1 - \delta}{\delta} (W_t - g(A_t)),$$

where $\delta$ is the discount factor. Thus, the expected movement of continuation values is proportional to $W_t - g(A_t)$.

**Proof.** First, let us prove that $W^i_t(A)$ has a representation (5). In order to identify how $W^i_t(A)$ depends on the public information $\{\mathcal{F}_t\}$, suppose that the players are actually following strategies $A$. Then $X_t - \int_0^t \mu(A_s) ds$ is a Brownian motion and the process $\{V^i_t(A)\}$ defined by

$$V^i_t(A) = r \int_0^t e^{-rs} g_i(A_s) \, ds + e^{-rt}W^i_t(A) = E_t \left[ r \int_0^\infty e^{-rs} g_i(A_s) \, ds | A \right]$$

(7)

is a martingale. By Proposition 3.4.14 from Karatzas and Shreve (from now on KS), we
can choose processes $\beta^i = (\beta^i_1 \ldots \beta^i_d)$ in $\mathcal{L}^*$ such that

$$V^i_t(A) = r \int_0^t e^{-rs} \beta^i_s \, (dX_s - \mu(A_s) \, ds) + V^X_t,$$

(8)

where $V^X_t$ is a martingale orthogonal to $X$.\footnote{Formally, Proposition 3.4.14 from KS only says that the processes $e^{-rt}\beta^i_t$ are in $\mathcal{L}^*$ and that $V^X_t$ is orthogonal to the underlying Brownian motion. However, trivially, $E[\int_0^T (\beta^i_t)^2 \, dt] \leq e^{2rt} E[\int_0^T e^{-2rt} (\beta^i_t)^2 \, dt] < \infty$, so $\beta^i_t$ are also in $\mathcal{L}^*$. Also, since $V^X_t$ is a martingale, it must be orthogonal to $X$ also.} If the filtration $\{\mathcal{F}_t\}$ is generated by $X$, then by the Martingale Representation Theorem (whose proof in KS, incidentally, relies on Proposition 3.4.14), we get the representation (8) with $V^X_t = V^X_0$ for all $t \geq 0$.

Putting together (7) and (8) and differentiating with respect to $t$, we get

$$re^{-rt} g^i(A_t) \, dt - re^{-rt} W^i_t(A) \, dt + e^{-rt} dW^i_t(A) = re^{-rt} \beta^i_t \, (dX_t - \mu(A_t) \, dt) + dV^X_t,$$

which implies (5) with $\tilde{\beta}^i_t = \int_0^t e^{s} \, dV^X_s$. If the filtration $\{\mathcal{F}_t\}$ is generated by $X$ then $\tilde{\beta}^i_t = 0$ for all $t \geq 0$. Note that $W^i_t(A)$ is a bounded process because $g^i$ is a bounded function.

Now, let us prove the converse: if a bounded process $W^i_t$ satisfies (5) (with $\tilde{\beta}^i_t = 0$ or not) then it must be $W^i_t(A)$. The process

$$V^i_t = r \int_0^t e^{-rs} g^i(A_s) \, ds + e^{-rt} W^i_t$$

is a martingale under the strategies $A$ because $dV^i_t = e^{-rt} (r \beta^i_t \, (dX_t - \mu(A_t) \, dt) + d\tilde{\beta}^i_t)$ from (5). Moreover, martingales $V^i_t$ and $V^i_t(A)$ converge because both $e^{-rt} W^i_t$ and $e^{-rt} W^i_t(A)$ converge to 0. We conclude that for all $t \geq 0$,

$$V^i_t = E_t[V^i_\infty] = E_t[V^i_\infty(A)] = V^i_t(A) \quad \Rightarrow \quad W^i_t = W^i_t(A).$$

It is important that even if players are following an alternative strategy profile $\hat{A}$, the process $W^i_t(A)$ is still well-defined. As emphasized by the conditioning on $\{A_s, s \geq t\}$ in the definition (4), $W^i_t(A)$ can be interpreted as the value that player $i$ would get if the play proceeds according to the strategy profile $A$ after time $t$. Because $A$ uniquely determines the players’ actions after all public histories, the value of $W^i_t(A)$ is completely determined by the public history at time $t$ independently of the actual strategy profile $\hat{A}$ that caused this history to realize. We conclude that the representation (5) for $W^i_t(A)$ is valid no matter
what strategy profile \( \hat{A} \) is being played, even though we derived (5) assuming that \( A \) is the actual profile followed. Moreover, from our assumptions \( \bar{\varepsilon}^i \) is still a martingale under an alternative strategy profile \( \hat{A} \). These facts are important for Proposition 2 that deals with incentives.\(^{17}\)

The process \( \beta^i \) represents the extent, to which player \( i \)'s value \( W^i_t(A) \) is driven by the public signal \( X \). Therefore, \( \beta^i \) is responsible for player \( i \)'s incentives, as shown below:

**Proposition 2. (Incentive Compatibility).** Strategy \( A^i \) of player \( i \) is optimal in response to strategy of \( A^j \) at all times if and only if the incentive compatibility condition

\[
\forall a^i_t \in A^i, \quad g_i(A_t) + \beta^i_t \mu(A_t) \geq g_i(a^i_t, A^j_t) + \beta^i_t \mu(a^i_t, A^j_t)
\]

holds for all \( t \). Therefore, a pair of strategies \( A \) is a PPE if and only if (9) holds for both players.

Let us interpret the incentive compatibility condition. Suppose that player \( i \) is contemplating a deviation to an alternative action \( a^i_0 \) at time \( t \). This will change his expected instantaneous payoff flow by \( g_i(a^i_0, A^j_t) - g_i(A_t) \). At the same time, this deviation changes the drift of \( X_t \) by \( \beta^i_t (\mu(a^i_0, A^j_t) - \mu(A_t)) \). Since \( \beta^i_t \) is the sensitivity of player \( i \)'s continuation value to \( dX_t \), this will change player \( i \)'s continuation value at rate \( \beta^i_t (\mu(a^i_0, A^j_t) - \mu(A_t)) \).

If the incentive compatibility condition holds, such an instantaneous deviation will affect player \( i \)'s expected payoff by

\[
g_i(a^i_0, A^j_t) - g_i(A_t) + \beta^i_t (\mu(a^i_0, A^j_t) - \mu(A_t)) \leq 0.
\]

Therefore, condition (9) states that an instantaneous deviation is not profitable. Proposition 2 is analogous to the one-shot deviation principle in discrete time.

In the proof of Proposition 2 we show that instantaneous incentive compatibility implies full incentive compatibility. Instantaneous losses from deviations integrate to a loss globally.

\(^{17}\)Because \( \bar{\varepsilon}^i \) is orthogonal to \( X \), it is also orthogonal to the relative density process \( \xi^i = 1 + \int_0^t \xi_s (\mu(\hat{A}) - \mu(A)) \) of the probability measures under \( \hat{A} \) and \( A \) (see footnote 8).

\(^{18}\)Note that \( W^i_t(\hat{A}) \), player \( i \)'s continuation value when a strategy profile \( \hat{A} \) is followed after time \( t \), is different from \( W^i_t(A) \). The representation of \( W^i_t(\hat{A}) \) involves different processes \( \beta^i(\hat{A}) \) and \( \bar{\varepsilon}^i(\hat{A}) \). To avoid confusion, in the entire paper \( \beta^i \) and \( \bar{\varepsilon}^i \) always denote the processes that represents specifically \( W^i_t(A) \), and not \( W^i_t(\hat{A}) \), even when we discuss a deviation to an alternative strategy in Proposition 2.
Proof. Since $e^{-rt}W^i_t(A)$ converges to 0 as $t \to \infty$, it follows that
\[
W^i_0(A) + \int_0^\infty d(e^{-rt}W^i_t(A)) = 0,
\]
where, by (6), $d(e^{-rt}W^i_t(A))$ is expressed as a function of public information $X$ and $\hat{e}^i$ as
\[
d(e^{-rt}W^i_t(A)) = re^{-rt} \left( -g_i(A_t) \ dt + \beta^i_t (dX_t - \mu(A_t) dt) + d\hat{e}^i_t \right).
\]

The expected payoff to player $i$ from deviating to a strategy $\hat{A}^i$ in response to $A^j$ can be expressed as
\[
W^i_0(\hat{A}^i, A^j) = E \left[ r \int_0^\infty g_i(\hat{A}^i_t, A^j_t) dt \mid \hat{A}^i, A^j \right] =
E \left[ W^i_0(A) + \int_0^\infty re^{-rt} \left( -g_i(A_t) \ dt + \beta^i_t (dX_t - \mu(A_t) dt) + d\hat{e}^i_t \right) + r \int_0^\infty e^{-rt} g_i(\hat{A}^i_t, A^j_t) dt \mid \hat{A}^i, A^j \right] =
W^i_0(A) + E \left[ r \int_0^\infty e^{-rt} \left( g_i(\hat{A}^i_t, A^j_t) - g_i(A_t) + \beta^i_t (\mu(\hat{A}^i_t, A^j_t) - \mu(A_t)) \right) dt \mid \hat{A}^i, A^j \right].
\]

Throughout the derivation we condition on the players’ strategies $(\hat{A}^i, A^j)$, which affect the probability measure over the paths of $X$. Under this measure $X_t$ has drift $\mu(\hat{A}^i_t, A^j_t)$ and $\hat{e}^i_t$ is still a martingale.

If condition (9) holds for all $t$, then $W^i_0(\hat{A}^i, A^j) \leq W^i_0(A)$ and player $i$ does not have a profitable deviation at time 0. By a similar argument, player $i$ will not have a profitable deviation after any public history. Conversely if (9) fails, choose a strategy $\hat{A}^i$ such that $\hat{A}^i_t$ maximizes $g_i(a_t, A^j_t) + \beta^i_t \mu(a_t, A^j_t)$ for all $t$. Then, $W^i_0(\hat{A}^i, A^j) > W^i_0(A)$ and $A^i$ is not an optimal response to the strategy $A^j$.

Definition. A $2 \times d$ matrix
\[
B = \begin{bmatrix} \beta^1 \\ \beta^2 \end{bmatrix} = \begin{bmatrix} \beta^{11} & \ldots & \beta^{1d} \\ \beta^{21} & \ldots & \beta^{2d} \end{bmatrix}
\]

\footnote{In this case the strategy $A^i$ is better than $A^j$ in response to $A^j$, but it does not have to be optimal. The reason is that $A^i_t$ does not have to maximize $g_i(a_t, A^j_t) + \beta^i_t \mu(a_t, A^j_t)$, where $\beta^i_t$, the exposure of $W(\hat{A}^i, A^j)$ to $X$, does not have to equal $\beta^i_t$.}
enforces action profile \( a \in \mathcal{A} \) if for \( i = 1, 2 \),
\[
\forall a_i' \in \mathcal{A}^i, \quad g_i(a) + \beta^i \mu(a) \geq g_i(a_i', a_j) + \beta^i \mu(a_i', a_j)
\] (11)

An action profile \( a \in \mathcal{A} \) is enforceable if there exists some matrix \( B \) that enforces it.

Together Propositions 1 and 2 provide two properties that the motion of continuation values has to satisfy in any PPE: promise keeping which determines the drift of continuation values, and incentive compatibility which determines their volatility. Moreover, Propositions 1 and 2 also imply the converse: if the motion of a bounded stochastic process \( W \) associated with strategies \( A \) satisfies promise keeping and incentive compatibility, then \( W = W(A) \) and \( A \) must be a PPE. We summarize this characterization of PPE in the following theorem:

**Theorem 1. Characterization of PPE.** In any PPE \( A \), the pair of continuation values \( W = W(A) \) is a process in \( \mathcal{V}^* \) that satisfies
\[
W_t = W_0 + r \int_0^t (W_s - g(A_s)) \, ds + r \int_0^t B_s \left( dX_s - \mu(A_s) \, ds \right) + \epsilon_t,
\] (12)

where

(i) \( B \) is a 2 \times d matrix process in \( \mathcal{L}^* \) such that \( B_t \) enforces \( A_t \) for all \( t \) and

(ii) \( \epsilon \) is a 2-dimensional martingale orthogonal to \( X \) with \( \epsilon_0 = (0, 0)^\top \).

If \( \{ \mathcal{F}_t \} \) is generated by \( X \) then \( \epsilon_t = (0, 0)^\top \) for all \( t \geq 0 \).

Conversely, if \( W \) is a bounded 2-dimensional process that satisfies equation (12) for \( A, B \) and \( \epsilon \) that satisfy properties (i) and (ii), then \( W \) is a pair of continuation values in public perfect equilibrium \( A \).

**Definition.** A set \( \mathcal{W} \subseteq \mathbb{R}^2 \) is self-generating if and only if for any point \( W_0 \in \mathcal{W} \) there exists a processes \( W \) that starts at \( W_0 \), stays in \( \mathcal{W} \) and satisfies (12) for some processes \( A, B \) and \( \epsilon \) that satisfy conditions (i) and (ii) of Theorem 1.

**Corollary 1.** \( \mathcal{E}(r) \) is the largest bounded self-generating set.

---

\(^{20}\)The Martingale Representation Theorem implies that if \( \{ \mathcal{F}_t \} \) is generated by \( X \) then \( \epsilon_t = (0, 0)^\top \), \( t \geq 0 \) is the only martingale that satisfies (ii).
Corollary 1 is a continuous-time analogue of Theorems 1 and 2 (self-generation and factorization) from APS, which imply that the set of equilibrium payoff vectors is the largest bounded self-generating set. The boundedness assumption in APS is related to the boundedness assumption in Corollary 1 and Proposition 1.

Corollary 1 formulates the problem of finding the set $\mathcal{E}(r)$ as a problem from optimal stochastic control. We will use this result to characterize the set $\mathcal{E}(r)$ and PPE that achieve extreme points of the set $\mathcal{E}(r)$ in the next section.

6 PPE with Extreme Values: a Derivation.

In this Section we use the characterization of PPE from Corollary 1 to derive our main result: an ordinary differential equation, called the optimality equation, which describes the boundary of $\mathcal{E}(r)$ and PPE that achieve extreme points of $\mathcal{E}(r)$. The boundary of $\mathcal{E}(r)$ is denoted by $\partial\mathcal{E}(r)$. First, we informally describe our results. Then in subsection 6.2 we argue informally that the boundary of $\mathcal{E}(r)$ is characterized by the optimality equation, a result proved formally in Proposition 5 in Appendix B. We also prove Proposition 3, which constructs PPE with extreme values and shows that $\mathcal{E}(r)$ is the largest bounded set whose boundary satisfies the optimality equation. Our main result, Theorem 2, follows from Propositions 3 and 5.

6.1 Informal Discussion.

Let us review the properties of PPE from the previous section, and then introduce the main results of this section about the geometry of the set $\mathcal{E}(r)$ and PPE that achieve extreme value pairs of $\mathcal{E}(r)$. According to Corollary 1, $\mathcal{E}(r)$ is the largest subset of $\mathcal{V}^*$ such that for any $W_0 \in \mathcal{E}(r)$ there exist processes $(A, B, \tilde{\varepsilon})$ that satisfy conditions (i) and (ii) of Theorem 1, so that the process $\{W_t\}$ given by

$$W_t = W_0 + r \int_0^t (W_s - g(A_s)) \, ds + r \int_0^t B_s \, dZ_s + \tilde{\varepsilon}_t$$  \hspace{1cm} (13)

remains in $\mathcal{E}(r)$. We have the freedom to choose actions $A$, volatilities $B$ that enforce those actions, and public randomization $\tilde{\varepsilon}$. If the initial value pair $W_0$ is inside the set $\mathcal{E}(r)$, this freedom gives a lot of room for very many equilibria. However, if the initial value pair $W_0$ is an extreme point of the set $\mathcal{E}(r)$, the choice of controls is severely restricted because
continuation values cannot escape from the set $E(r)$. In fact, we show that in a PPE that achieves an extreme value pair of the set $E(r)$,

(a) future continuation values $W_t$ must be extreme points of $E(r)$

(b) there is no public randomization, i.e. $\epsilon = 0$

(c) the span of $B_t$ is in the tangential direction to the set $E(r)$ at point $W_t$ at all times

(d) the choice of $A_t$ and $B_t$ is generically unique at all times

(e) if there are static Nash equilibria with payoff vectors on the boundary of $E(r)$, the players’ actions are eventually absorbed into one of those Nash equilibria with probability 1.

We also show that the entire boundary of $\partial E(r)$ outside $N$ has a strictly positive and continuous curvature and, therefore, consists of extreme points.

The spirit of properties (a)-(e) is present in the existing literature on repeated games. However, in discrete time these properties hold only under special continuity assumptions or in approximation. In relation to (a) and (b) in discrete time, one can always choose extreme continuation values if there is public randomization. Without public randomization, APS show that future continuation values can be chosen to be extreme points of the equilibrium value set if the distribution of signals is non-atomic. Moreover, under certain analyticity conditions, future continuation values have to be extreme. The property (c) that $B_t$ must have a tangential span is related to FLM’s concept of enforceability of action pairs on tangent hyperplanes that is used to prove the Folk Theorem. Fudenberg and Levine (1994) show that the Folk Theorem fails when equilibrium action pairs cannot be enforced on tangent hyperplanes.21 Also, the Folk Theorem typically fails in strongly symmetric equilibria that do not use tangent hyperplanes (see Proposition 8.2.1 in Mailath and Samuelson (2006) for the proof of this fact, and Green and Porter (1984) and APS (1986) for analyses of strongly symmetric equilibria).22 Point (d) holds only under very strict continuity assumptions (e.g. the analyticity assumptions of APS that guarantee that

Sannikov and Skrzypacz (2006) show that in the limit as the players act more and more frequently, Brownian signals cannot provide incentives in any other way than by tangential transfers of continuation values.

The observation after the proof of Lemma 6 in Appendix B implies that $E(r) = N$ if the set $E(r)$ has empty interior. It follows that there are no nontrivial strongly symmetric equilibria in continuous-time games with Brownian signals. Sannikov and Skrzypacz (2005) show that this is also true in discrete-time games with frequent actions.

21Sannikov and Skrzypacz (2006) show that in the limit as the players act more and more frequently, Brownian signals cannot provide incentives in any other way than by tangential transfers of continuation values.

22The observation after the proof of Lemma 6 in Appendix B implies that $E(r) = N$ if the set $E(r)$ has empty interior. It follows that there are no nontrivial strongly symmetric equilibria in continuous-time games with Brownian signals. Sannikov and Skrzypacz (2005) show that this is also true in discrete-time games with frequent actions.
continuation values must be extreme points). For point (e) if there is a unique way to support any extreme value pair, extreme Nash equilibrium payoff pairs would absorb equilibrium play if continuation values get there. However, in discrete time it may be possible for continuation values to never reach such an absorbing state.\footnote{See Hauser and Hopenhayn (2004) for a continuous-time example with Poisson signal arrival, in which continuation values never reach static Nash equilibria. This phenomenon can occur in discrete time, but not in our games with Brownian signals.}

Even though the spirit of properties (a)-(e) is present in discrete-time games, it is difficult to formalize them. However, they come out cleanly in our setting.

Besides proving (a)-(e) we also show that \( \partial \mathcal{E}(r) \setminus \mathcal{N} \) is characterized by the optimality equation. This ordinary differential equation connects the curvature of the boundary with the equilibrium actions and the stochastic motion of continuation values, and can be used for computation.\footnote{The characterization in terms of an ordinary differential equation, as well as property (e), rely upon the restriction to two players.} To understand this equation, we must first provide an analogue of FLM’s concept of enforceability on tangent hyperplanes in our setting:

**Definition.** A vector of tangential volatilities \( \phi \in \mathbb{R}^d \) enforces \( a \in \mathcal{A} \) on tangent \( T = (t_1, t_2) \) if the matrix

\[
B = T^\top \phi = \begin{bmatrix} t_1 \phi_1 \ldots t_1 \phi_d \\ t_2 \phi_1 \ldots t_2 \phi_d \end{bmatrix}
\]

enforces \( a \). Of all vectors \( \phi \) that enforce \( a \) on tangent \( T \), let \( \phi(a, T) \) be the one of the smallest length.

The main result of this section is that \( \mathcal{E}(r) \) is the largest bounded set with the curvature of the boundary outside \( \mathcal{N} \) given by the optimality equation

\[
\kappa(w) = \max_{a \in \mathcal{A} \setminus \mathcal{A}^N} \frac{2 \mathbf{N}(w)(g(a) - w)}{r|\phi(a, T(w))|^2},
\]

where \( T(w) \) and \( \mathbf{N}(w) \) are unit tangent and outward normal vectors to \( \partial \mathcal{E}(r) \) at \( w \in \partial \mathcal{E}(r) \setminus \mathcal{N} \) and \( |\phi| \) is the length of the vector \( \phi \). In the maximization problem in (14) some action profiles \( a \) may not be enforceable on \( T \); we substitute \( |\phi(a, T)| = \infty \) for those \( a \).

**Remark.** Lemma 2 in Appendix A, analogous to Lemma 5.5 in FLM, shows that under pairwise identifiability any enforceable action profile \( a \) is enforceable on all regular tangent vectors \( T = (t_1, t_2) \), such that \( t_1, t_2 \neq 0 \). An enforceable profile \( a \) is enforceable on a coordinate vector \( T \) with \( t_i = 0 \) if and only if \( a \) involves a best response of player \( i \).
6.2 Derivation.

In this subsection we justify our characterization. We start with a heuristic argument that the boundary of \( E(r) \) satisfies the optimality equation, a result proved formally in Proposition 5 in Appendix B. We proceed in four steps. First, we argue that when a current pair of continuation values is extreme, then public randomization cannot be used and the volatilities of continuation values must be tangential to the boundary of \( E(r) \). Second, we take a detour to explore the geometric properties of a two-dimensional diffusion, whose volatility is focused along one line, and identify a ‘natural curvature’ of this process. Third, we argue the curvature of the boundary of \( E(r) \) at any extreme point outside \( \mathcal{N} \) must satisfy equation (14). Fourth, we show that any point \( w \notin \mathcal{N} \) on the boundary of \( E(r) \) must be extreme.

After that we present Proposition 3, which implies that \( E(r) \) is the largest bounded set whose boundary satisfies equation (14) outside \( \mathcal{N} \) and constructs PPE that achieve its extreme values. At the end we comment on uniqueness and absorption in Nash equilibria.

Let us go through the details of our argument. Recall that the equilibrium motion of continuation values is described by

\[
dW_t = r(W_t - g(A_t)) \, dt + rB_t \, dZ_t + d\tilde{\epsilon}_t, \tag{15}
\]

where \( B_t \) enforces \( A_t \) and \( \tilde{\epsilon} \) is a martingale orthogonal to \( Z \).

**Public randomization and tangential volatility.** Suppose that \( W_t \) is an extreme point of the set \( E(r) \). We can immediately make two observations about the motion of \( W \). First, as in discrete time, public randomization should not be used at a time when \( W_t \) is an extreme payoff pair of \( E(r) \), so \( d\tilde{\epsilon}_t = 0 \). Second, matrix \( B_t \) must have span in the tangential direction to the set \( E(r) \) at point \( W_t \). Indeed, a normal component of volatility would instantaneously throw future continuation values outside the set \( E(r) \) with positive probability. Since the matrix \( B_t \) has a tangential span, we can represent it as \( B_t = T^T \phi_t \) for some \( \phi_t \in \mathbb{R}^d \), where \( T \) is a unit tangent vector at point \( W_t \).

**Curved trajectories of continuation values.** It turns out that when the span of \( B_t \neq 0 \) is focused along one line, the trajectories of continuation values become locally bent with a curvature that depends on the drift of \( W_t \). This property connects the geometry of the set \( E(r) \) and the stochastic motion of continuation values. To formalize the fact that
the trajectories of continuation values have a natural curvature, consider a diffusion process

\[ dW_t = r(W_t - g(A_t))\, dt + rT^\top \phi_t\, dZ_t \quad (16) \]

with \( W_t \) on a convex curve \( C \) at time \( t \), where \( T \) is a unit tangent vector to \( C \) at point \( W_t \). Let \( N \) be an outward unit normal vector to \( C \) at \( W_t \), such that the tangent line separates the direction of \( N \) from the rest of the curve \( C \). Let \( (x, f(x)) \) be a parameterization of \( C \) in tangential and normal coordinates and let

\[ D_{t+\epsilon} = NW_{t+\epsilon} - f(TW_{t+\epsilon}). \]

be a measure of the distance from \( W_{t+\epsilon} \) to the curve \( C \). Then in the next paragraph using Ito’s lemma we will show that \( D \) has volatility zero and drift

\[ rN(W_t - g(A_t)) + \frac{\kappa}{2} r^2 |\phi_t|^2 \quad (17) \]

at time \( t \), where \( \kappa \) is the curvature of \( C \) at \( W_t \). Note that \( \kappa = -f''(TW_t) \) because \( f'(TW_t) = 0 \). Then, speaking loosely, the natural curvature of the trajectories of \( W_t \) coincides with the curvature of \( C \) if and only if the drift of \( D \) is 0 at time \( t \), i.e.

\[ \kappa = \frac{2N(g(A_t) - W_t)}{r|\phi_t|^2}. \]

Now, let us demonstrate that (17) gives the drift of \( D_t \). By projecting equation (16) onto the tangent axis we get

\[ d(TW_t) = r(T(W_t - g(A_t)))\, dt + r\phi_t\, dZ_t. \quad (18) \]

Using Ito’s Lemma,

\[ df(TW_t) = \underbrace{f'(TW_t)}_{0} d(TW_t) + \underbrace{f''(TW_t)}_{-\kappa} r^2 |\phi_t|^2 \frac{dt}{2}. \quad (19) \]

By projecting (16) onto the normal axis we get

\[ d(NW_t) = rN(W_t - g(A_t))\, dt. \quad (20) \]

\footnote{Curvature is the rate at which the tangential angle changes with arc length.}
Combining (19) and (20) we get the desired result

\[ dD_t = d(NW_t - f(TW_t)) = \left( r N(W_t - g(A_t)) + \kappa \frac{r^2 |\phi_t|^2}{2} \right) dt. \]

**Optimality equation and extreme points of \( \mathcal{E}(r) \).** Let us argue that the curvature \( \kappa(W_t) \) of the set \( \mathcal{E}(r) \) is given by equation (14) when \( W_t \notin \mathcal{N} \) is an extreme point of \( \mathcal{E}(r) \). We do it in two steps.

First, let us show that

\[
\kappa(W_t) \leq \frac{2 N(g(A_t) - W_t)}{r |\phi_t|^2},
\]

where \( T^T \phi_t = B_t \). Note that \( A_t \notin \mathcal{A}^N \Rightarrow \phi_t \neq 0 \), because the drift of continuation values at time \( t \) cannot be directed outside \( \mathcal{E}(r) \) as shown in the left panel of Figure 6. If (21) failed, the trajectories of continuation values, represented by a dashed curve in the right panel of Figure 6, would have a smaller curvature than the curvature of \( \mathcal{E}(r) \) at \( W_t \). Then continuation values would instantaneously escape from \( \mathcal{E}(r) \), which leads to a contradiction.

Second, let us show that for any \( w \in \partial \mathcal{E}(r) \setminus \mathcal{N} \) and \( a \notin \mathcal{A}^N \)

\[
\kappa(w) \geq \frac{2 N(g(a) - w)}{r |\phi(a, T)|^2},
\]

Figure 5: The definition of \( D_{t+\epsilon} \).
Figure 6: Demonstrating that (21) holds.

where $T$ and $N$ are unit tangent and normal vectors at $w$. If (22) failed then the continuation values associated with the action profile $a$ enforced by $\phi(a, T)$ on tangent $T$ would have trajectories with a curvature greater than $\kappa(w)$. Intuitively this means that $w$ can be generated using continuation values strictly inside the set $\mathcal{E}(r)$, as shown in Figure 7. Then by moving continuation values in the direction of $N$, we would be able to generate a value pair $w + \epsilon N^T$ outside the set $\mathcal{E}(r)$ with the action profile $a$ and continuation values in the set $\mathcal{E}(r)$. This leads to a contradiction.

These two steps imply that $\phi_t = \phi(a, T)$, otherwise $A_t$ together with vector $\phi(A_t, T)$ would fail (22). Therefore, in (22) equality must be achieved by $a = A_t$, and so the curvature of $\mathcal{E}(r)$ must satisfy equation (14) at all extreme points $w \notin N$.

**All points of $\mathcal{E}(r) \setminus N$ are extreme.** See Corollary 2 of Proposition 5. Note that (22) holds for all points of $\partial \mathcal{E}(r) \setminus N$, not just extreme points. Intuitively, if there was a nonextreme point $w \in \partial \mathcal{E}(r) \setminus N$ then by (22) there would be no action profile enforceable on $T(w)$ such that $N(w)(g(a) - w) > 0$. Then in any PPE that achieves $w$, continuation values would have to stay on the tangent line and escape from $\mathcal{E}(r)$ due to positive volatility.

$\mathcal{E}(r)$ is the largest bounded set that satisfies (14) outside $N$. The following proposition, which is also used in the formal argument in the Appendix, implies that any bounded set with a boundary that satisfies the optimality equation outside $N$ must be a subset $\mathcal{E}(r)$.

**Proposition 3.** Suppose that the curve $C$ satisfies equation (14). Furthermore, suppose that either $C$ is a closed curve, or has endpoints achievable by some PPE. Then $C \subset \mathcal{E}(r)$.

**Proof.** By Theorem 1, to achieve $W_0 \in C$ in a PPE it is sufficient to construct a bounded
process $W_t$ that satisfies

$$W_t = W_0 + r \int_0^t (W_s - g(A_s)) \, ds + r \int_0^t B_s \, dZ_s, \quad B_t \text{ enforces } A_t$$

for all $t$.

Denote by $a : \mathcal{C} \to \mathcal{A} \setminus \mathcal{A}^N$ the maximizer in (14). Let us parameterize the curve $\mathcal{C}$ by arc length $l$. Let $l_t$ be a weak solution of equation

$$dl_t = r(W_t - g(A_t)) \, dt + r\phi(A_t, T(W_t)) \, dZ_t,$$

starting from an initial value that corresponds to the point $W_0$, until a stopping time $\tau$ when $l_t$ hits an endpoint of $\mathcal{C}$, where $W_t$ is the point on $\mathcal{C}$ that corresponds to $l_t$, $A_t = a(W_t)$ and $T(W_t)$ is the unit tangent vector to the curve $\mathcal{C}$ at point $W_t$.

Then $W_t$ has tangential drift $rT(W_t)(W_t - g(A_t))$ and volatility $rT(W_t)^T \phi(A_t, T(W_t))$. Since the function $f(x)$ that represents the curve $\mathcal{C}$ in tangential and normal coordinates at $W_t$ satisfies $f'(TW_t) = 0$ and $f''(TW_t) = -\kappa(W_t)$, by Ito’s lemma the normal component of the drift of $W_t$ is

$$0 \cdot rT(W)(W_t - g(A_t)) - \kappa(W_t) \frac{r^2 |\phi(A_t, T(W_t))|^2}{2} = rN(W_t)(W_t - g(A_t)).$$
for any $t \leq \tau$. Therefore, the process $W$ satisfies (23) until time $\tau$.

Let us extend process $W$ beyond time $\tau$ by letting it follow the path of a PPE that achieves value $W_\tau$. Then $W$ becomes a bounded random process that satisfies the conditions of Theorem 1 until time $\infty$. Therefore, we have constructed a PPE that achieves $W_0$. 

\[
\begin{array}{c}
\begin{array}{c}
g(a_N) \\
E(r) \setminus \mathcal{N}
\end{array}
\end{array}
\]

Figure 8: Extreme and non-extreme points of $\partial \mathcal{E}(r)$.

Comments on uniqueness and absorption in a Nash equilibrium. The optimality equation (14) assigns a generically unique action profile to each point $w \in \partial \mathcal{E}(r) \setminus \mathcal{N}$, which must be enforced by the vector of tangential volatilities $\phi(a, \mathbf{T}(w))$. These action profiles and volatilities uniquely pin down equilibrium dynamics in a PPE that achieves a point in $\partial \mathcal{E}(r) \setminus \mathcal{N}$. Since the volatilities are bounded away from 0, continuation payoffs must eventually hit the set $\mathcal{N}$ at an extreme point and become absorbed there whenever $\mathcal{N} \cap \partial \mathcal{E}(r) \neq \emptyset$.

The boundary of $\mathcal{E}(r)$ may include non-extreme points only if they are in $\mathcal{N}$. Figure 8 illustrates two such possibilities. In the left panel the boundary of $\mathcal{E}(r)$ in the left panel contains a line segment of non-extreme points, whose endpoints $g(a_N)$ and $g(a'_N)$ are Nash equilibrium payoff pairs. In the right panel, the set $\mathcal{E}(r) = \mathcal{N}$ has empty interior. For any non-extreme point $w \in \partial \mathcal{E}(r)$, there is no action profile $a \in \mathcal{A}$ enforceable on tangent $\mathbf{T}(w)$ with $\mathbf{N}(w)(g(a) - w) > 0$, and so equation (14) would not yield a positive curvature at $w$. There are many PPE that achieve any such point $w$, and in these PPE players do not need to become absorbed in a static Nash equilibrium. For either panel of Figure 8 players can achieve $w$ by alternating between $a_N$ and $a'_N$.

This completes the derivation of our main result, which is summarized in the next section. The next section also provides an intuitive discussion of the set $\mathcal{E}(r)$ and PPE that achieve extreme payoff pairs.
7 The Main Section: Summary and Discussion.

The following theorem characterizes the set $\mathcal{E}(r)$ and the public perfect equilibria (PPE) that achieve extreme value pairs of $\mathcal{E}(r)$.

**Theorem 2. Characterization.** $\mathcal{E}(r)$ is the largest closed subset of $\mathcal{V}^*$ with curvature

$$\kappa(w) = \max_{a \in \mathcal{A} \setminus \mathcal{A}^N} \frac{2 \mathbf{N}(w)(g(a) - w)}{r |\phi(a, \mathbf{T}(w))|^2},$$

(24)

at all points $w \notin \mathcal{N}$ on the boundary of $\mathcal{E}(r)$, where $\mathbf{T}(w)$ and $\mathbf{N}(w)$ are unit tangent and outward normal vectors at $w$. We call (24) the optimality equation.\footnote{In our model, we normalized each component of the signal $X$ to be independent of the others and have volatility 1. Alternatively, if the players observed signals $dX_t = (A^1_t, A^2_t) dt + \Sigma dZ_t$, where the volatility matrix $\Sigma$ has full rank, then after appropriate rescaling the optimality equation would be

$$\kappa(w) = \max_{a \in \mathcal{A} \setminus \mathcal{A}^N} \frac{2 \mathbf{N}(w)(g(a) - w)}{r |\phi(a, \mathbf{T}(w))\Sigma|^2},$$

where $\phi(a, \mathbf{T})$ is defined the same way as before.}

**PPE with extreme values.** Denote by $a : \partial \mathcal{E} \setminus \mathcal{N} \to \mathcal{A} \setminus \mathcal{A}^N$ the maximizing action pairs in equation (24), where $\partial \mathcal{E}(r)$ denotes the boundary of $\mathcal{E}(r)$. Any value pair $W_0 \in \partial \mathcal{E}(r) \setminus \mathcal{N}$ is achieved by a PPE with the following characteristics. The pair of continuation values under this PPE satisfies the SDE

$$W_t = W_0 + \int_0^t \left(\begin{array}{c}
\mathbf{r}(W_s - g(A_s)) \\
\mathbf{r}\mathbf{T}(W_s) \phi(A_s, \mathbf{T}(W_s)) (dX_s - A_s ds)
\end{array}\right) ds + \int_0^t \left(\begin{array}{c}
\mathbf{T}(W_s) \phi(A_s, \mathbf{T}(W_s)) (dX_s - A_s ds)
\end{array}\right)$$

(25)

until time $\tau$ when $W_t$ hits the set $\mathcal{N}$. For $t < \tau$, the players take action pairs $A_t = a(W_t)$. After time $\tau$, the players follow a static Nash equilibrium with value $W_\tau$. When $\partial \mathcal{E}(r) \cap \mathcal{N} = \emptyset$, then $\tau = \infty$. Otherwise, players become absorbed in a static Nash equilibrium with probability 1 in finite time.\footnote{There is a great multiplicity of equilibria that achieve non-extreme values. In those equilibria players do not need to become absorbed in a static Nash equilibrium.}

In the remainder of this section we discuss the implications of this result on various questions of interest: the equilibrium dynamics, the nature of inefficiency, the choice of equilibrium actions and the provision of incentives.
Let us describe dynamics in a PPE that achieves a value pair $W_0 \in \partial E(r) \setminus \mathcal{N}$. As soon as the game begins, the players’ continuation values $W_t$ start moving along the boundary of the set $E(r)$.\footnote{Typically, as in all our examples, the pair of continuation values will diffuse along the entire boundary of $E(r)$, not just its Pareto efficient portion.} This motion is a diffusion process defined by equation (25). Point $W_t$ plays the role of a single state variable in this equilibrium. As a state variable, $W_t$ determines the actions which the players take in a given instant, and the law by which $W_t$ itself evolves based on the observations of signal $X$. If there are Nash equilibrium payoff pairs on the boundary of $E(r)$, then a pair of continuation values must eventually hit one of them with probability 1. When that happens, the players become absorbed in a static Nash equilibrium forever. Of course, if all static Nash equilibrium payoff pairs are inside the set $E(r)$, then players never become absorbed in a Nash equilibrium, and the motion of continuation values never stops.

At times $t < \tau$ before the players become absorbed in a static Nash equilibrium (if ever), they choose action pairs $A_t$ and receive payoff flows $g(A_t) \notin E(r)$. The pair of continuation values $W_t$ has drift directed away from point $g(A_t)$ inside the set $E(r)$. This drift accounts for promise keeping: the current continuation value $W_t$ is always a weighted average of the current payoff flow $g(A_t)$ and the expected continuation value a moment later $E_t[W_{t+\epsilon}]$, as shown in Figure 9.

![Figure 9: The drift and volatility of continuation values.](image)

It may seem surprising that the drift of continuation values is directed inside $E(r)$ even though continuation values stay on the boundary. We can reconcile these two facts as follows: because continuation values diffuse along the boundary due to tangential volatility and because the boundary has curvature, the expectation of future continuation values must be inside the set $E(r)$.\footnote{Typically, as in all our examples, the pair of continuation values will diffuse along the entire boundary of $E(r)$, not just its Pareto efficient portion.}
The equilibrium actions pairs $A_t$ come from the optimality equation (24). The objective of this equation is to describe the largest set of payoff pairs achievable in equilibrium. The choice among action pairs involves a trade-off between the extremity of payoffs and the incentives required to enforce them. The extremity of a payoff pair is measured by the payoff gain in the direction of the normal vector (see the numerator of (24)). The incentives are measured by the instantaneous tangential variance of continuation values (see the denominator of (24)). An optimal action pair achieves the maximum in (24). This action pair can be enforced by using continuation values on the boundary of $\mathcal{E}(r)$. If we tried to enforce a suboptimal action pair, the required drift and tangential volatility of $W_t$ would take future continuation values outside $\mathcal{E}(r)$.

Let us discuss the provision of incentives. Before time $\tau$, actions $A_t$ are not static Nash equilibria, so players must have incentives to take actions that are not static best responses. These incentives arise because actions affect the drift of the public signals, which in turn affect continuation values. The volatility matrix in equation (25) is the sensitivity of continuation values to the signal $X$. From Section 5 we know that player $i$ has incentives not to deviate from action pair $A_t$ if his action maximizes the sum of his instantaneous payoff and the expected change of his continuation value, i.e.

$$g_i(A_t) + \beta^i_t \mu(A_t) = \max_{a_i} g_i(a_i, A^i_t) + \beta^i_t \mu(a_i, A^i_t),$$

(26)

where $\beta^i_t$ is row $i$ of the volatility matrix at time $t$. In an equilibrium that achieves an extreme payoff pair, the volatility matrix must be of the form $T(w)^\top \phi_t$ to have a tangential span. Generally, there could be many ways to enforce $A_t$ on a tangent line, but only the smallest tangential variance must be used in an equilibrium, for which $W_0$ is extreme. Our assumptions do not guarantee that all action pairs can be enforced on all tangent lines so the Folk Theorem may fail. To guarantee enforceability of all action profiles, one would need to assume also individual full rank, or make an appropriate concavity assumption, as we elaborate for games with a special signal structure in the next section.

### 7.1 Incentives in Games with Special Signal Structure.

The partnership example from Section 2 and the duopoly example from the Section 8 have a special signal structure, under which the provision of incentives is especially clear. For that class of games $\mathcal{A}_1, \mathcal{A}_2 \subseteq \mathbb{R}$, the public signal is two-dimensional and has drift $\mu(a_1, a_2) = (a_1, a_2)^\top$. Therefore, there is a separate signal that is indicative of each player’s
actions.

For this class of games the volatility matrix is $2 \times 2$ and condition (11) reduces to

$$g_i(A_t) + \beta_i^{ii} A_i^i = \max_{a_i} g_i(a_i, A_t^j) + \beta_i^{ii} a_i,$$

(27)

where $\beta_i^{ii}$ for $i = 1, 2$ are the diagonal entries of the volatility matrix $B_t$. When $W_t \in \partial E(r) \backslash N$, the tangential volatility condition pins down uniquely the off-diagonal entries of the $2 \times 2$ matrix $B_t$ given the diagonal entries $\beta_i^{ii}$. To enforce an action profile $A_t$ on a tangent with minimal volatility, we must choose $\beta_i^{ii}$ of the smallest absolute value for (27) to hold.

**Definition of $\gamma$.** Consider all values of $\beta_i^{ii}$ for which $a_i$ maximizes $g_i(a_i, a_j) + \beta_i^{ii} a_i$ given $a_j$. Of these values, define $\gamma_i(a_i, a_j)$ to be the smallest in terms of absolute value.

The matrix that enforces an action profile $A_t$ tangentially with minimal volatility has the form

$$B_t = \begin{bmatrix}
\gamma_1(A_t) & \gamma_2(A_t) \\
\frac{1}{\xi_1} & \frac{1}{\xi_2}
\end{bmatrix}.$$

We can make two useful observations about incentive provision for the games with special signal structure and in general.
1. Generally, because the local motion of continuation values is restricted to a tangent line, the necessity to provide incentives to one player affects the continuation value of another player. With special signal structure, player \( j \)’s continuation value has sensitivity \( \gamma_i(A_t)t_j/t_i \) to the signal \( X_i \), which reflects player \( i \)’s action exclusively.

2. In a game with special signal structure the incentives provided to different players do not interfere; there is a separate signal and a separate column of the matrix \( B_t \) that is responsible for the actions of each player. In general this is not true because the same signal can be affected by both players.

Let us comment on the enforceability of action pairs on tangent lines and the Folk Theorem in this class of games. If \( g_i \) is concave in \( a_i \), then \( \gamma_i(a) \) is well defined for all \( a \in A \) and \( i = 1, 2 \), so that all action profiles are enforceable. Then all action profiles can be enforced on all regular tangent lines by Lemma 2, and action profiles with a best response property for player \( i \) can be enforced on coordinate lines with \( t_i = 0 \). From the optimality equation we can see immediately that the Folk Theorem holds under these conditions. As \( r \) decreases to 0, the numerator \( 2N(g(a) - w) \) in the optimality equation also decreases to 0, making the set \( \mathcal{E}(r) \) expand towards the boundaries of \( \mathcal{V}^* \). Conversely, if the function \( g_i \) is not concave in \( a_i \) for \( i = 1 \) or 2, then \( \gamma_i(a) \) is sometimes undefined and the Folk Theorem may fail, i.e. the closure of \( \lim_{r \to 0} \mathcal{E}(r) \) may be smaller than \( \mathcal{V}^* \).

8 Computation.

In this section we discuss the computation of the set \( \mathcal{E}(r) \), and present the outcomes of computation for the partnership example of Section 2 and a new example of a duopoly with differentiated products.

To write the optimality equation in a form suitable for computation, recall that curvature is the rate at which the tangential angle changes with arc length. Therefore, \( \kappa(\theta) = d\theta/dl \), where \( \theta \) is the tangential angle (so that \( T(\theta) = (-\sin \theta, \cos \theta) \) and \( N(\theta) = (\cos \theta, \sin \theta) \)) and \( l \) is arc length. As the tangential angle \( \theta \) changes, the corresponding point \( w(\theta) \) moves along the curve in the tangential direction \( T(\theta) \) with speed \( dl/d\theta = 1/\kappa(\theta) \), so

\[
\frac{dw(\theta)}{d\theta} = \frac{T(\theta)\T}{\kappa(\theta)}. \tag{28}
\]

\(^{30}\)Note that the off-diagonal entries of \( B_t \) blow up when \( t_i = 0 \) and \( \gamma_i(a) \neq 0 \).
Equation (28) is easy to solve numerically starting from any initial conditions \((\theta, w) \in [0, 2\pi) \times \mathcal{V}^n\), treating the coordinates of \(w(\theta)\) as functions of \(\theta\), and using

\[
\kappa(\theta) = \max_{a \in \mathcal{A} \setminus \mathcal{A}^n} \frac{2 \mathbf{N}(\theta)(g(a) - w(\theta))}{r|\phi(a, \mathbf{T}(\theta))|^2}.
\] (29)

Generally, \(|\phi(a, \mathbf{T})|^2\) can be found by solving a quadratic program

\[
|\phi(a, (t_1, t_2))|^2 = \min_{\phi} |\phi|^2
\]

s.t. \(\forall i = 1, 2 \forall a'_i \in \mathcal{A}^i, \ g_i(a) + t_i \phi \mu(a) \geq g_i(a'_i, a_j) + t_i \phi \mu(a'_i, a_j)\).

For our examples and other games with a special structure,

\[
|\phi(a, (t_1, t_2))|^2 = \frac{\gamma_1(a)^2}{t_1^2} + \frac{\gamma_2(a)^2}{t_2^2}.
\]

We present computational examples in an increasing order of difficulty.

### 8.1 Partnership.

From symmetry considerations, the boundary of the set \(\mathcal{E}(r)\) must contain a point on the 45-degree line with an outward unit normal \(\mathbf{N} = (\cos(45^\circ), \sin(45^\circ))\). Also, point \((0, 0)\) will be on the boundary as well. For all points \(w\) on the line segment between the origin and point \((1, 1)\), consider the curve \(\mathcal{C}(w)\) that solves the optimality equation from initial conditions \((w, \mathbf{N})\). To compute the set \(\mathcal{E}(r)\), we search along the 45-degree line and find point \(w\), removed furthest from the origin, such that the curve \(\mathcal{C}(w)\) reaches the origin. First, we do a grid search to identify an interval where the desired point \(w\) is located. After that, we do a binary search within the interval to compute \(w\) exactly. Figure 11 illustrates the computational procedure for \(r = 0.2\).

From the grid search on Figure 11a, we know that there are two symmetric closed curves which satisfy the optimality equation everywhere except in the origin: one in the interval \((0.2, 0.3)\), and one in the interval \((0.8, 0.9)\). We are interested in the latter curve, because it is larger. That curve can be found by means of a binary search in the interval \((0.8, 0.9)\).

The computed boundary of \(\mathcal{E}(r)\), along with recommended action pairs at every point, is shown in Figure 11b.

There is another easy method to compute the set \(\mathcal{E}(r)\) in this example, using the fact
that $\mathcal{N}$ must be on the boundary of $\mathcal{E}(r)$. This method involves a one-dimensional search over the slopes of the boundary of $\mathcal{E}(r)$ at point $\mathcal{N}$. In the next subsection we see how computation can be performed on an asymmetric example, in which $\mathcal{N}$ is in the interior of the set $\mathcal{V}^*$.

\section*{8.2 Duopoly with Differentiated Products.}

Consider the following example. There are two firms, whose products are imperfect substitutes. The private actions of firm $i$ are supply rates from the set $\mathcal{A}^i = \{0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10\}$. The instantaneous prices of firms 1 and 2 are given by the increments of the processes

\[ dP^1_t = (25 - 2A^1_t - A^2_t) \, dt + \text{noise} \quad \text{and} \quad dP^2_t = (30 - 2A^2_t - 2A^1_t) \, dt + \text{noise}. \]

Prices are publicly observable, and the noise structure is such that firms can isolate a signal about each firm’s quantity from the prices

\[
\begin{align*}
\left\{ \begin{array}{l}
\frac{1}{2} dP^1_t + dP^2_t + 10 \, dt = A^1_t \, dt + dZ^1_t \\
X^1_t = \frac{1}{2} dP^1_t - dP^2_t + 5 \, dt = A^2_t \, dt + dZ^2_t
\end{array} \right.
\end{align*}
\]
where $Z^1$ and $Z^2$ are independent standard Brownian motions. The payoffs of firms 1 and 2 are given by
\[ r \int_0^\infty e^{-rt} A^1_t \, dP^1_t \quad \text{and} \quad r \int_0^\infty e^{-rt} A^2_t \, dP^2_t. \]
The payoff functions can be identified as
\[ g_1(a_1, a_2) = a_1(25 - 2a_1 - a_2) \quad \text{and} \quad g_2(a_1, a_2) = a_2(30 - 2a_2 - 2a_1). \]
This stage game has a unique Nash equilibrium $(5, 5)$, but ideally firms could collude by producing $(4, 4)$.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{asymmetric_game}
\caption{Computation: an asymmetric game.}
\end{figure}

For this game the computational procedure is illustrated in Figure 12. We start at an arbitrary point $w^1$ on the boundary of the set $\mathcal{V}^*$, and compute the solutions of the optimality equation from initial conditions $(w^1, \theta)$ for $\theta \geq \pi$. We raise $\theta$ continuously, until the corresponding solution $C^1$ (for some angle $\hat{\theta}^1$) hits point $w^1$ after making a loop, as shown in Figure 12a. We claim that the resulting solution must enclose the set $\mathcal{E}(r)$. If not, as we vary $\theta$ continuously between $\pi$ to $\hat{\theta}^1$, some solution would have to be tangent to $\mathcal{E}(r)$. However, this is impossible, because then the solution would have to coincide with the boundary of $\mathcal{E}(r)$ (from the uniqueness of solutions given the initial conditions at the point of tangency).

Next, take point $w^2$ on the curve $C^1$ with an outward unit normal $(1, 0)$. Again, we compute the solutions of the optimality equation from initial conditions $(w^2, \theta)$ for $\theta \geq 0$. We raise $\theta$ continuously, until the corresponding solution $C^2$ (for some angle $\hat{\theta}^2$) hits point $w^2$ after making a loop, as shown in Figure 12b. Then the curve $C^2$ must enclose the set.
Figure 13: Set $\mathcal{E}(r)$ in Duopoly.

$\mathcal{E}(r)$ inside. By continuing this procedure iteratively, we will converge to the set $\mathcal{E}(r)$.

Figure 13 illustrates the outcome of computation for discount rate $r = 1.5$. The boundary of $\mathcal{E}(r)$ is divided into many segments on which players keep their actions constant. Figure 13 illustrates the general pattern of actions, as well as an interpretation of each portion on the boundary of the set $\mathcal{E}(r)$.$^{31}$ For comparison, recall that a static Nash equilibrium is $(5, 5)$. Along the Pareto frontier of $\mathcal{E}(r)$, players collude by producing less than their static best responses. We call this regime “market sharing.” In this regime, when a player’s continuation value increases, his market share also increases. Therefore, players are rewarded for underproducing by an increased future market share. On top of the set $\mathcal{E}(r)$, player 2 receives the maximal payoff that he possibly could in a PPE. At that point, player 1 produces very little, while player 2 produces close to his monopoly quantity. While player 2 chooses a static best response, player 1 needs strong incentives to “stay

$^{31}$I am thankful to William Fuchs for helping me find these interpretations.
out.” To reward player 1 for “staying out,” player 2 accommodates, and to punish player 1 for cheating, player 2 fights. We call this regime “entrant and incumbent.” On the left side of $\mathcal{E}(r)$ player 1 is acting passively by producing a static best response, while player 2 is overproducing aggressively. At this point, player 2 is rewarded for overproducing by being able to drive player 1 out of the market. We call this regime “contestability.” At the bottom left portion of $\mathcal{E}(r)$, players are fighting a “price war” by overproducing. They have incentives to do so because the player that looks more aggressive will come out as a winner of the price war. The winner gets his reward by becoming a monopolist for some period of time.

9 Conclusion.

This paper introduces a new class of games in continuous time, in which the players’ observations of each other’s actions are distorted by Brownian motion. In these games, the set of value pairs which are achievable in public perfect equilibria has a clean characterization. The form of public perfect equilibria that achieve values on the boundary of the set $\mathcal{E}(r)$ and the way by which the players organize the provision of incentives are intuitive. We saw examples of various economic interactions that can be modeled as continuous-time games. Besides our examples of a partnership and a duopoly, our model can be applied to principal-agent problems, risk-sharing models, etc. One is hopeful that the simplicity of characterizations in continuous-time models will allow deeper analysis of applications to various dynamic incentive problems with imperfect information.

Let us discuss several questions for development of future theory. First, it is necessary to illustrate the connection between discrete-time repeated games and continuous-time games and to understand how continuous-time games can be used to approximate repeated games in discrete time. Second, it is beneficial to extend the continuous-time approach to games with private information. DeMarzo and Sannikov (2004) show how to attack the issue of private information in a setting with one-sided imperfect information. Third, one has to extend the continuous-time approach to settings where more than one state variable is required. Finally, it would be interesting to explore other computational procedures to find the set $\mathcal{E}(r)$. 
Appendix A: The Optimality Equation.

Appendix A explores the enforceability of action pairs on tangent lines and the regularity properties of the optimality equation. Our first lemma formalizes the notion that pairwise identifiability allows the provision of incentives to one player without interfering with the incentives of the other player. Recall that the $d \times (|A| - 1)$ matrix $M_i(a)$ is composed of columns $\mu(a'_i, a_j) - \mu(a)$, $a'_i \neq a_i$. Similarly denote by $G_i(a)$ the row vector with $|A| - 1$ components $g_i(a'_i, a_j) - g_i(a)$, $a'_i \neq a_i$. Then a matrix $B$ enforces an action profile $a$ if and only if

$$G_i(a) \leq \beta^i M_i(a) \text{ for } i = 1, 2,$$

where $\beta^i$ is the $i$-th row of $B$. Also, a vector $\beta$ enforces an action profile $a$ on tangent $T$ if and only if

$$G_i(a) \leq t_i \beta M_i(a) \text{ for } i = 1, 2.$$

**Lemma 1.** For each action profile $a \in A$ and $i = 1, 2$ there exists a $d \times d$ idempotent matrix $Q_i(a)$ such that $Q_i(a) M_i(a) = M_i(a)$ and $Q_i(a) M_j(a) = 0$.

**Proof.** For $i = 1, 2$ let us construct a matrix $M'_i(a)$ whose columns form the basis of the column space of $M_i(a)$. Pairwise identifiability of $a$ implies that there is no linear dependence among the columns of $[M'_1(a), M'_2(a)]$. Let us choose a matrix $L(a)$ that makes

$$[M'_1(a), M'_2(a), L(a)]$$

into a $d \times d$ invertible matrix. Then an idempotent matrix that satisfies the required properties can be defined by

$$Q_i(a) = [M'_1(a), 0, 0] [M'_i(a), M'_j(a), L(a)]^{-1} \Leftrightarrow Q_i(a) [M'_1(a), M'_j(a), L(a)] = [M'_i(a), 0, 0].$$
The matrix $Q_i(a)$ isolates the incentives of player $i$ from a given vector $\beta$, since $\beta Q_i(a) M_i(a) = \beta M_i(a)$ and $\beta Q_i(a) M_j(a) = 0$. The following bound will be useful:

$$\bar{Q} = \max_{a,i,\beta} |\beta Q_i(a)|.$$  

We can use $Q_i(a)$ to prove an analogue of Lemma 5.5 from FLM.

**Lemma 2.** Any enforceable action profile is enforceable on all $T = (t_1, t_2)$ with $t_1, t_2 \neq 0$.

**Proof.** If a matrix $B$ with rows $\beta^1$ and $\beta^2$ enforces an action profile $a$, then $\beta^1 Q_1(a)/t_1 + \beta^2 Q_2(a)/t_2$ enforces $a$ on the tangent $T = (t_1, t_2)$. Indeed,

$$\left(\frac{\beta^1 Q_1(a)}{t_1} + \frac{\beta^2 Q_2(a)}{t_2}\right) [t_1 M_1(a), t_2 M_2(a)] = \left[\beta^1 M_1(a), \beta^2 M_2(a)\right] \geq [G_1(a), G_2(a)]$$

Next, our task is to show that the right-hand side of the optimality equation is Lipschitz-continuous in $w$ and $T$. This property guarantees the existence of solutions to the optimality equation from any initial conditions, and helps us characterize the set $\mathcal{E}(r)$. The following lemma provides a bound for $\phi(a, T)$.

**Lemma 3.** Let $\psi_i(a)$ be the vector of minimal length such that $G_i(a) \leq \psi_i(a) M_i(a)$. Then

$$|\phi(a, T)| \geq |\psi_i(a)/t_i|.$$  

Moreover, if $a$ has a best response property for player $j$ and $|t_j|$ is sufficiently small then

$$\phi(a, T) = \psi_i(a)/t_i.$$  

**Proof.** Recall that $\phi(a, T)$ is defined as the shortest vector such that $G_i(a) \leq t_i \phi(a, T) M_i(a)$ for $i = 1, 2$. Thus, (30) follows because $\psi_i(a)/t_i$ is the shortest vector of such that only $G_i(a) \leq t_i (\psi_i(a)/t_i) M_i(a)$ holds.

Suppose also that $a$ has a best response property for player $j$ and $|t_j|$ is sufficiently small. If we show that $G_j(a) \leq t_j (\psi_i(a)/t_i) M_j(a)$ holds, we can conclude (31).

We must rely on Assumption 2 from Section 3. When part (i) of Assumption 2 holds, i.e. $a_j$ is a unique best response to $a_i$, then $G_j(a) < 0$ and $G_j(a) < t_j (\psi_i(a)/t_i) M_j(a)$ when $|t_j|$ is sufficiently small. Suppose part (ii) of Assumption 2 holds, i.e. the game has a product structure. Because $\psi_i(a)$ is the shortest vector that satisfies $G_i(a) \leq \psi_i(a) M_i(a)$, $\psi_i(a)$ is in the column space of $M_i(a)$, which is orthogonal to the column space of $M_j(a)$ due to the product structure. Again, we have $G_j(a) \leq t_j (\psi_i(a)/t_i) M_j(a) = 0$. 

\[\square\]
Lemma 3 implies a useful lower bound (34) for $\phi(a, T)$. Let $\epsilon_\psi \in (0, 1)$ be a constant such that (31) holds whenever $a$ has a best response property for player $j$ and $|t_j| < \epsilon_\psi$. Denote

$$\Psi = \epsilon_\psi \min_{a,i} |\psi_i(a)|,$$

where the minimization is over $i = 1, 2$ and all action profiles $a$ without best response property for player $i$. If $a \not\in A^N$ has a best response property for player $i$ but $|t_i| > \epsilon_\psi$ then (30) implies that

$$|\phi(a, T)| \geq |\psi_j(a)/t_j| \geq \Psi/|t_i|.$$

If $a$ does not have a best response property for player $i$, then

$$|\phi(a, T)| \geq |\psi_i(a)/t_i| > \Psi/|t_i|.$$

We conclude that for all $a \not\in A^N$

$$|\phi(a, T)| \geq \frac{\Psi}{|t_i|},$$

unless $|t_i| < \epsilon_\psi$ and $a$ involves a best response of player $i$.

The following lemma is a key ingredient in the proof of Proposition 4, which deals with the regularity properties of the optimality equation.

**Lemma 4.** Denote $T(\theta) = (-\sin \theta, \cos \theta)$ and $N(\theta) = (\cos \theta, \sin \theta)$. Then for all $a \not\in A^N$,

$$H_a(w, \theta) = \frac{2N(\theta)(g(a) - w)}{r|\phi(a, T(\theta))|^2}$$

is Lipschitz-continuous in $w$ and $\theta$ when $N(\theta)(g(a) - w) \geq 0$, where we interpret $H_a(w, \theta)$ to be 0 when $a$ is not enforceable on $T(\theta)$.

**Proof.** First, $H_a(w, \theta)$ is Lipschitz-continuous in $w$ since $|\phi(a, T(\theta))|$ is bounded away from 0 (by Lemma 3) for all $a \not\in A^N$.

To prove Lipschitz-continuity in $\theta$, first consider the case when for some $i = 1, 2$ we have $|t_i(\theta)| < \epsilon_\psi$ and $a$ involves a best response of player $i$. Then (31) implies that

$$H_a(w, \theta) = \frac{2t_j(\theta)^2 N(\theta)(g(a) - w)}{r|\psi_j(a)|^2},$$

which is continuously differentiable (and thus Lipschitz-continuous) in $\theta$.

Otherwise, the bound (34) holds for $i = 1, 2$. Let $\beta^i = \phi(a, T(\theta))Q_i(a)$. Then

$$\beta(\theta') = \phi(a, T(\theta)) + \left(\frac{t_1(\theta)}{t_1(\theta')} - 1\right) \beta^1 + \left(\frac{t_2(\theta)}{t_2(\theta')} - 1\right) \beta^2$$
enforces \( a \) on tangent \( T(\theta) \), so \( |\beta(\theta)| \geq |\phi(a, T(\theta))| \). As long as \( N(\theta')(g(a) - w) \geq 0 \),

\[
F(\theta') = \frac{2N(\theta')(g(a) - w)}{r|\beta(\theta')|^2} \leq H_a(w, \theta')
\]

with equality when \( \theta = \theta' \). For \( \theta' \) near \( \theta \) we have

\[
\left| \frac{dF(\theta')}{d\theta'} \right| = \left| \frac{2T(\theta')(g(a) - w)}{r|\beta(\theta')|^2} - \frac{4N(\theta')(g(a) - w)}{r|\beta(\theta')|^4} \left( \frac{n_1(\theta')t_1(\theta)}{t_1(\theta')^2} \beta + \frac{n_2(\theta')t_2(\theta)}{t_2(\theta')^2} \beta^2 \right) \right| \\
\leq \frac{2|\mathcal{V}|}{r \Psi^2} + 4|\mathcal{V}| \left( \frac{1}{t_1(\theta')^2} + \frac{1}{t_2(\theta')^2} \right) \tilde{Q}|\beta(\theta)||\beta(\theta')| \\
\leq \frac{2|\mathcal{V}|}{r \Psi^2} + 4|\mathcal{V}| \tilde{Q} \leq K,
\]

where we used \( |\beta(\theta')|^2 \geq |\phi(a, T(\theta'))|^2 \) and (34). It follows that

\[
H_a(w, \theta) - H_a(w, \theta') \leq F(\theta) - F(\theta') \leq |\theta - \theta'| K,
\]

so \( H_a \) is Lipschitz-continuous in \( \theta \).

The consequence of Lipschitz continuity is summarized in the following proposition.

**Proposition 4.** Consider the following version of the optimality equation

\[
\kappa(w, \theta) = \max \left( 0, \max_{a \notin \mathcal{A}^N} H_a(w, \theta) \right). \tag{36}
\]

Solutions to (36) exist and are unique and continuous in initial conditions. Moreover, if the curvature is positive at initial conditions, then it stays positive along the solution.

**Proof.** Lemma 4 implies that the right hand side of (36) is Lipschitz-continuous in \( w \) and \( \theta \). Thus, the solutions to (36) exist and are unique and continuous in initial conditions.

For the sign of the curvature, note that if \( \kappa(w, \theta) = 0 \), then the line that passes through \( w \) parallel to \( T(\theta) \) is a unique solution from the initial conditions \((w, \theta)\). It has zero curvature throughout. Therefore, if the initial curvature is positive, then it must stay positive along the solution. Had it reached 0, the entire solution would have been a straight line by uniqueness.

The following lemma is provides an important bound, which is used in Appendix B.

**Lemma 5.** There exists a constant \( K > 0 \) such that for any \( a \notin \mathcal{A}^N \) and a matrix \( B = T^\top \phi + N^\top \chi \) that enforces \( a \), where \( T \) and \( N \) are orthogonal unit vectors,

\[
\frac{4\tilde{Q}}{\Psi} |\chi| \geq 1 - \frac{|\phi|^2}{|\phi(a, T)|^2}. \tag{37}
\]
Proof. Suppose that $|\phi| \leq |\phi(a, T)|$, since otherwise (37) obviously holds.

First, consider the case when (34) holds for $i = 1$ and 2. Then

$$\beta = \phi + \frac{n_1}{t_1} \chi Q_1(a) + \frac{n_2}{t_2} \chi Q_2(a)$$

enforces $a$ on tangent $T = (t_1, t_2)$. Therefore,

$$|\phi| + \left( \frac{1}{|t_1|} + \frac{1}{|t_2|} \right) \bar{Q}|\chi| \geq |\beta| \geq |\phi(a, T)| \quad \Rightarrow$$

$$|\phi(a, T)| - |\phi| \leq \left( \frac{1}{|t_1|} + \frac{1}{|t_2|} \right) \bar{Q}|\chi| \leq \frac{2|\phi(a, T)|}{\bar{Q}} \bar{Q}|\chi| \quad \Rightarrow$$

$$\frac{2\bar{Q}}{|\phi(a, T)|} \geq \frac{|\phi(a, T)| - |\phi|}{|\phi|} \geq |\phi(a, T)|^2 - |\phi|^2 \quad \Rightarrow$$

Second, consider the case when (34) may fail, i.e. $|t_i| \leq \epsilon_\phi$ and $a$ involves a best response of player $i$ for $i = 1$ or 2. Then

$$(t_j \phi + n_j \chi) M_j(a) \geq G_j(a) \quad \Rightarrow \quad |t_j \phi| + |\chi| \geq |t_j \phi + n_j \chi| \geq |\psi_j(a)| = |t_j \phi(a, T)| \quad \Rightarrow$$

$$|\phi(a, T)| - |\phi| \leq \frac{|\chi|}{|t_j|} \leq \frac{|\chi|}{|\psi_j(a)|} \leq \frac{|\chi|}{|\phi(a, T)|} \quad \Rightarrow \quad \frac{|\chi|}{|\psi_j(a)|} \geq \frac{|\phi(a, T)| - |\phi|}{|\phi(a, T)|} \geq \frac{|\phi(a, T)|^2 - |\phi|^2}{2|\phi(a, T)|^2},$$

and (37) follows since $\bar{Q} \geq 1$.

\[\square\]

**Appendix B: The Boundary of the Set $E(r)$.

In Section 6 we argue heuristically that the boundary of the set $E(r)$ satisfies the optimality equation at all points outside $\mathcal{N}$. To prove this result formally, consider an arbitrary point $w \in \partial E(r) \setminus \mathcal{N}$. We will show that a tangent solution to the optimality equation through point $w$ coincides with the boundary of $E(r)$. Therefore, the curvature of the boundary of $E(r)$ outside $\mathcal{N}$ is continuous and must satisfy the optimality equation.

**Proposition 5. Tangent curves.** There is a unique tangent vector $T(w)$ at any point $w \in \partial E(r) \setminus \mathcal{N}$. Also, the curve $C$ that solves equation (36) from initial conditions $(w, T(w))$ coincides with the boundary of $E(r)$ in a neighborhood of $w$.

\[\text{Proof.}\] The proof goes in two steps. First, we show that the curve $C$ must not go outside the boundary of the set $E(r)$ in a neighborhood of $w$. Otherwise, by altering initial conditions slightly, we would be able to find a curve $C'$ that solves equation (36) and cuts through the boundary of the set $E(r)$ as shown in Figure 15. Lemma 6 shows that this leads to a contradiction. It follows that the tangent vector is unique at any point $w \in \partial E(r) \setminus \mathcal{N}$ since

---

$^{32}$We have $\bar{Q} \geq 1$ because the matrices $Q_i(a)$ are idempotent, and some of them are nonzero.
otherwise a tangent solution would go outside the boundary of $\mathcal{E}(r)$. Second, we show that the curve $\mathcal{C}$ does not enter the interior $\mathcal{E}(r)$. Otherwise, we would be able to construct PPE that achieves a value pair outside $\mathcal{E}(r)$, as shown in Lemma 8. The analysis relies heavily on Proposition 4, which shows that the solutions equation (36) change continuously with initial conditions.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure15.png}
\caption{Constructing a curve that cuts through $\mathcal{E}(r)$.}
\end{figure}

Suppose that there are points $v \in \mathcal{C}$ arbitrarily close to $w$ that satisfy
\[
\{v + x\mathbf{N}(w)^\top, x \geq 0\} \cap \text{cl} \mathcal{E}(r) = \emptyset,
\]
where cl $\mathcal{E}(r)$ denotes the closure of $\mathcal{E}(r)$. Then, by adjusting initial conditions slightly, we can draw a curve $\mathcal{C}'$ that also solves equation (36) and cuts through a small portion of the boundary of $\mathcal{E}(r)$, as shown in Figure 15. The left panel shows that when the set $\mathcal{E}(r)$ has a kink at $w$, we can find $\mathcal{C}'$ by moving initial conditions inside the set. The right panel shows that when the set $\mathcal{E}(r)$ has a unique tangent at $w$, we can draw $\mathcal{C}'$ from the same point $w$ but with a rotated angle. Moreover, we can perform these adjustments to guarantee that the curve $\mathcal{C}'$ satisfies all conditions of Lemma 6.\footnote{Clearly, (i) must hold for the vector $\mathbf{N}(w)$ and (iii) holds by construction. Condition (ii) is easy to satisfy by the continuity of solutions in initial conditions if $\mathbf{N}(w)w > \max_{v_N \in \mathcal{N}} \mathbf{N}(w)v_N$. For the case when there is no kink at $w$, it may occur that $\mathbf{N}(w)w = \mathbf{N}(w)v_N$ for some $v_N \in \mathcal{N}$. Suppose that $v_N$ is to the left of $w$. Then $\mathcal{C}$ cannot go above the boundary of $\mathcal{E}(r)$ to the left of $w$, so it must do so to the right of $w$. But then, by rotating the initial condition clockwise slightly, we get a curve $\mathcal{C}'$ as in the right panel of Figure 15, for which (ii) holds.}

**Lemma 6.** It is impossible for a solution $\mathcal{C}'$ of (36) with endpoints $v_L$ and $v_H$ to satisfy the following properties simultaneously

1. there is a unit vector $\mathbf{N}$ such that $\forall x > 0, v_L^x + x\mathbf{N}^\top \notin \mathcal{E}(r)$ and $v_H^x + x\mathbf{N}^\top \notin \mathcal{E}(r)$.
2. for all $w \in \mathcal{C}'$ with an outward unit normal $\mathbf{N}$, we have
\[
\max_{v_N \in \mathcal{N}} \mathbf{N}v_N < \mathbf{N}w.
\]
(iii) \( C' \) “cuts through” \( \mathcal{E}(r) \), i.e. there exists a point \( v \in C' \) such that \( W_0 = v + x\mathbf{N}^\top \in \mathcal{E}(r) \) for some \( x > 0 \).

**Proof.** Suppose such a curve \( C' \) existed. Then there must be a PPE that achieves point \( W_0 = v + x\mathbf{N}^\top \in \mathcal{E}(r) \). Denote by \( W_t \) the continuation values in this PPE. We will show that such PPE is impossible.

Consider the region \( \mathcal{R} \) spanned by the 'level curves' \( C'(x) = C' + x\mathbf{N}^\top, x \geq 0 \) and let \( f : \mathcal{R} \to \mathbb{R} \) be the level function defined by

\[
v \in C'(f(v)).
\]

Let us show that \( f(W_t) \) increases indefinitely with positive probability, and thus \( W_t \) must escape from the set \( \mathcal{V} \), leading to a contradiction. Note that (i) implies that \( W_t \) cannot escape from \( \mathcal{R} \) through the sides \( \{v_L + x\mathbf{N}^\top\} \) and \( \{v_H + x\mathbf{N}^\top\} \).

To construct an escape argument, consider any moment of time \( t \) while \( W_t \) is still in \( \mathcal{R} \), and let us find the drift and volatility of \( f(W_t) \). Let us introduce a coordinate system \( (u_t, u_n) \) with the origin at \( W_t \) and axes parallel to the unit tangent and normal vectors \( \mathbf{T} \) and \( \mathbf{N} \) to the curve \( C'(f(W_t)) \) at \( W_t \). Then at \( W_t \) in these coordinates \( f \) has the derivative vector

\[
[\frac{\partial f}{\partial u_t}, \frac{\partial f}{\partial u_n}] = [0, (\mathbf{T}\mathbf{T}^\top)^{-1}]
\]

and the Hessian

\[
\begin{bmatrix}
\frac{\partial^2 f}{\partial u_t^2} & \frac{\partial^2 f}{\partial u_t \partial u_n} \\
\frac{\partial^2 f}{\partial u_t \partial u_n} & \frac{\partial^2 f}{\partial u_n^2}
\end{bmatrix} = \begin{bmatrix}
\kappa(\mathbf{T}\mathbf{T}^\top)^{-1} & 0 \\
0 & 0
\end{bmatrix}
\]

where \( \kappa \) is the curvature of \( C'(f(W_t)) \) at point \( W_t \), which equals the curvature of \( C' \) at point \( v = W_t - f(W_t)\mathbf{N}^\top \).

If there is no public randomization, then the evolution of \( W \) in the \( \mathbf{T}-\mathbf{N} \) coordinates is given by

\[
\begin{bmatrix}
d(W_t) \\
d(\mathbf{N}W_t)
\end{bmatrix} = r \begin{bmatrix}
\mathbf{T}(W_t - g(A_t)) \\
\mathbf{N}(W_t - g(A_t))
\end{bmatrix} dt + r \begin{bmatrix}
\mathbf{B}_t \\
\mathbf{B}_t
\end{bmatrix} dZ_t
\]

Using Itô’s Lemma

\[
df(W_t) = \left( r \begin{bmatrix}
0 & \frac{1}{\mathbf{T}\mathbf{T}^\top}
\end{bmatrix} \begin{bmatrix}
\mathbf{T}(W_t - g(A_t)) \\
\mathbf{N}(W_t - g(A_t))
\end{bmatrix} + \frac{1}{2} \frac{\kappa r^2}{\mathbf{T}\mathbf{T}^\top} |\mathbf{B}_t|^2 \right) dt +
\]

\[
r \begin{bmatrix}
0 & \frac{1}{\mathbf{T}\mathbf{T}^\top}
\end{bmatrix} \begin{bmatrix}
\mathbf{B}_t \\
\mathbf{B}_t
\end{bmatrix} dZ_t = \left( r \mathbf{N}(W_t - g(A_t)) dt + \frac{\kappa}{2} r |\mathbf{B}_t|^2 dt + \mathbf{B}_t dZ_t \right)
\]

Let us show that the drift of \( f(W_t) \) is greater than or equal to \( rf(W_t) - Kr(\mathbf{T}\mathbf{T}^\top)^{-1}|\mathbf{B}_t| \) for an appropriate constant \( K > 0 \). We have

\[
\mathbf{N}(W_t - g(A_t)) = \mathbf{N}\mathbf{N}^\top f(W_t) - \mathbf{N}(g(A_t) - v).
\]

(38)
If $N(g(A_t) - v) \leq 0$ (and by (ii) this is always the case when $a \in A^N$), then the drift of $f(W_t)$ is greater than or equal to $rf(W_t)$. If $N(g(A_t) - v) > 0$ (and thus $a \notin A^N$, we have

$$\kappa \geq \frac{2N(g(A_t) - v)}{r|\phi(A_t, T)|^2}$$

(39)

because $C'$ solves equation (36). Therefore, the drift of $f(W_t)$ is greater than or equal to

$$\frac{r}{TT^\top} \left( N\hat{N}^\top f(W_t) - N(g(A_t) - v) \left(1 - \frac{|TB_t|^2}{|\phi(A_t, T)|^2}\right) \right) \geq rf(W_t) - \frac{r}{TT^\top} |V| \frac{4Q}{\Psi} |NB_t|,$$

where we used Lemma 5.

Therefore, by Lemma 7 there exists a probability measure equivalent to the measure induced by $A$, under which the process $f(W_t)$ has drift greater than $rf(W_t)$. It follows that $f(W_t)$ would escape from $V$ with positive probability, since $f(W_0) > 0$.

With public randomization the expression for $df(W_t)$ would include an extra term, a submartingale orthogonal to $Z_t$, since $f$ is a convex function. Again, Lemma 7 implies that $f(W_t)$ escapes from $V$ with positive probability. \qed

If $\mathcal{E}(r) \neq N$, then Lemma 6 implies that $\mathcal{E}(r)$ has nonempty interior. Indeed, if $\mathcal{E}(r)$ were an interval (or a point), its endpoints would have to be in $N$ because the boundary of $\mathcal{E}(r)$ cannot have kinks outside $N$.

**Lemma 7.** Let $F$ be a process that satisfies

$$F_0 > 0 \quad \text{and} \quad F_t = F_0 + \int_0^t \mu_s \, ds + \int_0^t \sigma_s \, dZ_s + G_t,$$

where $\mu_t \geq rF_t - K|\sigma_t|$ while $F_t \geq 0$ for some constant $K > 0$, $Z$ is a Brownian motion and $G$ is a submartingale orthogonal to $Z$. Then there is an equivalent measure under which

$$F_t = F_0 + \int_0^t \mu'_s \, ds + \int_0^t \sigma_s \, dZ'_s + G_t,$$

where $\mu'_t \geq rF_t$ while $F_t \geq 0$, and under the new measure $Z'$ is a Brownian motion and $G$ is still a submartingale.

**Proof.** By Girsanov’s theorem, the density process

$$\zeta_0 = 1, \quad d\zeta_t = K\zeta_t \frac{\sigma_t}{|\sigma_t|} dZ_t$$

defines an equivalent probability measure $Q'$ with the Brownian motion

$$Z'_t = Z_t - K \int_0^t \frac{\sigma_t}{|\sigma_t|} \, dt.$$
Novikov’s condition holds since the process $K\sigma_t/|\sigma_t|$ is bounded. Thus,

$$F_t = F_0 + \int_0^t (\mu_s + K|\sigma_s|) \, ds + \int_0^t \sigma_s \, dZ_s + dG_t,$$

where $\mu_t + K|\sigma_t| \geq rF_t$ while $F_t \geq 0$. The process $G_t$ is still a submartingale because the density process $\zeta$ is orthogonal to $G$.

Next, we need to prove that a solution to the optimality equation that is tangent to the boundary of $\mathcal{E}(r)$ at an arbitrary point $w \in \partial \mathcal{E}(r) \setminus \mathcal{N}$ does not enter the interior of $\mathcal{E}(r)$, denoted by $\mathcal{E}(r)^\circ$.

**Lemma 8. Tangent curves do not enter $\mathcal{E}(r)$**. Consider point $w \in \partial \mathcal{E}(r) \setminus \mathcal{N}$ with an outward unit normal vector $\mathbf{N}$. Then the curve $\mathcal{C}$, which solves equation (24) from initial conditions $(w, \mathbf{N})$, lies completely outside or on the boundary of the set $\mathcal{E}(r)$. It does not enter the interior of $\mathcal{E}(r)$.

**Proof.** Suppose there is $v \in \mathcal{C} \cap \mathcal{E}(r)^\circ$, as shown in Figure 16. We will show how to construct a curve $\mathcal{C}'$ with two endpoints $v_L, v_R \in \mathcal{E}(r)$ and a point $W_0 \notin \mathcal{E}(r)$ between them.

![Figure 16: Proof of Lemma 8.](image-url)

Take a neighborhood $N_\delta$ around point $v$ in the interior of $\mathcal{E}(r)$. Without loss of generality, assume that point $v$ is found by moving in the clockwise direction from point $w$ along the curve $\mathcal{C}$, as shown in Figure 16. Let us choose a normal vector $\mathbf{N}'$ by rotating $\mathbf{N}$ in the counterclockwise direction. Consider the curve $\mathcal{C}'$ that solves the optimality equation from initial conditions $(w, \mathbf{N}')$. From the continuity of solutions of the optimality equation
in initial conditions, if $N'$ is sufficiently close to $N$, then the curve $C'$ will enter the neighborhood $N_\delta$ of $v$. Because $N'$ is rotated counterclockwise relative to $N$, the curve $C'$ will pass above the line $P_w$ tangent to $E(r)$ at $w$ between $w$ and $N_\delta$. Because there a unique tangent line $P_w$ at point $w$, as argued earlier, the curve $C'$ will enter the interior of $E(r)$ in the counterclockwise direction from $w$. Therefore, we can choose $W_1 \notin E(r)$ that is between points $v_L$ and $v_R \in E(r)^\circ$ on the curve $C'$, as shown in Figure 16. By Proposition 3, there is a PPE that achieves the value pair $W_1$, so $W_1 \in E(r)$, a contradiction. We conclude that the curve $C$ cannot enter the interior of the set $E(r)$. 

This concludes the proof of the Proposition 5.

**Corollary 2.** The set $E(r)$ has a strictly positive curvature at all points $w \in \partial E(r) \setminus N$.

*Proof.* If a tangent solution of equation (36) had zero curvature at point $w \in \partial E(r) \setminus N$, then it must be a straight line. Since $E(r)$ is a bounded set, Proposition 5 implies that this solution must reach the set $N$ on both sides of $w$. But then $w \in N$, a contradiction.
