Some curious consequences follow from this, as to vision under water. An eye placed under perfectly still water (that of a fish, or of a diver) will see external objects only through a circular aperture (as it were) of 96° 55' 20" in diameter overhead. But all objects down to the horizon will be visible in this space; and those near the horizon much distorted and contracted in dimensions, especially in height. Beyond the limits of this circle will be seen the bottom of the water, and all subaqueous objects, reflected, and as vividly depicted as by direct vision. In addition to these peculiarities, the circular space above-mentioned will appear surrounded with a perpetual rainbow, of faint but delicate colours, the cause of which we shall take occasion to explain further on. But we need not immerse ourselves in water to see, at least, a part of these phenomena. We actually live under an ocean of air, a feebly refracting medium, it is true, in comparison with water; and our vision of external objects is much modified accordingly. They are seen distorted from their true form, and contracted in their vertical dimensions; thus the sun at setting, instead of appearing circular, assumes an elliptical, or rather compressed figure, the lower half being more flattened than the upper, and this change of figure is considerable enough to be very evident to even a careless spectator. The spherical form of the atmosphere, and its decrease of density in the higher regions, however, prevent the rest of the appearances above described from being seen in it.

If a medium be bounded by parallel plane surfaces, a ray refracted through it will have its final direction after both refractions the same as before entering the medium.

Let A B, D F be the parallel surfaces of the medium, and S C E T a ray refracted through it, P C p, Q E q, perpendiculars to the surfaces at C and E, then we have

\[
\sin S C P : \sin p C E = \sin S C E Q : \sin q C T = \mu : 1 \}
\]

and, compounding these proportions,

\[
\sin S C P = \sin q E T, \text{ and therefore } S C P = q E T, \text{ and the ray } E T \text{ is parallel to } S C.
\]

This proposition may be proved experimentally, by placing the plane glass of a sextant (unsilvered) before the object-glass of a telescope directed to a distant object, or before the naked eye, and inclining it at any angle to the visual ray. The apparent place of the object will be unchanged.

**Experiment.** Let a plate of glass, or any other transparent medium, be placed parallel to the horizon, and on it let any transparent fluid be poured, so as to form a compound medium consisting of two media of different refractive indices, in contact, and bounded by parallel planes; and let an object above this combination, a star, for instance, be viewed by an eye placed below it, or through a telescope. It will be found to appear precisely in the same situation as if the media were removed, whatever be the altitude of the object, or star. It follows from this, that a ray S B (fig. 26, No. 2) incident on such a combination of media, A F and D I, as described, will emerge in a direction H T parallel to the incident ray S B.

**Proposition.** Let there be any two media (No. 1 and 2) whose respective indices of refraction from a vacuum into each are \( \mu \) and \( \mu' \). Then if these media are brought into perfect contact, (such as that of a fluid with a solid, or of two fluids with one another,) the refraction from either of them (No. 1) into the other (No. 2) will be the same as that from a vacuum into a medium, whose index of refraction is \( \frac{\mu'}{\mu} \), the index of refraction of the second medium divided by that of the first.

Let D E F (fig. 26, No. 2) be the common surface of the two media, and let them be formed into parallel plates A F, D I, as in the experiment last described; then any ray S B incident at any angle on the surface A C will emerge at G I in a direction H T parallel to S B. Let B E H be its path within the media, and draw the perpendiculars P B p, Q E q, R H r, then
L I G H T.

\[
\sin \beta \epsilon \phi : \sin \epsilon \phi \gamma = \sin \beta \epsilon \theta : \mu = 1
\]

and, compounding these proportions,

\[
\sin \gamma \epsilon \phi : \sin \epsilon \phi \gamma : \mu : \mu' = \frac{\sin \beta \epsilon \theta}{\sin \gamma \epsilon \phi} = \mu' \mu.
\]

Absolute and relative indices of refraction.

But \( \beta \epsilon \theta \phi \) is the angle of incidence, and \( \gamma \epsilon \phi \theta \) that of refraction, at the common surface of the media, consequently the relative index, or index of refraction from the first into the second, is equal to the quotient \( \mu' \mu \) of the absolute indices \( \mu', \mu \), of the second and first, or their indices of refraction from vacuum.

This demonstration, it is true, holds good only for the case when the angles of incidence and refraction at the common surface are both less than the limits of the angles of refraction from vacuum into each medium. If they exceed these limits, the proposition however still holds good, as may be shown by direct measures of the angles of incidence and refraction in any proposed case. At present, therefore, we must receive it as an experimental truth.

Example. Required the ratio of the sine of incidence to that of refraction out of water into flint glass. The refractive index of flint glass is 1.60, and that of water 1.336, therefore the refractive ratio required is

\[
\frac{1.60}{1.336} = 1.197.
\]

If the index \( \mu = -1 \), the general law of refraction coincides with that of reflexion. Thus all the cases of reflexion, as far as the direction of the reflected ray is concerned, are included in those of refraction.

Of the Ordinary Refraction of Light through a System of Plane Surfaces, and of Refraction through Prisms.

Definition. In Optics, any medium having two plane surfaces, through which light may be transmitted, inclined to each other at any angle, is called a prism.

Definition. The edge of the prism is the line, real or imaginary, in which the two plane surfaces meet, or would meet if produced.

Definition. The refracting angle of the prism is the angle on which its two plane surfaces are inclined to each other.

Definition. The faces of a prism are the two plane surfaces.

Definition. The plane perpendicular to both surfaces, and therefore to the edge of a prism, is called the principal section of the prism, or of the two surfaces. This expression has been used in this general sense already, under the head of reflexion.

To determine the direction of a Ray after Refraction through any System of Plane Surfaces.

Construction. Since the direction of the ray is the same whether refracted at the given surfaces, or at others parallel to them, conceive surfaces parallel to the given ones, all passing through one point, and from this point, but wholly exterior to the refracting media, let perpendiculars \( CP, CP', CP'', \&c. \) be drawn to each of the surfaces, (fig. 27.) Let \( SC \) be the direction of the incident ray. Between \( CP \) and \( CS' \) draw \( CS'' \) in the plane of the first, and \( PS'P' \) the angle which the planes of the first and second refraction make with each other.

\[
\theta = PS'P' = \text{the angle which the planes of the first and second refraction make with each other.}
\]

\[
\psi = SPP' = \text{the angle made by the plane of the first refraction with the principal section of the two first refracting surfaces.}
\]

\[
\phi = S'P'P = \text{the angle made by the plane of the second refraction with the same principal section.}
\]

\[
\rho = PCS' = \text{the first, and } \rho' = P'CS' = \text{the second angle of refraction.}
\]

\[
D = SCS'' \text{ the deviation after the second refraction.}
\]
Light. We have (conceiving \( S S' S'' PP' \) to be a portion of a spherical surface having \( C \) for its centre) in the spherical triangle \( S'P'P '' \) given \( P'S', P'P'', \) and the included angle, required \( S'P' \) and the angles \( P'S', P'P'' \); and, again, in the triangle \( S S' S'' \) given \( S'S', S'S'' \) and the angle \( S S' S'' \), required \( S'' \) the deviation. Or, in symbols, since \( \rho \) and \( \rho' \) are the angles of refraction corresponding to the angles of incidence \( \alpha, \alpha' \) and the indices of refraction \( \mu, \mu' \),

\[
\begin{align*}
\sin \alpha &= \mu \cdot \sin \rho; \\
\cos \alpha &= \cos \rho \cdot \cos \alpha + \sin \rho \cdot \cos \alpha \\
\sin \alpha &= \mu' \cdot \sin \rho' \\
\sin \alpha' &= \sin \theta = \sin \alpha \cdot \sin \phi \\
\sin \alpha' &= \sin \phi = \sin \rho \cdot \sin \phi \\
\cos \theta &= \cos (\alpha - \rho) \cdot \cos (\alpha' - \rho') - \sin (\alpha - \rho) \cdot \sin (\alpha' - \rho') \cdot \cos \theta.
\end{align*}
\]

From these equations, which, however, are rather more involved than in the case of reflection, (Art. 99, equation A,) we may determine in all circumstances the course of the ray after the second refraction; and, in like manner, as in the case of reflection, of any of the eleven quantities \( \alpha, \alpha', \rho, \rho', \mu, \mu', \theta, \phi, \gamma, \) \( D, \) any five being given the remaining six may be found, and we may then go on to the next refraction, and so on as far as we please. It is needless to observe, however, that, except in particular cases, the complication of the formula becomes exceedingly embarrassing when more than two refractions are considered. Such is the general analysis of the problem; but the importance of it in optical researches requires an examination in some detail of a variety of particular cases.

Case 1. When two plane surfaces only are concerned, at both of which the refractions are made in one plane, viz. that of the principal section of the two planes, or of the prism which they include. Let the ray \( SC \) (fig. 28) be incident from vacuum on any refracting surface \( AC \) of a prism \( CAD, \) in the plane of its principal section; draw \( PC \) perpendicular to that surface, and draw \( CS' \) so that \( \sin PC S' = \sin \alpha \cdot \sin \rho \).

Again, draw \( CP' \) perpendicular to \( AD, \) and take the angle \( S'' CP', \) such that \( \sin P' CS' = \mu' \cdot \sin (\alpha' - \rho'), \) \( \mu' \) being the relative index of refraction from the medium \( ACD \) into the medium \( ADE, \) then will \( S''C \) be parallel to the ray after the second refraction; draw, therefore, \( DE \) parallel to \( S''C, \) and \( DE \) will be the twice refracted ray. As in the general case, calling \( SCP, \alpha; S'CP, \rho; S'CP', \alpha'; S'C P', \rho'; \) and \( PCP', \theta, \alpha, \rho, \rho', \mu, \mu', \) we have

\[
\begin{align*}
\sin \alpha &= \mu \cdot \sin \rho; \\
\sin \rho &= \mu \cdot \sin \alpha \\
\sin \rho &= \mu \cdot \sin \alpha \\
\sin \theta &= \sin \alpha \cdot \sin \phi \\
\sin \phi &= \sin \rho \cdot \sin \phi \\
\cos \theta &= \cos (\alpha - \rho) \cdot \cos (\alpha' - \rho') - \sin (\alpha - \rho) \cdot \sin (\alpha' - \rho') \cdot \cos \theta.
\end{align*}
\]

The first of these equations gives \( \rho \) when \( \mu \) and \( \alpha \) are known; the second gives the value of \( \alpha' \) when \( \rho \) is found; the third gives \( \rho' \) when \( \alpha' \) and \( \rho' \) are known; and the last exhibits the deviation \( D. \)

The sign of \( D \) is ambiguous. If we regard a deviation from the original direction towards the thicker part of the prism, or from its edge as positive, which for future use will be most convenient, we must use the lower sign or take

\[
D = \rho - \alpha - \rho';
\]

but if vice versa, then the upper sign must be used. We shall adhere to the former notation.

Case 2. If, in case 1, we suppose the medium into which the ray emerges to be the same as that from which it originally entered the prism, (a vacuum, for example,) we have \( \mu' = \frac{1}{\mu}. \) This is the case of refraction through an ordinary prism of glass, or any transparent substance. In this case, \( I \) is the refracting angle of the prism, \( \mu \) its refractive index, (its absolute refractive index if the prism be placed in vacuo, its relative, if in any other medium,) and the system of equations representing the deviation and direction of the refracted ray becomes

\[
\begin{align*}
\sin \alpha &= \mu \cdot \sin \rho \\
\sin \alpha' &= \mu \cdot \sin \alpha \\
\sin \alpha' &= \sin \phi = \sin \rho \cdot \sin \phi \\
\sin D &= \rho - \alpha - \rho'.
\end{align*}
\]

Corol. 1. The deviation may be expressed in another form, which it will be convenient hereafter to refer to.

For we have

\[
\sin (I + D + \alpha) = \sin \rho = \mu \cdot \sin \alpha = \mu \cdot \sin (I + \rho)
\]

\[
\mu \left\{ \sin \rho \cdot \cos I + \cos \rho \cdot \sin I \right\}
\]

\[
\mu \left\{ \sin \rho - 2 \sin \rho \left( \sin \frac{I}{2} \right)^2 + \cos \rho \cdot \cos \frac{I}{2} \cdot \sin \frac{I}{2} \right\}
\]

\[
3 \cdot 2
\]

Corol. 2. Both refractions in one plane at the faces of a prism in vacuo.
L I G H T.

because

\[ \cos I = 1 - 2 \left( \sin \frac{I}{2} \right)^2 \text{ and } \sin I = 2 \cdot \sin \frac{I}{2} \cdot \cos \frac{I}{2}. \]

Now \( \mu \cdot \sin \rho = \sin \alpha \) by the first of the equations (c), hence we get (equation d)

\[ \sin (I + D + \alpha) = \sin \alpha + 2 \mu \cdot \sin \frac{I}{2} \cdot \cos \left( \frac{I}{2} + \rho \right); \tag{d} \]

whence, \( I \) and \( \alpha \) being given, and \( \rho \) calculated from the equation \( \sin \rho = \frac{1}{\mu} \sin \alpha \), \( D \) is easily had.

205. Corol. 2. If \( \alpha = 0 \), or if the ray be intromitted perpendicularly into the first surface, we have also \( \rho = \alpha \), and the expression (d) becomes simply

\[ \sin (I + D) = \mu \cdot \sin I; \tag{e} \]

whence also

\[ \mu = \frac{\sin (I + D)}{\sin I}; \tag{f} \]

Thus we see that if \( \mu \cdot \sin I > 1 \), or if \( I \), the angle of the prism, be greater than \( \sin^{-1} \frac{1}{\mu} \), the critical angle, or the least angle of total internal reflexion, the deviation becomes imaginary, and the ray cannot be transmitted at such an incidence.

206. Corol. 3. The equation (f) affords a direct method of determining by experiment the refractive index of any medium which can be formed into a prism. We have only to measure the angle of the prism, and the deviation of a ray intromitted perpendicularly to one of its faces. Thus \( I \) and \( D \) being given by observation, \( \mu \) is known. This is not, however, the most convenient way; a better will soon appear.

Definitions. One medium in Optics is said to be denser or rarer than another, according as a ray in passing from the former into the latter is bent towards or from the perpendicular. When we speak of the refractive density of a medium, we mean that quality by which it turns the ray more or less from its course towards the perpendicular (from a vacuum,) and whose numerical measure is the quantity \( \mu \) the index of refraction.

Proposition. Given the index of refraction of a prism, to find the limit of its refracting angle, or that which if exceeded, no ray can be directly transmitted through both its faces.

This limit is evidently that value of \( I \) which just renders the angle of refraction \( \rho \) imaginary for all angles of incidence on the first surface, or for all values of \( \alpha \), that is, which renders in all cases

\[ \mu \cdot \sin \left\{ I + \rho \right\} - 1 \text{ positive,} \]

or, \( \sin (1 + \rho) - \frac{1}{\mu} \) positive; that is, (since \( I + \rho \) cannot exceed 90°) which renders in all cases \( I + \rho - \sin^{-1} \left( \frac{1}{\mu} \right) \) positive. Now \( \rho = \sin^{-1} \frac{\sin \alpha}{\mu} \), and consequently the value of \( \alpha \) least favourable to a positive value of the function under consideration is \( -90^\circ \), which makes \( \rho = \sin^{-1} \left( \frac{1}{\mu} \right) \), its greatest negative value. Consequently, in order that no second refraction shall take place, \( I \) must at least be such that \( I = 2 \sin^{-1} \left( \frac{1}{\mu} \right) \) shall be positive; that is, \( I \), the angle of inclination of the faces of the prism to each other, or as it is briefly expressed, the angle of the prism, must be at least twice the maximum angle of internal incidence.

For example, if \( \mu = 2 \), \( I \) must be at least 60°. In this case no ray can be transmitted directly through an equilateral prism of the medium in question.

Corol. 4. If \( \mu > 1 \), or if the prism be denser than the surrounding medium, \( \mu \cdot \sin I \) is \( \geq I \) and \( \sin^{-1} (\mu \cdot \sin I) \geq I \), so that the value of \( D \) (equation (d), Art. 204) is positive, or the ray is bent towards the thicker part of the prism, (see fig. 29.) If \( \mu < 1 \), or the prism be rarer than the medium, the contrary is the case, (see fig. 30.)

Problem. The same case being supposed, (that of a prism in vacuo, or in a medium of equal density on both sides,) required to find in what direction a ray must be incident on its first surface so as to undergo the least possible deviation.

Since \( D = \rho - \alpha - I \); (c) Art. 203, and by the condition of the minimum, \( d \cdot D = 0 \), we must have

\[ d \rho = d \alpha. \]

Now the equations (c) give by differentiation

\[ d \alpha \cdot \cos a = \mu \cdot d \rho \cdot \cos \rho; \quad d' = d \rho; \quad d \rho' \cdot \cos \rho' = \mu \cdot d \alpha' \cdot \cos \alpha', \]

that is

\[ d \rho' \cdot \cos \rho' = \mu \cdot d \rho \cdot \cos \alpha' = d \alpha \cdot \frac{\cos a \cdot \cos a'}{\cos \rho}. \]

* The reader will observe, that by the expression \( \sin^{-1} \frac{1}{\mu} \) is meant what in most books would be expressed by \( \arcsin \frac{1}{\mu} \).
By squaring,
\[(1 - \sin a^2)(1 - \sin a'^2) = (1 - \sin p^2)(1 - \sin p'^2)\]
in which, for \(\sin a\) and \(\sin a'\) writing their equals, \(\mu^2\) \(\sin p^2\) and \(\mu^2\) \(\sin a'^2\), we get
\[\frac{1 - \mu^2 \sin a^2}{1 - \sin a^2} = \frac{1 - \mu^2 \sin a'^2}{1 - \sin a'^2},\]
which gives, on reduction, simply \(\sin p^2 = \sin a^2\), and therefore \(p = \pm a'\), that is \(I + p = I + a'\), or \(a' = I + a'\). The upper sign is unsatisfactory, as it would give \(I = 0\). The lower therefore must be taken,
which gives \(a' = \frac{I}{2}\), which satisfies the conditions of the question. We therefore have
\[
\begin{align*}
I &= \frac{I}{2}; & p &= -\frac{I}{2}; & \sin a &= -\mu \sin \left(\frac{I}{2}\right); & \sin a' &= +\mu \sin \left(\frac{I}{2}\right). \\
\end{align*}
\]
This state of things is represented in fig. 31, for the case where \(\mu > 1\), or where the prism is denser than the surrounding medium, and in fig. 32, for that in which it is rarer, or \(\mu < 1\). In both cases, \(a\), being negative, indicates that the incident ray must fall on the side of the perpendicular \(CP\), from the edge \(A\) of the prism (as \(SC\)). In both cases, the equations \(\rho = \frac{1}{2} I (\sin = \frac{1}{2} PCP')\) and \(a' = P'C' = + \frac{1}{2} PCP'\), indicate that the once refracted ray \(SC'\) bisects the angle \(PCP'\), and therefore that the portion of it \(CD\) within the prism makes equal angles with both its faces. In both cases, also, the equality of the angles \(a\) and \(a'\) (without reference to their signs) shows that the incident and emergent rays make equal angles with the faces of the prism, and therefore that it is of no consequence on which face the ray is first received.

Corol. 5. In this case, also, we have the actual amount of the deviation
\[
D = \rho' - a - I = 2 \sin^{-1} \left(\mu \sin \frac{I}{2}\right) - I. \tag{f}
\]
Hence also
\[
\sin \left(\frac{I + D}{2}\right) = \mu \sin \frac{I}{2}. \tag{g}
\]
Corol. 6. In the same case, \(I\) being given by direct measurement, and \(D\) by observation, of the actual minimum deviation of a ray refracted through any prism, the value of \(\mu\), its index of refraction, is given at once, for we have
\[
\mu = \frac{\sin \left(\frac{I + D}{2}\right)}{\sin \left(\frac{I}{2}\right)}. \tag{h}
\]
And this affords the easiest and most exact means of ascertaining the refractive index of any substance capable of being formed into a prism.

Example. A prism of silicate of lead, consisting of silica and oxide of lead, atom to atom, had its refracting angle \(21° 12'\). It produced a deviation of \(24° 46'\) at the minimum in a ray of homogeneous extreme red light: Example, what was the refractive index for that ray?

\[
I = 21° 12', \quad \frac{I}{2} = 10° 36', \quad D = 24° 46', \quad \frac{D}{2} = 12° 23' \\
\sin \left(\frac{I}{2} + \frac{D}{2}\right) = \sin 22° 59' = 0.395158 \\
\sin \frac{I}{2} = \sin 10° 36' = 0.176470 \\
\mu = 2.123 \\
0.32688
\]

Case 3. Let us now take a somewhat more general case, viz. to find the final direction and total deviation of a ray, after any number of refractions at plane surfaces, all the refractions being performed in one plane, and, of course, all the common sections of the surfaces being supposed parallel.

Supposing (as above) \(I\) to represent the inclination of the first surface to the second; \(I'\) that of the second to the third, &c.; and \(I, I', &c\). to be negative when the surfaces incline the contrary way from one certain side assumed as positive, taking also \(\delta, \delta', \delta'', &c. \ldots \delta^{(s-1)}\) to represent the several partial bendings of the rays at the first, second, third, \(s\)th surface respectively, and the other symbols remaining as before, we have the total deviation, \(D = \delta + \delta' + \ldots + \delta^{(s-1)}\). Now we have, since in each case \(\theta = 180°\),
Hence we get (supposing $n$ to represent the number of surfaces)

$$
\sin \rho = \frac{1}{\mu} \cdot \sin a \\
\sin \rho' = \frac{1}{\mu'} \cdot \sin (I + \rho) \\
\sin \rho'' = \frac{1}{\mu''} \cdot \sin (I' + \rho') \\
\vdots
$$

whence the series of values $\rho, \rho', \&c.$ may be continued to the end. These determined, we get $a, a', \&c.$ by the equations

$$
a = a; \quad a' = \rho + I; \quad a'' = \rho' + I'; \quad \ldots \quad a^{(n-1)} = \rho^{(n-2)} + I^{(n-2)}.
$$

and finally

$$
D = \{a + a' + \ldots + a^{(n-1)}\} - \{\rho + \rho' + \ldots + \rho^{(n-1)}\}
$$

$\equiv a + \{I + I' + \ldots + I^{(n-2)}\} - \rho^{(n-1)}.$

Now $I + I' + \ldots I^{(n-2)}$ is the inclination of the first to the last surface, or the angle (A) of the compound prism, formed of the assemblage of them all, so that we have in general

$$
D = a + A - \rho^{(n-1)} \quad \text{(A)}
$$

Let us now inquire, how a ray must be incident on such a system of surfaces so that its total deviation shall be a minimum.

Since $dD = 0$ and $I, I', \&c.$ are constant, we must have

$$
d a = d \rho^{(n-1)},
$$

but

$$
\mu \cdot \sin \rho = \sin a \\
\mu' \cdot \sin \rho = \sin (\rho + I) \\
\mu'' \cdot \sin \rho = \sin (\rho' + I') \\
\mu^{(n-1)} \cdot \sin \rho^{(n-1)} = \sin (\rho^{(n-2)} + I^{(n-2)})
$$

and multiplying all these equations together

$$
\mu \cdot \mu' \cdot \mu'' \cdot \ldots \cdot \mu^{(n-1)} \cdot \cos \rho \cos \rho' \cdot \ldots \cdot \cos \rho^{(n-1)} \cdot \frac{d \rho^{(n-1)}}{d a} = \cos a \cdot \cos (\rho + I) \cdot \ldots \cdot \cos (\rho^{(n-2)} + I^{(n-2)})
$$
or simply

$$
\mu \cdot \mu' \cdot \ldots \cdot \mu^{(n-1)} \cdot \cos \rho \cos \rho' \cdot \ldots \cdot \cos \rho^{(n-1)} = \cos a \cdot \cos a' \cdot \ldots \cdot \cos a^{(n-1)}; \quad \text{(i)}
$$

this equation, combined with the relations already stated, between the successive values of $\rho$ and those of $a$, afford a solution of the problem; but the final equations to which it leads are of great complexity and high dimensions. Thus, in the case of only three refractions, the final equation in $\sin \rho$ or $\sin \rho'$, &c. rises to the sixteenth degree; and though its form is only that of an equation of the eighth, yet there appears no obvious substitution by which it can be brought lower. The only case where it assumes a tractable form is that of two surfaces, when the equation (i) which in general may be put under the form

$$
\mu \cdot \mu' \cdot \ldots \cdot \mu^{(n-1)} (1 - \sin \xi) (1 - \sin \eta), \&c. = (1 - \mu \cdot \mu' \cdot \ldots \cdot \mu^{(n-1)} (1 - \sin \xi) (1 - \mu' \cdot \ldots \cdot \mu^{(n-1)} (1 - \sin \eta), \&c. \quad \text{(j)}
$$

reduces itself by putting

$$
\sin \xi = x, \quad \text{and} \quad \sin \eta = y,
$$
to

$$
(\mu \cdot \mu' \cdot \ldots \cdot \mu^{(n-1)} - \mu \cdot \mu' \cdot \ldots \cdot \mu^{(n-1)} x - \mu' \cdot \mu^{(n-1)} y = 0,
$$

which, combined with the equation

$$
\mu' \cdot \sin \rho' = \sin (\rho' + I)
$$
or

$$
(\mu' \cdot y + x - \sin I) = 4 \mu' \cdot \cos I \cdot x y,
$$
gives a final equation of a quadratic form for determining $x$ or $y$, and which in the particular case of $\mu = 1$, or when the second refraction is made into the same medium in which the ray originally moved before its first incidence, gives the same result we have already found for that case by a similar process. Meanwhile, though we may not be able to resolve the final equations in the general case, the equation (j) affords a criterion of the state of minimum deviation which may prove useful in a variety of cases.
Case 4. When the planes of the first and second refraction are at right angles to each other, required the relations arising from this condition.

In this case we have $\theta = 90^\circ$, $\cos \theta = 0$, $\sin \theta = 1$, so that the general equation (B, 199) becomes

$$
\begin{align*}
\sin \alpha &= \mu \cdot \sin \phi \\
\sin \alpha' &= \mu' \cdot \sin \phi' \\
\sin \alpha'' &= \sin \psi
\end{align*}
$$

and $\cos \alpha'' = \cos \theta \cdot \cos \phi + \sin \theta \cdot \sin \phi \cdot \cos \psi$.

The last of these equations, by transposition and squaring, becomes

$$
\cos \alpha''^2 - 2 \cdot \cos \alpha' \cdot \cos \phi \cdot \cos \alpha + \cos \psi^2 = 0,
$$

in which, substituting for $\sin \psi$ its value $\frac{\sin \alpha''}{\sin \psi}$ deduced from the third equation, and reducing as much as possible, we obtain

$$
\cos \alpha'' \cdot \cos \phi - 2 \cdot \cos \alpha' \cdot \cos \phi \cdot \cos \alpha + \cos \psi^2 = 0,
$$

which, being a complete square, gives simply

$$
\cos \phi \cdot \cos \alpha'' = \cos \psi.
$$

This answers to the equation $\cos \alpha \cdot \cos \alpha' = \cos \psi$, obtained, on the same hypothesis, in the case of reflexion (104); for since the latter case is included in the case of refraction, by putting $\mu = -1$ (Art. 192) we have then $\alpha = -\phi$ and $\cos \phi = \cos \alpha$.

Corol. I. If $i$ and $i'$ be the inclinations to the first and second surfaces respectively of that part of the ray which lies between the surfaces, we have

$$
i = 90^\circ - \phi \quad \text{and} \quad i' = 90^\circ - \phi',
$$

so that the equation above found, gives

$$
\sin i \cdot \sin i' = \cos \psi,
$$
or the product of the sines of the inclination of the ray between the surfaces to either surface is equal to the cosine of the inclination of the two surfaces. The same relation may be expressed otherwise, thus: if we suppose the ray to pass both ways from within, out of the prism, the product of the cosines of its interior incidences on the two surfaces is equal to the cosine of their inclination to each other. In this way of stating it, the case of reflexion is included.

Corol. 2. We have also in the present case

$$
\sin \phi = \frac{1}{\mu} \cdot \sin \alpha; \quad \sin \phi' = \sqrt{\frac{\mu^2 \cdot \sin \alpha^2 - \sin \alpha}{\mu^2 - \sin \alpha^2}}; \quad \sin \phi'' = \frac{1}{\mu^2} \cdot \sqrt{\frac{\mu^2 \cdot \sin \alpha^2 - \sin \alpha}{\mu^2 - \sin \alpha^2}}
$$

and

$$
\cos D = \cos (\alpha - \phi) \cdot \cos (\alpha' - \phi')
$$

so that $\alpha$ being given, all the rest become known. The last equation corresponds to the equation $\cos D = \cos \psi \cdot \cos \alpha''$ in the case of reflexion.

§ VII. Of Ordinary Refraction at Curved Surfaces, and of Diacausties, or Caustics by Refraction.

The refraction at a curved surface being the same as at a plane, a tangent at the point of incidence, if we know the nature of the surface, we may investigate, by the rules of refraction at plane surfaces, combined with the relations expressed by the equation of the surface, in all cases, the course of the refracted ray. We shall confine ourselves to the simple case of a surface of revolution, having the radiant point in the axis.

Proposition. Given a radiant point in the axis of any refracting surface of revolution, required the focus of any annulus of the surface.

Let $CP$ be the curve, $Q$ the radiant point, $QqN$ the axis, $PM$ any ordinate, $PN$ a normal, and $Pq$ or $qP$ the direction of the refracted ray, and therefore $q$ the focus of the annulus described by the revolution of $P$.

Then if we put $\mu$ for the refractive index, and, assuming $Q$ for the origin of the coordinates, put $QM = x$,

$$
MP = y, \quad r = \sqrt{x^2 + y^2}, \quad p = \frac{dy}{dx}, \quad \text{we have}
$$

$$
\sin QPM = \frac{x}{r}; \quad \cos QPM = \frac{y}{r};
$$
Light.

$$\sin NPM = \frac{p}{\sqrt{1 + p^2}}; \quad \cos NPM = \frac{1}{\sqrt{1 + p^2}}$$

consequently

$$\sin NPQ = \sin QPM \cdot \cos NPM + \sin NPM \cdot \cos QPM$$

$$= \frac{x + py}{r \cdot \sqrt{1 + p^2}},$$

and therefore

$$\sin NPQ = \frac{1}{\mu} \cdot \sin NPQ = \frac{x + py}{\mu r \sqrt{1 + p^2}};$$

and

$$\cos NPQ = \frac{Z}{\mu r \sqrt{1 + p^2}},$$

if we put

$$Z = \sqrt{\mu^2 r^2 (1 + p^2) - (x + py)^2};$$

consequently since

$$\sin MPQ = \cos NPQ + NPM,$$

we get

$$\sin MPQ = \frac{x + py + pZ}{\mu r (1 + p^2)}; \quad \text{and} \quad \cos MPQ = \frac{-p(x + py) + Z}{\mu r (1 + p^2)};$$

whence

$$\tan MPQ = \frac{\sin MPQ}{\cos MPQ} = \frac{x + py + pZ}{-p(x + py) + Z}.$$ 

Now we have

$$MP = PM \cdot \tan MP = \frac{y(z + (x + py))}{Z - p(x + py)};$$

and consequently

$$QQ = x + y \cdot \tan MP = (x + py) \cdot \frac{p x - y - Z}{p(x + py) - Z}. \quad (c)$$

2.22. Corol. 1. If we put $s$ for the arc $CP$ of the curve, we have, since $rdr = xdx + ydy = dx(x + py)$,

$$Z = \sqrt{\mu^2 r^2 \left( \frac{ds}{dx} \right)^2 - \left( \frac{dr}{dx} \right)^2} = r \cdot \sqrt{\mu^2 \left( \frac{ds}{dx} \right)^2 - \left( \frac{dr}{dx} \right)^2}; \quad (d)$$

2.23. Corol. 2. If $\mu = -1$, in which case the refraction becomes a reflection, we have

$$Z = \sqrt{r^2 (1 + p^2) - (x + py)^2} = y - px,$$

writing for $r^2$ its value $x^2 + y^2$; so that the general value above found for $QQ$ reduces itself to

$$QQ = 2 \cdot \frac{(x + py) (px - y)}{2px - y (1 - p^2)},$$

which is the same as that found in (b) Art. 109, in the case of reflection.

2.21. Corol. 3. If we put $P = \tan MP = \cotan MPQ = \frac{1}{\tan MPQ}$,

we have

$$P = \frac{-p(x + py) + Z}{x + py + pZ}, \quad (e)$$

and the equation of the refracted ray, if $X$ and $Y$ be its coordinates, ($Q$ being their origin) will be (since $Y$ lies on the opposite side of the curve from $Q$)

$$Y - y = -P \cdot (X - x) \quad (f)$$

2.25. In the case of parallel rays these expressions become (by putting first $x + a$ for $x$, and then making $a$ infinite)

$$Z = a \sqrt{\mu^2 (1 + p^2)} - 1 \quad \{ \text{g} \}$$

$$P = \frac{-p + \sqrt{\mu^2 (1 + p^2)} - 1}{1 + p \sqrt{\mu^2 (1 + p^2)} - 1} \quad \{ \text{g} \}$$

$$AQ = x + y \cdot \frac{1 + p \sqrt{\mu^2 (1 + p^2)} - 1}{\sqrt{\mu^2 (1 + p^2)} - 1 - p}. \quad (h)$$
The theory of Diacaustics is in all respects analogous to that of Catacaustics already explained. To find the coordinates $X$ and $Y$ of the point in the diacaustic which corresponds to the point $P$ in the refracting curve, we have only to regard the equation (f) and its differential with respect to $x$, $y$, and $p$ alone, as subsisting together, and we get the necessary equations for determining $X$ and $Y$ in terms of $x$, $y$, as in the case of reflection, and these are

$$X = x + \frac{P + p}{dP} \, dx; \quad Y = y - P \cdot \frac{P + p}{dP} \, dx;$$

(1)

the only difference is in the signs and in the value of $P$, which, instead of the formula (c, Art. 110,) is here expressed by the more complicated function (e, Art. 223,) and the equation of the diacaustic will be obtained as before by eliminating all but $X$, $Y$ from these.

It is, evident, moreover, that if we suppose, as in the theory of Catacaustics, $M = \frac{P + p}{dP} \, dx$; and put $S$ for the length of the caustic, and $f$ for the line $P'y$, we shall have, exactly as in that theory,

$$f = M \cdot \sqrt{1 + P^2}; \quad -P = \frac{dY}{dX}; \quad \text{and} \quad dS = d f + \frac{1 - Pp}{\sqrt{1 + P^2}}.$$

(226)

See Art. 139, 143, 144.

Now we have, substituting for $P$ its value (e),

$$\sqrt{1 + P^2} = \frac{\mu r (1 + p^2)}{x + py + p z}; \quad 1 - Pp = \frac{(x + py) (1 + p^2)}{x + py + p z};$$

(227)

and consequently the value of $d S$ becomes

$$dS = df + \frac{(x + py) \, dx}{\mu r}, \quad \text{because} \quad (x + py) \, dx = r \, dr,$$

and integrating

$$S = \text{const} + f + \frac{r}{\mu};$$

so that we have, finally, (fig. 34,)

$$\text{arc} \, Fy = (CF - P'y) + \frac{1}{\mu} (QC - QP).$$

(228)

(1)

In the case of reflexion, $\mu = -1$, but at the same time the sign of $f$ is negative, because in this case the reflected ray lies on the same side of the point of incidence with the incident one; thus both terms of the formula change their sign, and this expression coincides with that found Art. 144.

In the case of parallel rays, we must use the value of $P$ found in Art. 225, equation (g). Putting $dQ = \frac{dp}{dx}$, and executing the operations, we find, then,

$$X = x - \frac{1}{P} \cdot \frac{\mu^2 (1 + p^2) - 1}{\mu^2 q} \cdot \frac{1}{P} \cdot \frac{dP}{dx};$$

$$Y = y + \frac{\mu^2 (1 + p^2) - 1}{\mu^2 q} \cdot \frac{1}{P} \cdot \frac{dP}{dx};$$

(229)

(230)

(231)

Corol. If we suppose $\mu = \infty$, or the refractive power infinite, the refracted ray will coincide with the normal, and the caustic will be identical with the evolute; and it is evident that the expressions (m), when $\mu = \infty$, resolve themselves into the well-known values of the coordinates of the evolute.

If the rays incident on the refracting curve do not diverge from one point, but be all tangents to a curve $V'V''$, (fig. 35,) we must put $x - a$ for $x$ in the value of $P$, (eq. (c) Art. 224;) and fix the origin of the coordinates at $A$, putting $AQ = a$; and if, then, we regard $a$ as variable according to any given law, or regard $x - a$ at once as a given function of $x$, and take the differential of $P$ on this supposition, the equations (i) still hold good, and suffice to define the caustic.

Problem. The radiant point and refractive index of a medium being given, to determine the nature of the curve surface which shall refract all the rays to one point.

Here we are required to find the relation between $x$ and $y$, so as to make $Qq$ invariable. Let $Qq = c$, and we have

$$c = (x + py) \cdot \frac{p(x - y - Z)}{p(x + py) - Z}; \quad \text{where} \quad Z = \sqrt{\mu^2 (x^2 + y^2)(1 + p^2)} - (x + py).$$

This equation gives

$$(x + py) \cdot (p (x - c) - y) = Z (x - c + py).$$

(232)
Squaring both sides, and substituting for \(Z\) its value, we get

\[(x + py)^2 (y^2 + (x - c)^2) = \mu^2 (x - c + py)^2 (y^2 + \alpha^2)\]

which, on executing the operations indicated on the left hand side, becomes totally divisible by \(1 + p\), and reduces itself to

\[(x + py)^2 (y^2 + (x - c)^2) = \mu^2 (x - c + py)^2 (y^2 + \alpha^2)\]

that is, putting for \(p\) its value \(\frac{dy}{dx}\), multiplying by \(dx^2\), and extracting the square root,

\[\frac{x dx + y dy}{\sqrt{x^2 + y^2}} = \mu \cdot \frac{(x - c) dx + y dy}{\sqrt{(x - c)^2 + y^2}},\]

and integrating (each side being a complete differential)

\[\sqrt{x^2 + y^2} = b + \mu \cdot \sqrt{(x - c)^2 + y^2},\]

which is the equation of the curve required, and belongs, generally, to a curve of the fourth order.

**Corol. 1.** About \(Q\) (fig. 36), with any radius \(QA\) arbitrarily assumed, describe a circle \(ABDE\), then if \(CP\) be the refracting curve, and we put \(QA = b\), we have \(QP = \sqrt{x^2 + y^2}\), \(PQ = \sqrt{(x - c)^2 + y^2}\), and the nature of the curve is expressed by the property

\[\frac{BP}{PQ} = \frac{\mu}{\rho}, \quad \text{or} \quad \frac{BP}{PQ} : \mu : 1.\]

**Corol. 2.** If \(b = 0\), or the circle \(ABE\) be infinitely small, we have \(QP : PQ : \mu : 1\), which is a well known property of the circle. In fact, in this case we have simply

\[x^2 + y^2 = \mu^2 \{(x - c)^2 + y^2\}\]

In this, if we change the origin of the coordinates by writing \(x + \frac{\mu^2}{\mu^2 - 1} c\) for \(x\), we find

\[y^2 = \left(\frac{\mu}{\mu^2 - 1} c\right)^2 - x^2.\]

The radius of the circle, therefore, is equal to \(\frac{\mu^2}{\mu^2 - 1} \times QQ\), and the distance of its centre from the radiant point is \(\frac{\mu^2}{\mu^2 - 1} \times QQ\). Take therefore any circle \(HPC\) whose centre is \(E\), (fig. 37,) and two points \(Q, q\), such that \(QE = \mu \times EC\) and \(QC : Cq : \mu : 1\). Then if rays diverge from \(Q\), and fall on the surface \(PH\) beyond the centre, they will, after refraction into the medium \(M\), all diverge from \(q\).

**Corol. 3.** If \(\mu = -1\), the equation \((n)\), when freed from radicals, is only of the second degree between \(x\) and \(y\), and therefore belongs to a conic section. On executing the reduction we get

\[y^2 = \left(1 - \frac{c^2}{b^2}\right) \left(\frac{1}{2}\right)^2 = \left(x - \frac{c}{2}\right)^2,\]

which shows that the radiant point \(Q\) is in one focus and \(q\) in the other, which is the same result as that before found by a different mode of integration.

**Corol. 4.** When \(Q\) is infinitely distant, and the rays are parallel, we must shift the origin of the coordinates for parallel from \(Q\) to \(q\), by putting \(c - x\) for \(x\), and afterwards supposing \(c\) infinite. This gives

\[\sqrt{c^2 - 2cx + x^2 + y^2} = b + \mu \sqrt{x^2 + y^2}.\]

Developing the first term in a descending series, we find

\[(c - b) - x + \frac{x^2 + y^2}{2c} + &c. = \mu \cdot \sqrt{x^2 + y^2}.\]

Let \(c = b = h\), which, since \(b\) is arbitrary, is equally general, and may represent any finite quantity, then, as \(c\) increases and at length becomes infinite, this equation becomes ultimately

\[h = x = \mu \sqrt{x^2 + y^2}.\]

Let \(CP\) be a conic section, \(q\) its focus, and \(AB\) its directrix, \(QM = x\), and \(PM = y\), then will \(QP = h - x\) if we take \(Q A = h\), and the above equation we see expresses that well known property of a conic section, in virtue of which \(QP : PQ\) in a constant ratio. (\(\mu : 1\)).

**Corol. 5.** The curve is an ellipse when \(QP \geq PQ\), or when the ray is incident from a rarer on a denser medium, and an hyperbola in the contrary case. If \(QP = PQ\), the curve is a parabola; in this case \(\mu = 1\), and the rays converge to the focus at an infinite distance, i.e. remain parallel.

To take a single example of the investigation of the diacaustic curve, from the general expressions above...
Light. — let the refracting surface be a plane, and we shall have, fixing the origin of the coordinates at the radiant point, and supposing the axis of the $x$ perpendicular to the refracting plane $ACB$,

$$s = \text{constant} = QC = a, \quad p = \frac{dy}{dx} = \infty.$$  

Thus we get

$$Z = p \sqrt{(\mu^2 - 1) y^2 + \mu^2 a^2}; \quad P = - \frac{y}{\sqrt{(\mu^2 - 1) y^2 + \mu^2 a^2}};$$

$$\frac{dP}{dx} = - \frac{\mu^2 a^2 p}{\sqrt{(\mu^2 - 1) y^2 + \mu^2 a^2}};$$

and therefore by the equations (i) we get, substituting these values,

$$\mu^2 a^2 (a - X) = \{ (\mu^2 - 1) y^2 + \mu^2 a^2 \} \frac{y}{a}$$

$$Y = \frac{1 - \mu^2}{\mu^4} \cdot \frac{y^2}{a^2}.$$

Eliminating $y$ from these, we have the equation of the caustic

$$\left( \frac{a - X}{\mu a} \right)^{\frac{1}{\mu}} + \left( \frac{\sqrt{1 - \mu^2}}{\mu} \cdot \frac{Y}{a} \right)^{\frac{1}{\mu}} = 1$$

This is the equation of the evolute of a conic section whose centre is $C$, and focus the radiant point $Q$. If $\mu$ be greater than unity, or the refraction be made into a rarer medium from a denser, the conic section is an ellipse, (see fig. 39), and in the contrary case an hyperbola, (fig. 40.)

§ IX. Of the Foci of Spherical Surfaces for Central Rays.

Definitions. The curvature of any spherical surface is the reciprocal of its radius, or a fraction whose numerator is unity, and denominator the number of units of any scale of linear measure to which the radius is equal.

The proximity of one point to another is the reciprocal of their mutual distance, or the quotient of unity by the number of units of linear measure in that distance.

The focal distance of a spherical surface is the distance from the vertex, of the point to which rays converge, or from which rays diverge after refraction or reflexion.

The principal focal distance, or focal length, is the distance from the vertex of the point to which parallel and central rays converge, or from which they diverge after refraction or reflexion.

The power of a surface is the reciprocal of its principal focal distance, or focal length, estimated as in the definitions of curvature and proximity.

Problem. To find the focus of a spherical refracting surface after one refraction, for central rays.

Here, putting $a$ for the distance of the focus of incident rays $Q$, (fig. 41.) from the centre $E$, we have

$$(a - x)^2 + y^2 = r^2; \quad p = \frac{a - x}{y}; \quad 1 + p^2 = \frac{r^2}{y^2}; \quad x + py = a;$$

and these substituted in the general expressions Art. 221, give

$$y Z = \sqrt{\mu^2 r^2 x^2 + (\mu^2 r^2 - a^2) y^2};$$

$$Q q = a \left\{ 1 - \frac{r^2}{a(a - x) - y Z} \right\};$$

$$C q = r \left\{ 1 - \frac{\mu^2}{a(a - x) - y Z} \right\}.$$

These values of $Q q$ and $C q$ contain the rigorous solution of the problem, whatever be the amplitude ($y$) of the focus for annulus whose focus $q$ is, and we shall accordingly again have recourse to them. At present, however, our concern being only with central rays, we must put $y = 0$, when we find $x = a - r; \quad y Z = \mu r x = \mu r (a - r)$.

$$\frac{Q q}{a} = \frac{(a - r)(1 - \mu)}{a - \mu a + \mu r}; \quad \frac{C q}{r} = \frac{\mu r (r - a)}{a - \mu a + \mu r}. \quad (a)$$

Corol. 1. This latter is the focal distance for central rays. Now, since $a - r \equiv QC$, this gives the following proportion,

$$\mu QC = QE : \mu QC : : CE : C q. \quad (b)$$

312
Corol. 2. If we suppose the focus of incident rays infinitely distant, or \( a = \infty \), and take \( F \) the place of \( q \) for central rays, on that supposition, \( F \) will be the principal focus, and we shall have

\[
C F = \frac{\mu r}{\mu - 1}; \quad \text{that is, } C E : C F :: \mu - 1 : \mu
\]

whence we also find

\[
C E : E F :: \mu - 1 : 1, \quad \text{and } C F : F E :: \mu : 1
\]

247. These results will be expressed more conveniently for our future reference by adopting a different notation.

Let, then,

\[
R = \frac{1}{r} \quad \text{= curvature of the surface, and let positive values of } r \text{ and } R \text{ correspond to the case where the centre } E \text{ lies to the right of the vertex } C, \text{ or in the direction in which the rays proceed.}
\]

\[
D = \frac{1}{Q C} \quad \text{(fig. 42) = proximity of the focus of incident rays to the surface, } D \text{ being regarded as positive when } Q \text{ lies to the right of } C, \text{ as in fig. 42, and as negative when to the left, as in fig. 41. Then, since } Q E = a, \text{ and since in the foregoing analysis } a \text{ is regarded as positive when } Q \text{ is to the left of } E, \text{ we must have (fig. 42) } Q E = -a, \text{ and } Q C = Q E + E C = \tau - a, \text{ so that}
\]

\[
D = \frac{1}{\tau - a}; \quad a = \frac{1}{R} - \frac{1}{D}. \quad \text{Let also } m = \frac{1}{\mu}:
\]

\[
F = \frac{1}{C F} = \text{power of the surface:}
\]

\[
f = \frac{1}{C q} = \text{proximity of the focus of refracted rays to the surface.}
\]

Positive values of \( F \) and \( f \), as well as of \( D \) and \( R \), being supposed to indicate situations of the points \( F, f, Q, E \), respectively, to the right of \( C \), or in the direction towards which the light travels. This is, in fact, assuming for our positive case that of converging rays incident on a convex surface of a denser medium. We shall have, then,

\[
r = \frac{1}{R}; \quad \tau' - a = \frac{1}{D}; \quad a = \frac{1}{R} - \frac{1}{D}; \quad \mu = \frac{1}{m}.
\]

Fundamental equation for the foci of central rays.

But equation (b) gives

\[
\frac{1}{C q} = \frac{a + \mu (\tau - a)}{\mu \tau (\tau - a)}
\]

and substituting we shall get

\[
f = (1 - m) R + m D.
\]

This equation comprises the whole doctrine of the foci of spherical surfaces for central rays, and may be regarded as the fundamental equation in their theory.

248. General expression for the power of any surface.

In the case of parallel rays, we have \( D = 0 \), whether the rays be incident from left to right, or from right to left. In either case, then, \( f \) has the same value, viz. (1 – \( m \)). \( R \), and the principal focal distance \( F \) in either case is the same, being given by the equation

\[
F = (1 - m) R,
\]

which shows, moreover, that the power of any spherical surface is in the direct ratio of its curvature.

Hence also we have

\[
f = F + m D.
\]

249. In the case of reflexion, where \( \mu = -1 \), or \( m = -1 \), these equations become respectively

\[
F = 2 R; \quad f = 2 R - D; \quad f = F - D.
\]

250. Such are the expressions for the central foci in the case of a single surface. Let us now consider that of any system of spherical surfaces.

Problem. To find the central focus of any system of spherical surfaces.

Let \( C, C', C'', \&c. \) be the surfaces. \( Q' \) the focus of rays incident on \( C \), \( Q'' \) that of refracted rays, or the focus of rays incident on \( C'' \), and so on. Call also \( R', R'', \&c. \) the radii of the first, second, \&c. surfaces \( \mu', \mu'', \&c. \) their refractive indices, or

\[
\text{sin inc} = \frac{1}{\sin \text{ref}}
\]

into each medium from that immediately preceding, \( m' = \frac{1}{\mu'} \), \( m'' = \frac{1}{\mu''} \), \&c. Also let \( D' = \frac{1}{C' Q'} \), \( D'' = \frac{1}{C'' Q''} \) \&c. and moreover let \( C' C'' = \ell', C'' C'' = \ell'', \&c. \ell', \ell'', \&c. \) being regarded as positive when \( C'', C''', \&c. \) respectively lie to the right of \( C', C'', \&c. \) or in the direction in which the light travels; and if we put

\[
\frac{1}{C' Q'} = \ell', \quad \frac{1}{C'' Q''} = \ell'', \&c.
\]

we shall have by (249)

\[
f = F' + \ell' D'; \quad f' = F'' + \ell'' D'', \&c.
\]

Part I.
but we have also

\[ C'Q' = \frac{1}{D'}; \quad C''Q'' = \frac{1}{D''} = C'Q' - C''Q'' = \frac{1}{f} - \ell; \]
and so on; so that we have, besides, the following relations,

\[ D' = D'; \quad D'' = \frac{f'}{1 - f' \ell}; \quad D''' = \frac{f''}{1 - f'' \ell}, \text{ &c.;} \quad (j) \]

and substituting these values of \( D''', D'''', \&c. \) in the equations (i), and in each subsequent one, introducing the values of \( f', f''', \&c. \) obtained from those preceding, we shall obtain explicit values of \( f', f''', \&c. \) to the end.

The systems of equations (i) and (j) contain the general solution of the problem, whatever be the intervals between the surfaces. On executing the operations, however, for general values of \( \ell', \ell''', \&c. \) the resulting expressions are found to become exceedingly complex, nor is there any way of simplifying them, the complication being in the subject, not in the method of treating it. For further information on this point, consult Lagrange, (Sur la Théorie des Lunettes, Berlin, Acad. 1778.) We shall here only examine the principal cases.

**Problem. To find the focal distance of any system of spherical surfaces placed close together.**

Here \( \ell', \ell''', \&c. \) all vanish, and the equations (i) and (j) become simply

\[ D' = D'; \quad D'' = f'; \quad D''' = f'', \text{ &c.;} \]

whence by substitution we obtain

\[ f''' = F'' + m'' F + m'' m'' D''; \]
\[ f'' = F'' + m'' F'' + m'' m'' F'' + m'' m'' m'' D''', \]

which it is easy to continue as far as we please.

**Corol. 1.** Let the number of surfaces be \( n \), and let \( M' \) represent \( \mu' \), or the absolute refractive index out of vacuum into the first medium; \( M'' = \mu''/\mu''' \), or the absolute refractive index from vacuum into the second medium, and so on; \( \mu', \mu'', \&c. \) representing only the relative refractive indices from each medium into that succeeding it. Thus we shall have

\[ M (\mu') \phi'''' = D' + M' F' + M'' F'' + \ldots \]
\[ M (\mu') \phi''' = M' F' + M'' F'' + \ldots \]

**Cor. 2.** For parallel rays, in whichever direction incident, we have \( D' = 0 \); and the principal focal length of the system, which we will call \( 1 / \phi'''' \), is given by the equation

\[ M (\mu') \phi'''' = D' \]

\[ M (\mu') \phi''' = M' F' + M'' F'' + \ldots \]

**Cor. 3.** Hence it appears that \( \phi'''' \), the power of the system, or its reciprocal focal length for parallel rays, being found by the last equation, the focus for any converging or diverging rays is had at once by the equation

\[ M (\mu') \phi'''' = M (\mu') \phi''' + D' \]

For brevity and convenience, let us, however, modify our notation as follows: confining the accentuated letters to the several individual surfaces of which the system consists, let the unaccented ones be conceived to relate to their combined action as a system. Thus, \( F', F''', \ldots \) \( F'''' \) representing the individual powers of the respective surfaces; let \( F \), without an accent, denote the resulting power of the system. In this view \( D' \) may be used indifferently; accentuated, as relating to the incidence on the first surface; or unaccented, as expressing the proximity of the focus of incident rays to the vertex of the whole system. Similarly, \( M (\mu') \phi'''' \) may be used without an accent, if we regard the total refractive index of the system as that of a ray passing at one refraction into the last medium. This supposed, the equations (k) and (l) become

\[ M F = M' F' + M'' F'' + \ldots \]
\[ M f = M F + D; \quad M (F - f) + D = 0. \]

If the whole system be placed in vacuo, or if the last refraction be made into vacuum, we have \( M = 1 = M (\mu') \); and the equations become

\[ F = M' F' + M'' F'' + \ldots \]
\[ f = M + D \]

**Definitions.** A lens in Optics is a portion of a refracting medium included between two surfaces of revolution whose axes coincide. If the surfaces do not meet, and therefore do not include space, an additional boundary is required, and this is a cylindrical surface, having its axis coincident with that of the surfaces.

The **axis of the lens** is the common axis of all the bounding surfaces.

**Lenses** are distinguished (after the nature of their surfaces) into double-convex, with both surfaces convex, (fig. 44;) plano-convex, with one surface plane, the other convex, (fig. 45;) concavo-convex, (fig. 46;) double-concave, (fig. 47;) plano-concave, (fig. 48;) and meniscus, (fig. 49;) in which the concave surface is less curved than the convex. Also into spherical, (when the surfaces are segments of spheres;) conoidal, when portions of ellipsoids, hyperboloids, &c.
Light.

These different species are distinguished, algebraically, by the equations of the surfaces, and by the signs of their radii of curvature. In the case of spherical lenses, to which our attention will be chiefly confined, if we suppose a positive value of the radius of curvature to correspond to a surface whose convexity is turned towards the left, or towards the incident rays, and a negative to that whose convexity is turned to the right, or from them, we shall have the following varieties of denomination:

- **Meniscus**: both radii, as fig. 46, 49, a, or concavo-convex if both radii are of opposite sign.
- **Plano-convex**: radius of first surface +, of second surface infinite, fig. 45, a.
- **Plano-concave**: radius of first surface −, of second surface +, fig. 45, a.
- **Double-convex**: radius of first surface +, of second surface −, fig. 44.
- **Double-concave**: radius of first surface −, of second surface +, fig. 47.

...the rays being supposed in all cases to pass from left to right.

A compound lens is a lens consisting of several lenses placed close together.

An aplanatic lens is one which refracts all the rays incident on it to one and the same focus.

**Problem. To find the power and foci of a single thin lens in vacuo.**

Let \( R' \) and \( R'' \) be the curvatures of its first and second surfaces respectively, \( \mu \) the refractive index of the medium of which it consists, \( m = \frac{1}{\mu} \); its power: then we have, since the last refraction is made into vacuum,

\[
F = \mu F' + F''; \quad f = F + D;
\]

but, \( F' = (1 - m') R' \) and, \( F'' = (1 - m'') R'' \); and as \( \mu' = \frac{1}{m'} \) and \( m'' = \mu \), these become respectively

\[
\frac{1}{\mu} (\mu - 1) R' \quad \text{and} \quad - (\mu - 1) R'', \quad \text{so that the foci of the lens are finally determined by the equations}
\]

\[
F = (\mu - 1) R' \quad \text{and} \quad f = F + D
\]

Fundamental equations.

**Corol. 1.** The power of a lens is proportional to the difference of the curvatures of the surfaces in a meniscus or concavo-convex lens; and to their sum, in a double-convex or double-concave.

**Corol. 2.** In double-convex lenses \( R' \) is positive and \( R'' \) negative, so that when \( \mu > 1 \), \( F \) is positive, or the rays converge to a focus behind the lens. In plano-convex, \( R'' = 0 \) and \( R' \) is +; or \( R' = 0 \) and \( R'' \) is negative, (260); hence in both cases \( F \) is positive and the rays also converge. In meniscus lenses also, \( R' \) is +, and \( R'' \), though +, is less than \( R' \); (fig. 49) ; therefore in these, also, the same holds good. In all these cases the focus is said to be real, because the rays actually meet there. In double-concave, plano-convex, or concavo-concave lenses, the reverse holds good; the focus lies on the opposite side, or towards the incident rays, and parallel rays, after refraction, diverge from it. In this case, therefore, they never meet, and the focus is called a virtual focus.

**Corol. 3.** If \( \mu < 1 \), or the lens be formed of a medium rarer than the ambient medium (which need not be vacuum, provided the whole system be immersed in it,) \( \mu - 1 \) is negative, and all the above cases are reversed. In this case convex lenses give virtual, and concave, real foci.

**Corol. 4.** For lenses of denser media, the powers of double-convex, plano-convex, and meniscus are positive; and those of double plano-convex and concavo-convex lenses, negative; vice versa for rarer media.

**Corol. 5.** The focus of parallel rays is at the same distance, on whichever side of the lens the rays fall. For if the lens be turned above, \( R' \) becomes \( R'' \), and vice versa; but, since they also change their signs, \( F \) remains unaltered.

**Corol. 6.** The equation \( f = F + D \) gives \( df = dD \). This shows that the foci of incident and refracted rays move always in the same direction, if the former be supposed to shift its place along the axis; and, moreover, that their proximities to the lens vary by equal increments or decrements for each.

**Problem. To determine the central foci of any system of lenses placed close together, the lenses being supposed infinitely thin.**

The general problem of a system of spherical surfaces contains this as a particular case; for we may regard the posterior surface of the first lens, and the anterior of the second, as forming a lens of vacuum interposed between the two lenses, and so for the rest. Thus the system of lenses is resolved into a system of spherical surfaces in contact throughout their whole extent; the alternate media having their refractive indices, or the alternate values of \( M \), unity. If then we call \( \mu', \mu'', \mu''' \), &c. the refractive indices of the lenses, we shall have

\[
M = 1; \quad M' = \mu'; \quad M'' = 1; \quad M''' = \mu''; \quad M'''' = 1, \; &c.
\]
Light. The compound power $F$ then will (258, o) be represented by

$$F = F' + F'' + F''' + F'''' + \ldots + F^n + F^m + \ldots,$$  

But

$$F' = (1 - m') R' = \frac{1}{\mu} (F' - 1) R',$$  

$$F'' = (1 - m'') R'' = (1 - \mu') R''',$$

because $m' = \frac{1}{\mu'}$ and $m'' = \mu'$. Consequently,

$$F' + F'' = (\mu' - 1) (R' - R''),$$

and similarly

$$F'' + F''' = (\mu'' - 1) (R'' - R'''),$$

so that we get, finally,

$$F = (\mu' - 1) (R' - R'') + (\mu'' - 1) (R'' - R''') + \ldots$$

Now, the several terms of which this consists are (by Art. 261) the respective powers of the individual lenses of which the system consists, so that if we put (according to the same principle of notation) $L'$, $L''$, $L'''$, &c. for the powers of the single lenses, and $L$ for their joint power as a system, we have

$$L = L' + L'' + L''' + \ldots$$

which shows that the power of any system of lenses is the sum of the powers of the individual lenses which compose it; the word sum being taken in its algebraic sense, when any of the lenses has a negative power. Moreover it is easy to see that we also have $L = L + D$, as in the case of a single lens.

Reciprocally, we may regard a system of spherical surfaces forming the boundaries of contiguous media (as in the instance of a hollow lens of glass enclosing water) as consisting of distinct lenses, by imagining the concavity of one medium and the convexity of that in immediate contact with it separated by an infinitely thin film of vacuum, or of any medium having its surfaces equicurved, as in fig. 50; and thus a system of any number (n) of media, whose surfaces are in contact throughout their whole extent, may be conceived replaced by an equivalent system of $2n - 1$ lenses, the alternate ones being vacuum, or void of power. This way of considering the subject has often its use. It, moreover, leads to the result, that the power of any system of spherical surfaces placed in vacuo is the sum of the powers of the several lenses into which it can be resolved, each placed in vacuo and acting alone.

Let us now return to the case of surfaces separated by finite intervals; and, first, let us inquire the foci of a system of surfaces separated by intervals so small that their squares may be neglected. In this case the equations (j), Art. 251, become simply

$$D' = D; \quad D'' = f' + f'' t; \quad D''' = f'' + f''' t', \quad \ldots$$

and substituting these values in the equations (i), and retaining the notation of Art. 257, we find

$$M f = M^{(a)} f^{(a)} = M f' + M f'' + \ldots + M f''') + D$$

$$+ M f' t + M f'' t' + \ldots + M f^{(a-1)} t^{(a-1)} + \ldots$$

Now in this we are to consider that

$$f' = F' + m' D, \quad f'' = F'' + m'' F' + m' m'' D', \quad \ldots$$

and the values of $f'$, $f''$, &c. so expressed, being substituted in the foregoing equation, we find

$$M f = M f' + M f'' + M f'' + \ldots + \ldots + D$$

$$+ M f' t + M f'' t' + \ldots + M f^{(a)} t^{(a)} + \ldots$$

Corol. In the case of two surfaces, supposing $M = 1$, or in the case of a single lens in vacuo, this gives

$$f = (\mu - 1) (R' - R'') + D + \frac{1}{\mu} \{ (\mu - 1) R' + D \} t.$$

For parallel rays, this becomes

$$F = (\mu - 1) (R' - R'') + \frac{(\mu - 1)^2}{\mu} R' t;$$

$t$ being here put for $t'$, the interval between the surfaces or total thickness of the lens.

Problem. To determine the foci of a lens, whose thickness is so considerable as to allow of any of its powers, being neglected.

Here we must take the strict formule

$$D' = D; \quad D'' = \frac{f'}{1 - f'} t; \quad f' = (1 - m') R' + m' D; \quad \text{and} f'' = (1 - m'') R'' + m'' D'.$$

The latter equation gives, on substitution, and recollecting that $m' = \frac{1}{\mu} = m$ and $m'' = \mu$,
384 \textbf{L I G H T.}

\begin{equation}
f = f'' = \frac{(\mu - 1) (R' - R'')} + D + \frac{\mu - 1}{\mu} \left\{ \left( \frac{\mu - 1}{\mu} \right) R' + D \right\} R'' t \end{equation}

\begin{equation}
1 - \frac{1}{\mu} \left\{ \left( \frac{\mu - 1}{\mu} \right) R' + D \right\} t
\end{equation}

and for parallel rays

\begin{equation}
F = \frac{\mu (\mu - 1) (R' - R'') + (\mu - 1)^2 R' R'' t}{\mu - t. (\mu - 1) R'}
\end{equation}

273. \textbf{Example 1. To determine the foci of a sphere.}

Here \( R' = -R' = -R ; \quad t = \frac{2}{R} ; \quad \text{and the equations (u) and (v) become} \)

\begin{equation}
f = \frac{(2 \mu - 2) R + (2 - \mu) D}{(2 - \mu) R - 2D} R ; \quad F = \frac{2\mu - 2}{2 - \mu} R.
\end{equation}

274. \textbf{Corol. 1. If} \( \mu = 2 \), \textit{for instance}, these values become

\begin{equation}
f = \frac{R^3}{D} ; \quad F = \infty.
\end{equation}

In this case, then, since \( f \) and \( F \) express the proximities of the foci to the posterior surface of the sphere, we see that the focus for parallel rays falls on this surface, and that in any other case (as in fig. 51 and 52) \( q \) is given by the proportion

\[ QC : CE :: EH : HQ. \]

275. \textbf{Corol. 2. Whatever be the value of \( \mu \), the focus for parallel rays after the second refraction bisects the distance between the posterior surface of the sphere, and the focus after the first refraction.}

276. \textbf{Example 2. To determine the foci of a hemisphere, in the two cases; first, when the convex, secondly, when the plane surface receives the incident light.}

In the first case, \( R' = R ; \quad R'' = 0 ; \quad t = \frac{1}{R} \); \textit{therefore we find}

\begin{equation}
f = \frac{(\mu - 1) R + D}{R - D}. R ; \quad F = (\mu - 1) R.
\end{equation}

277. In the other case, when the rays fall first on the plane side, \( R' = 0, R'' = -R \), and \( t = \frac{1}{R} \), so that

\begin{equation}
f = \frac{\mu (\mu - 1) R + D}{\mu R - D} R ; \quad F = (\mu - 1) R.
\end{equation}

278. If the thickness of a spherical segment exposed with its convex side to the incident rays be to the radius as \( \mu \) to \( \mu - 1 \), or if \( t = \frac{\mu}{\mu - 1}. \frac{1}{R} = \frac{1}{(1 - \mu) R} \), and \( R'' = 0 \), the expressions (u) and (v) become

\begin{equation}
f = - (\mu - 1). \frac{R}{D} \left\{ (\mu - 1) R + D \right\} ; \quad F = \infty
\end{equation}

In this case the focus for parallel rays falls on the posterior surface of the segment.

In general, for any spherical segment, if exposed with its convex side to the rays, \( R'' = 0 \), and

\begin{equation}
f = \frac{\mu (\mu - 1) R + D}{\mu + \left\{ (\mu - 1) R + D \right\} t} ; \quad F = \frac{\mu (\mu - 1) R}{\mu + (\mu - 1) R t}.
\end{equation}

If the plane side be exposed to the rays

\begin{equation}
f = (\mu - 1) R + \frac{\mu D}{\mu - t. D} ; \quad F = (\mu - 1) R.
\end{equation}

279. \textbf{If} \( R' = R'' \), or if the lens be a spherical lamina of equal curvatures, the one convex, the other concave,

\begin{equation}
f = \frac{\mu D + (\mu - 1) \left\{ (\mu - 1) R + D \right\} R t}{\mu - \left\{ (\mu - 1) R + D \right\} t} ; \quad F = \frac{(\mu - 1)^2 R^3 t}{\mu - (\mu - 1) R t}.
\end{equation}
§ X. Of the Aberration of a System of Spherical Surfaces.

**Problem.** To determine the focus of any annulus of a spherical refracting or reflecting surface.

The equations (a) of Art. 244, of the last section, in fact, contain a general solution of this problem; but the applications of practical Optics require an approximate solution for annuli of small diameter, or in which the annulus is small compared with \( r \). Conceiving \( y \), then, so small that its fourth and higher powers may be neglected, the expressions in the article cited give

\[
x = a + \sqrt{a^2 - y^2} = a - r + \frac{y^2}{2r}; \quad a - x = r - \frac{y^2}{2r}
\]

and substituting these in the value of \( C_q \), found in the same article, we get for the distance of the focus of refracted rays from the vertex

\[
\frac{1}{C_q} = \frac{\mu r (r-a)}{a - \mu r + \mu r} + \frac{1}{r^2} \cdot \frac{a^2 (a + \mu r)}{(a-r) (a+\mu r)^2} \cdot \frac{y^2}{r^2} \tag{a}
\]

In conformity, however, with the system of notation adopted in the last section, instead of expressing directly \( C_q \), we will take its reciprocal. As we have hitherto represented the value of this reciprocal for central rays by \( f \), we will continue to do so; and for rays incident at the distance \( y \) from the vertex, we will represent the same reciprocal by \( f + \Delta f \); \( f + \Delta f \) then will be that part of \( f \) due to the deviation of the point of incidence from the vertex. Now, neglecting \( y^2 \), we have

\[
\frac{1}{C_q} = \frac{a - \mu a + \mu r}{\mu r (r-a)} + \frac{1}{r^2} \cdot \frac{a^2 (a + \mu r)}{(a-r) (a+\mu r)^2} \cdot \frac{y^2}{r^2} \tag{b}
\]

Now if we put, as we have hitherto done, \( \mu = \frac{1}{m} \), \( r = \frac{1}{R} \), \( a = \frac{1}{R} - \frac{1}{D} \), and substitute these in the above, we shall get the value of \( \frac{1}{C_q} \), or of \( f + \Delta f \), in terms of \( m \), \( R \), and \( D \); and from this, subtracting the term independent of \( y^2 \), which is the value of \( f \), we shall get \( \Delta f \) as follows,

\[
\Delta f = m \frac{(1 - m)}{2} \left( R - D \right) \cdot \left( m R - (1 + m) D \right) \cdot y^2. \tag{c}
\]

**Definition.** The **longitudinal aberration**, is the distance between the focus for central rays and the focus \( q \) of the annulus, whose semidiameter, or aperture, is \( y = MP \). The **lateral aberration** at the focus, is the deviation from the axis of the refracted ray, or the portion \( f k \), intercepted by the extreme ray, of a perpendicular to the axis drawn through the central focus.

**Corol.** These aberrations are readily found from the value of \( \Delta f \) above given; for since \( C_q = \frac{1}{f} \), we have \( \Delta C_q \) (= longitudinal aberration) = \( \Delta \left( \frac{1}{f} \right) = - \frac{\Delta f}{f^2} \); or, calling \( \omega \) this aberration,

\[
\omega = - \frac{\Delta f}{f^2}; \tag{d}
\]

and since

\[
C_q : qk :: y : f k, \text{ or } \frac{1}{f} : \omega :: y : f k,
\]

we have \( f k \), or the lateral aberration = \( f \cdot y \cdot \omega = - \frac{\Delta f}{f} \cdot y \); \( \omega \) where

\[
f = (1 - m) R + m D.
\]

Thus the whole theory of aberration is made to depend on the value of \( \Delta f \), and we come therefore to consider the various cases of this which present themselves.

**Case 1.** For parallel rays \( D = 0 \); and, therefore,

\[
\Delta f = \frac{m^2 (1 - m)}{2} \frac{R^3 y^3}{2 (1 - m) R y^3}; \quad \omega = - \frac{m^2}{2 (1 - m) R y^3} \left\{ \frac{R^3 y^3}{2} \right\}; \tag{f}
\]

**VOL. IV.**
Case 2. In reflectors, \( m = \mu = -1 \), and
\[
\Delta f = R (R - D)^2 y^2;
\]
\[
\omega = -\frac{R (R - D)^2}{(2 R - D)^2} \frac{1}{D} y^2;
\]
\[
lateral aberration = -\frac{1}{3} (R - D)^2 y^3 .
\]
which, for parallel rays, become
\[
\Delta f = R^2 y^2;
\]
\[
\omega = -\frac{1}{3} R y^3;
\]
\[
lateral aberration = -\frac{1}{3} R y^3 .
\]
In the general case, if we put either \( D = R \), or
\[
m R - (1 + m) D = 0 , \text{ which gives } D = \frac{m}{m + 1} R ; \quad \frac{1}{D} = (\mu + 1) - \frac{1}{R} ,
\]
the value of \( \Delta f \), and therefore of the aberration, vanishes. The former case is that of rays converging to the centre of curvature, in which, of course, they undergo no refraction. In the latter, the point is the same with that already determined, Art. 234. It is evident, from what was there demonstrated, that every spherical surface, \( CP \), has two points \( Q, q \) in its axis, so related, that all rays converging to or diverging from one of them, shall after refraction rigorously converge to or diverge from the other. These points may be called the aplanatic foci of the surface; and, to distinguish them, \( Q \) may be called the aplanatic focus for incident, and \( q \) for refracted rays. To find them in any proposed case, in the axis of any proposed surface \( C \), and on the concave side of the surface, take \( C Q = (\mu + 1) \times \text{radius } C E \) of the surface, and \( C q = \left( \frac{1}{\mu + 1} \right) \times \text{radius} \).

Then will \( Q \) and \( q \) be the aplanatic foci required. In the case of reflexion, when \( \mu = -1 \), \( C Q = C q = 0 \), and both the aplanatic foci coincide with the vertex of the reflector.

Let us next trace the effect of aberration in lengthening or shortening the focus, for all the varieties of position of the focus of incident rays; and, first, when \( D = 0 \), or for parallel rays, \( \Delta f \) is of the same, and therefore \( \omega \) of the contrary sign with \( R \), and therefore with \( F \), which is equal to \( (1 - m) \cdot R \). Hence it is evident, that the effect of aberration in this case must be to shorten the focus of exterior rays.

\( Q \) in this case is infinitely distant. As it approaches the surface, or as the rays from being parallel become more and more convergent, or divergent, the aberration diminishes; but the focus of exterior rays is still always nearer the surface than that of central, till \( Q \) comes up to the aplanatic focus \( A \) for incident rays on the concave, or to the focus \( F \) of parallel rays on the convex side. When \( Q \) is at the former of these points, the aberration is 0; at the latter, infinite.

When \( Q \) is situated anywhere between these points, however, the reverse is the case, and the effect of aberration is to throw the focus for exterior rays farther from the surface than that for central ones. These results are easily deduced from the consideration of all the particular cases, and hold good for all varieties of curvature, and for refracting media of all kinds. In reflectors, the aplanatic foci coincide with the vertex. In these, the focus for exterior rays is shorter than for interior in every case, except when the radiant point is situated between the surface and the principal focus on the concave side of the reflecting surface; but between these points, longer.

Problem. To determine the aberrations of any system of spherical refracting surfaces placed close together.

Retaining the notation of Art. 257, let us suppose the ray, after passing through the first surface, to be incident on the second. Its aberration at this will arise from two distinct causes: first, that after traversing the first surface, instead of converging to or diverging from the focus for central rays, its direction was really to or from a point in the axis distant from that focus by the total aberration of the first surface; and, secondly, that being incident at a distance from the vertex of the second surface, a new aberration will be produced here, which (being, as well as the other, of small amount) the principles of the differential calculus allow us to regard as independent of it, and which being computed separately, and added to it, gives the whole aberration of the two surfaces regarded as a system.

The same is true of the small alterations in the values of \( f', f'' \), &c. produced by the aberrations. If then we denote by \( \delta f'' \) the change in the value of \( f'' \), produced by the action of the first surface, and by \( \delta f'' \), that arising immediately from the action of the second, and by \( \Delta f'' \), the total alteration produced by both causes, we shall have
\[
\Delta f'' = \delta f'' + \delta f'' + \delta f''
\]
Now, first, to investigate the partial alteration \( \delta f'' \) arising from the total alteration \( \Delta f'' \) in the value of \( f'' \), or from the aberration of the first surface, we have
\[
f'' = (1 - m) \cdot R'' + m'' f', \text{ and therefore } \delta f'' = m'' \Delta f',
\]
since, in this case,
\[
D' = D, \quad D'' = f', \quad D''' = f'', \&c.
\]
Again, to discover the partial variation \( \delta f'' \) in \( f'' \), arising immediately from the action of the second surface, we have, by the equation (c) at once, putting \( f'' \) for \( D'' \), and neglecting \( y'' \), &c.
\[
\delta f'' = m''(1 - m'') \cdot (R'' - f'')^2 \{ m'' R'' - (1 + m'') f' \} y'' ;
\]
but we have, by the same equation, also
\[
\delta f'' = m' \cdot f' = m'' m' (1 - m') \cdot (R' - D)^2 \{ m' R' - (1 + m') D \} y'' .
\]
Consequently, uniting the two, we have the value of \( \Delta f'' \). Similarly, the value of \( \Delta f''' \) may be derived from that of \( \Delta f'' \), by a process exactly the same, and which gives

\[
\Delta f''' = \Delta f'' + \frac{m''(1 - m''t)}{2} \{ \frac{R''}{R'' - f''} (R'' - f') - (1 + m''t) f'' \} y^2,
\]

and so on. Calling, then, as in Art. 257, \( M', M'', M''', \ldots, M^{(n)} \) the absolute refracting indices of the several media into which the successive refractions are made, and putting \( M^{(n)} = M \), we shall have no difficulty in arriving at the following general expression, where \( \Delta f \) denotes the total effect of aberration on the value of \( f \), the reciprocal focal distance of the system,

\[
M \cdot \Delta f = \begin{cases} 
M'. \frac{m'(1 - m')}{2} (R' - D)^2 \{ m' R' - (1 + m') D \} \\
+ M''. \frac{m''(1 - m'')}{2} (R'' - f') \{ m'' R'' - (1 + m'') f'' \} \\
+ M'''. \frac{m'''(1 - m''')}{2} (R''' - f''') \{ m''' R''' - (1 + m''') f''' \} \\
+ \text{&c.}
\end{cases} \quad (i)
\]

in which it will be recollected that

\[
\begin{align*}
f' &= (1 - m') R' + m' D \\
f'' &= (1 - m'') R'' + m'' R' + m' m'' D \\
& \quad \vdots \\
& \text{&c.}
\end{align*}
\]

and these values being substituted give, if required, an explicit resulting value of \( \Delta f \) in terms of the radii and refractive indices, or their reciprocals, of the surfaces.

If the system of surfaces be placed in vacuo, or the last refraction be made into vacuum, \( M = 1 \), and the second member of the equation \((i)\) exhibits simply the value of \( \Delta f \). In all cases, the aberration \( \omega \) is given as before by the equation

\[
\omega = -\frac{\Delta f}{f^2}, \quad \text{and the lateral aberration is} \quad -\frac{\Delta f}{f} \cdot y.
\]

To express the aberration of any infinitely thin lens in vacuo, let the terms of the general equation be denoted respectively by \( Q', Q'', \ldots \), so as to make

\[
M \cdot \Delta f = \{ Q' + Q'' + Q''' + \ldots \} y^2. \quad (k)
\]

Then, for the case of a single lens in vacuo, when \( m'' = \frac{1}{m''} \), \( M' = \frac{1}{m'} \), \( M'' = 1 \), \( M = 1 \), we have \( \Delta f = Q' + Q'' \); and putting, for a moment, \( R' - D = B \), \( R' - R'' = C \), we find

\[
Q' = \frac{1 - m'}{2} y^2 B^2 \{ m' B - D \}
\]

\[
Q'' = \frac{1 - m'}{2 m''} y^2 (m' B - C)^2 \{ m'' B - m' D - C \}
\]

whence

\[
Q' + Q'' = \frac{1 - m'}{2 m''} y^2 C \{ (2 m' B - C) (m'' B - m' D) + (C - m' B)^2 \}
\]

The expression in brackets, putting for \( B \) and \( C \) their values, and \( \frac{1}{m''} \) for \( m' \), will become

\[
\frac{1}{\mu} \{ ((2 - \mu) R' + \mu R'' - 2 D) (R' - (1 + \mu) D) + \mu ((\mu - 1) R' - \mu R'' + D)^2 \}
\]

If now we multiply out, arranging according to powers of \( D \), and substitute the result, as also the value of \( m' \), \((= \frac{1}{\mu})\), and of \( C \), \((= R' - R'')\) in \( Q' + Q'' \), or \( \Delta f \); we get

\[
\Delta f = (\mu - 1) (R' - R'') \cdot \frac{y^2}{2 \mu} \{ \alpha - \beta D + \gamma D^2 \}
\]

where

\[
\begin{align*}
\alpha &= (2 - 2 \mu^2 + \mu^3) R'' + (\mu + \frac{3}{2} \mu^2 - 2 \mu^3) R' R'' + \mu \frac{3}{2} \mu^3 R''^2 \\
\beta &= (4 + 3 \mu - 3 \mu^2) R' + (\mu + 3 \mu^2) R'' \\
\gamma &= 2 - 3 \mu
\end{align*}
\]

and these values being substituted give, if required, an explicit resulting value of \( \Delta f \) in terms of the radii and refractive indices, or their reciprocals, of the surfaces.
L I G H T.

Now it has been shown, (Art. 261,) that \((\mu - 1) (R' - R'')\) expresses the power of the lens, so that, putting \(L\) for this, we have

\[\Delta f = \frac{L}{2 \mu} (\alpha - \beta D + \gamma D^2) y^2.\]  \(\text{(m)}\)

Such then is the general expression for \(\Delta f\), the fundamental quantity, from which the aberration \(\omega\) may be had in any lens by the equation \(\omega = -\frac{\Delta f}{f^2}\).

**Corol. 1.** The aberration of a lens vanishes when \(D\) is so related to \(R', R''\) and \(\mu\), as to give

\[a - \beta D + \gamma D^2 = 0; \quad D = \frac{\beta \pm \sqrt{\beta^2 - 4 \alpha \gamma}}{2 \gamma}.\]  \(\text{(n)}\)

Now we find, by substitution and reduction,

\[\beta^2 - 4 \alpha \gamma = \mu^2 \{ (R' + R'')^2 - (2 \mu + 3 \mu') (R' - R'')^2 \}\]

and unless this quantity be positive, that is, unless

\[\left(\frac{R' + R''}{R' - R''}\right)^2 > 2 \mu + 3 \mu';\]  \(\text{(o)}\)

the focus of incident rays cannot be so situated as to render the aberration nothing. But, if the curvatures \(R'\) and \(R''\) of the surfaces be such as to satisfy this condition, the value of \(D\) may be calculated at once from the equation \((k)\).

**Corol. 2.** Whenever, in meniscus or concavo-convex lenses, the difference of the curvatures of the surfaces is small in comparison with their sum, that is, whenever a moderate focal length is produced by great curvatures, the aberration admits of being rendered evanescent by properly placing the focus of incident rays. In a lens of crown glass where \(\mu = 1.52\), we have \(\sqrt{2} \mu + 3 \mu^2 = 3.16\); therefore the sum of the curvatures must be at least 3.16 times their difference, to satisfy the condition of possibility. In double-convex or double-concave lenses, \(R'\) and \(R''\) having opposite signs, the condition can never be satisfied.

**Corol. 3.** If \(a = 0\), the aberration vanishes for parallel rays. This condition is, however, only to be satisfied by real values of \(R'\) and \(R''\) when \(\mu\) is equal to or less than \(\frac{1}{2}\), and no such media are known to exist.

**Corol. 4.** The effect of aberration will be to shorten or lengthen the focus for exterior rays, according as the sign of \(\Delta f\) is the same as, or the opposite to, that of \(f\). In particular cases it will, of course, however, depend on the values of \(\mu, R, R'\), and \(D\) which shall take place. The principal case is that of parallel rays, in which \(D = 0\), and

\[\Delta f = \frac{y^2}{2 \mu} \cdot \frac{L}{(\mu + 2 \mu^2 + \mu') R' R'' + \mu^3 R' R''};\]

and the focus of external rays will be shorter or longer than that of central ones, according as this quantity has the same, or opposite sign with \(L\), that is, according as

\[(2 - 2 \mu^2 + \mu^2) R' R'' + (\mu + 2 \mu^3 - 2 \mu') R' R'' + \mu^3 R' R''\]

is positive or negative. Now, from what we have already seen in the last corollary, this quantity never can be rendered negative by any real values of \(R'\) and \(R''\), unless \(\mu\) be less than \(\frac{1}{2}\). For all other media, therefore, (comprehending all yet known to exist in nature,) every lens, whatever be the curvatures of its surfaces, has the exterior focal length for parallel rays shorter than the central.

**Corol. 5.** In a glass meniscus, when the radiant point is on the convex side, and the rays diverge, we have \(4 + 3 \mu - 3 \mu^2\) a positive quantity; and, \(R'\) and \(R''\) being both positive, \(\beta\) is so; hence \((D\) being negative in this case) the term \(- \beta D\), and therefore the whole factor \(a - \beta D + \gamma D^2\) is positive; and \(L\) being also positive, \(\Delta f\) is so; and, therefore, \(\omega\), the aberration, negative. Hence, when \(Q\) is beyond \(F\), the focus for parallel rays incident the other way, the exterior focus is the shorter; but when between \(F\) and \(C\), the longer.

**Corol. 6.** Unless \(\left(\frac{R' + R''}{R' - R''}\right)^2 > 2 \mu + 3 \mu\), no real value of \(D\) can render \(a - \beta D + \gamma D^2\) negative.

It appears, therefore, that in all double-convex or concave lenses, as well as in all meniscus and concavo-convex ones, in which the sum of the curvatures of the surfaces is greater than \(\sqrt{2} \mu + 3 \mu^2\) times their difference, the factor \(a - \beta D + \gamma D^2\) is positive for all values of \(D\), and therefore the aberration \(\omega\) has in all such lenses the sign opposite to that of \(L\). Hence, for all such lenses, we have the following simple and general rule: the effect of aberration will be to throw the focus of exterior rays more towards the incident light than that of central ones, when the lens is of a positive character, or makes parallel rays converge, but more from the incident light if of a negative, or if it cause parallel rays to diverge.

**Corol. 7.** All other lenses have, as in the case of single surfaces, aplanatic foci, corresponding to the roots of the equation \(a - \beta D + \gamma D^2 = 0\). In general there are two such foci of incident and two of refracted rays: and
Light rules might easily be laid down for determining in what positions of the radiant point, with respect to these foci and the lens, the aberration tends to shorten or lengthen the exterior focus; but it is simpler and readier to have recourse at once to the algebraic expressions.

Corol. 8. In the case of reflexion, as when rays are reflected between the surfaces of thin lenses of transparent media, we have \( m = m'' = \&c. = \rho = m'' = \&c. = -1 \); \( M'' = 1 \), \( M'' = +1 \), \&c., and \( M = \pm 1 \), according as the number of reflexions is even or odd; therefore for \( n \) reflexions we have

\[
\begin{align*}
    f' &= 2 R' - D \\
    f'' &= 2 R'' - 2 R' + D \\
    f''' &= 2 R''' - 2 R'' + 2 R' - D \\
    \&c.
\end{align*}
\]

and

\[
\Delta f = \left\{ \begin{array}{l}
    R'(R' - D)^y \\
    - R'' (R'' - 2 R' + D)^y \\
    + R''' (R''' - 2 R'' + 2 R' - D)^y \\
    \&c.
\end{array} \right. \quad \text{(q)}
\]

which formulae serve to determine, in all cases of internal reflexion between spherical surfaces, both the places of the successive foci and the aberrations.

Corol. 9. If the reflexions take place between equicurve surfaces, having their concavities turned opposite ways, \( f', f'', \&c. \) are in arithmetical, and therefore their reciprocals, or the focal distances, in harmonic progression.

Problem. To construct an aplanatic lens, or one which shall refract all rays, for a given refractive index, and converging to or diverging from any given point, to or from any other.

Let \( Q \) and \( q \) be the points, the former being the focus of incident, the latter of refracted rays. Let \( \mu = \text{index of refraction} \); and putting \( q = 2 \mu \) and assuming \( b \) any arbitrary quantity, construct the curve whose equation is \( n \), Art. 232. Let \( H P C \), (fig. 36,) be this curve; and with centre \( q \), and any radius \( qn \) less than \( qP \), any one of the refracted rays describe the circle \( HN K \). Then since the ray \( QP \), by the nature of the curve \( HPC \), is after reflexion directed to or from \( q \), and, being incident perpendicularly on the second surface, suffers there no flexure, it will, if supposed to emerge from the medium, here continue its course to or from \( q \). If then we suppose the figure \( CPHNK \) to revolve round \( Qq \), it will generate a solid, which, being composed of the proposed medium, is the lens required. If the rays be parallel, as in fig. 38, the curve \( HPC \), as we have seen, is a conic section, which, if the lens be denser than the ambient medium, is an ellipse. Thus, a glass meniscus lens, whose anterior convex surface is elliptic, and posterior spherical, having its centre in the focus of rays refracted by the first surface, is aplanatic.

But, without having recourse to the conic sections, the same thing may, in certain cases, be accomplished by spherical surfaces only. For if \( Q \) and \( q \) (fig. 53) be the aplanatic foci of the spherical refracting surface, and if with the centre \( q \) and any radius greater than \( qC \), when the incident rays diverge from \( Q \), as in the lower portion of the figure, but less if they converge to \( Q \) as in the upper, we describe a circle \( KL \), or \( kL \), and turn the whole figure about \( Qq \) as an axis, the surfaces \( CPKL \), or \( cpkl \), will generate the aplanatic lens in question. This also follows evidently from the general formula, (i, Art. 291,) for if \( R'' = f' \), the expression of \( \Delta f \) for the lens becomes simply

\[
\frac{1 - \mu^2}{2} (R' - D)^y \left\{ m' R' - (1 + m') D \right\} y^y,
\]

which vanishes when \( D = \frac{m' R'}{1 + m'} \), or when \( Q \) is the aplanatic focus of incident rays for the first surface.

More generally, however, the equation \( a - \beta D + \gamma D^y = 0 \), assigns the universal relation between \( \mu, D, R', \) \( R'' \), which constitutes the lens aplanatic. See Cor. 1, Art. 294.

Problem. To assign the most advantageous form for a single lens, or that which, with a given power, has the least possible aberration for parallel rays.

Since the aberration cannot be rigorously made to vanish for parallel rays, when \( \mu > \frac{1}{2} \) (Art. 296) we have to make it a minimum. Now \( \omega = - \frac{\Delta f}{f^y} = - \frac{\Delta f}{L^y} \) for parallel rays, or

\[
\omega = - \frac{y^y}{2 \mu} \frac{a}{L} \quad \text{and, in general,} \quad \omega = - \frac{y^y}{2 \mu} \left\{ L d a - a d L \right\}
\]

In the present case \( L \) is given, therefore we must put \( d a = 0 \), which gives

\[
0 = 2 (2 - 2 \mu^2 + \mu^4) R' d R' + (\mu + 2 \mu^2 - 2 \mu^2) (R' d R'' + R'' d R') + 2 \mu^2 R'' d R'.
\]

But the condition \( d L = 0 \) gives \( d R' = d R'' \); so that our equation becomes, on substitution and reduction,

\[
0 = (4 + \mu - 2 \mu^2) R' + (\mu + 2 \mu^2) R''.
\]
Light. that is to say

\[ \frac{R''}{R'} = \frac{2 \mu^2 - \mu - 4}{2 \mu^3 + \mu}. \]  

In the case of a glass lens, taking \( \mu = 1.5 \), this fraction becomes equal to \( -\frac{1}{6} \), which shows that the lens must be double-convex, having the curvature of the posterior surface only \( \frac{1}{6} \) that of the anterior, or its radius six times as great. Artists sometimes call such a lens a "crossed lens."

Corol. 1. If \( \mu = 1.6561 \), as is nearly the case with several of the precious stones and the more refractive glasses, \( R'' = 0 \); and the most advantageous figure for collecting all the light in one place is plano-convex, having its convex side turned to the incident rays.

Corol. 2. Calling the aberration of a lens of the best figure \( \omega \), we shall have \( \omega = -\frac{15}{14} \cdot y^3 \cdot L \), for glass whose refractive index is 1.5, and the proportional aberrations of other forms will be as follows:

- Plano-convex, plane side first (or towards the light) \( 4.2 \times \omega \)
- Plano-convex, curved surface first \( 1.081 \times \omega \)
- Double equi-convex, or concave \( 1.567 \times \omega \)

Problem. To investigate a general expression for the aberration of any system of infinitely thin lenses placed close together in vacuo.

The general expression for \( M \Delta f \) or, since \( M = 1 \) in the case before us, of \( \Delta f \), is

\[ (Q' + Q'' + Q''' + Q''', \ldots) y^3, \]

which divides itself into terms originating with the successive lenses in the following manner,

\[ \Delta f = (Q' + Q'') y^3 + (Q''' + Q''') y^3 + \ldots \]

The first of these quantities we have already considered; let us now, therefore, examine the constitution of the rest. Let then \( \mu' \) be the refractive index of the first lens, \( \mu'' \) of the second, \( \mu''' \) of the third; and let \( \alpha', \beta', \gamma' \), represent the values of \( \alpha, \beta, \gamma \) for the first lens, or the expressions in (I, 292,) writing only \( \mu' \) for \( \mu \); also let \( \alpha'', \beta'', \gamma'' \), represent their values for the second lens, or what the same expressions become when \( \mu'' \) is put for \( \mu \), and \( R'' \) and \( R''' \) respectively for \( R' \) and \( R'' \), and so on for the rest of the lenses.

Now if we consider the values of \( Q'' \) and \( Q''' \), it will be seen that they are composed of the quantities \( m'', m''', M'', M''' \), \( R'' \), \( R''' \), \( f'' \) and \( f''' \), precisely in the same manner that \( Q' \) and \( Q'' \) are of \( m', m'', M', M'' \), \( R' \), \( R'' \), \( D \) and \( f' \).

Moreover, since by Art. 251 we have

\[ f' = (1 - m') R' + m' D \]
\[ f'' = (1 - m'') R'' + m'' f' \]
\[ (m - 1) (R' - R'') + D, \text{ since } m' = \frac{1}{\mu'}, m'' = \mu. \]
\[ = L + D' \; \text{; call this } D''' \; \text{; (} L \text{ is the power of the first lens)} \]
\[ f''' = (1 - m''') R''' + m''' D''' \]
\[ f''' = (1 - m'''') R''' + m''''. \quad \text{as before; } (L'' \text{ is the power of the second lens}) \]

And it is clear that \( Q''' + Q'' \) will be the same function of, i.e. similarly composed of, the refractive index and curvatures of the surfaces of the second lens, and of the quantities \( D'' \) and \( f'' \), that \( Q' + Q'' \) is of the refractive index and curvatures of the first lens, and of \( D \) and \( f' \). It follows, therefore, that the very same system of reductions which led to the equation

\[ Q' + Q'' = \frac{L}{2 \mu} (a - \beta D + \gamma D') \]

being pursued in the case of \( Q''' + Q'' \), must lead to the precisely similar equation

\[ Q''' + Q'''' = \frac{L''}{2 \mu''} (a'' - \beta'' D'' + \gamma'' D''') \]

and so on for the remaining lenses; so that we shall have, ultimately, for the whole system (writing \( L', D', \mu' \) for \( L, D, \mu \))

\[ \Delta f = \frac{y^3}{2} \left\{ \frac{L'}{\mu'} (a' - \beta' D' + \gamma' D') + \frac{L''}{\mu''} (a'' - \beta'' D'' + \gamma'' D''') + \ldots \right\}; \quad (i) \]

in which there are as many terms as lenses.
Although the aberration of a single lens for parallel rays admits of being destroyed only on a certain hypothesis of the refractive index, which has no place in nature, yet, by combining two or more lenses, it may be destroyed in a variety of ways. Thus, in the case of two lenses, the expression \((\ell)\) being put equal to zero, gives an equation involving \(u', u'', L', L'', R', R'', R''', R''''\); or (since \(L'\) and \(L''\) are given in terms of \(\mu', \mu''\) and \(R', R'', \&c., and since \(\mu', \mu''\) are given quantities) only the four unknown quantities \(R', R'', R''', R''''\). Now as there are four of these, and only one equation, it may be satisfied in an infinite variety of ways, and the problem of the destruction of the spherical aberration (as it is termed) becomes indeterminate.

The equation in the case of two lenses for parallel rays is

\[
\theta = \frac{L'}{\mu'} \left\{ (2 - 2 \mu'' + \mu'^3) R'' + (\mu'' - 2 \mu'^2 - 2 \mu''') R'' R'' + \mu'' R'' R'' \right\} + \frac{L''}{\mu''} \left\{ (2 - 2 \mu'' + \mu'^3) R'' + (\mu'' - 2 \mu'^2 - 2 \mu''') R'' R'' + \mu'' R'' R'' \right\} - \frac{L' L''}{\mu'} \left\{ 4 + 3 \mu'' - 3 \mu'^3 \right\} R'''' + \frac{R'''}{\mu' \mu''} \left\{ 2 + 3 \mu'' \right\}.
\]

This equation, if \(L'\) and \(L''\), the powers of the separate lenses, be assigned, is of a quadratic form in either \(R', R'', R''', R''''\); it will therefore depend on the supposition adopted to limit the problem, whether these quantities admit real corresponding values. Now the equations \(L' = (\mu' - 1) (R' - R'')\) and \(L'' = (\mu'' - 1) (R'' - R''')\) afford the means of eliminating two of them, and the resulting equation (in \(R'\) and \(R''\) for instance) is

\[
0 = L' \left\{ \frac{2 + \mu'}{\mu'} R'' - \frac{2 \mu' + 1}{\mu' - 1} L' R'' \right\} + L'' \left\{ \frac{2 + \mu''}{\mu''} R'' + \frac{4 (\mu'' + 1)}{\mu'' - 1} L' + \frac{2 \mu'' + 1}{\mu'' - 1} L'' \right\} - \frac{L' L''}{\mu'} \left\{ \frac{3 \mu'' + 1}{\mu'' - 1} L' L'' + \frac{2 + 3 \mu''}{\mu''} L' L'' \right\}.
\]

and, as the unknown quantities \(R', R''\) are not combined by multiplication, the equation when \(L'\) and \(L''\) are given is of an ordinary quadratic form with respect to each. This equation will be of use to us hereafter, when we come to treat of the theory of refracting telescopes.

If \(L'\) and \(L''\) be not given, since either of them is of the first degree in terms of \(R', R'', \&c., the equation \((u)\) is of the third degree in either of the quantities \(R', R'', \&c., or in \(L', L''\), if either \(R''\) or \(R''\) is eliminated. Now as an equation of the third degree must necessarily have at least one real root, we conclude, first, that in a double lens, if the curvatures of three of the surfaces be given, that of the fourth may be found, so as to destroy the spherical aberration.

Secondly. That if the curvature of one surface of each lens, and the power of either, or that of the two combined, be given, the power of the other may be found so as to destroy the spherical aberration. This is evident; for, supposing \(R'\) and \(R''\) given, and either \(L'\) or \(L''\), or \(L' + L''\), also given, the equation \((v)\) becomes an ordinary cubic in which \(L'\) or \(L''\), as the case may be, is the only unknown quantity, and therefore necessarily admits a real value.

As examples of aplana tic combinations, we may set down the following cases, in which a lens of glass of the refraction 1.50, and of the best form, having the radii of its surfaces respectively + 5.833 and - 35.000 inches, and its focal length 10.000 inches, has its aberration corrected by applying behind it another lens of similar glass, as in fig. 55. This lens is a meniscus. If its curvatures be determined by the condition of Fig. 55, giving the maximum of power to the combination, the radii of its surfaces and its focal length will be as follows: radius of first surface, \(+ 2.054\) inches; radius of second surface, \(+ 5.128\); focal length of correcting lens, \(+ 5.497\); focal length of the two combined, \(+ 3.474\). On the other hand, if we determine the second lens by the condition of the resulting combination, having a focal length as nearly 10.000 as is consistent with perfect aplanaticity, we shall find radius of first surface, \(+ 3.688\); radius of second, \(+ 6.291\); focal length of correcting lens, \(+ 17.829\); focal length of the combination, \(+ 6.407\).

The effect of aberration may be very prettily exhibited by covering a large convex lens with a paper.
Light.

Lightscreen full of small round holes, regularly disposed, and, exposing it to the sun, receiving the converged rays on a white paper behind the lens, which should be first placed very near it, and then gradually withdrawn. The pencils which pass through the holes will form spots on the screen, and their disposition will become more and more unequal over the surface, as the screen is further removed; those at the circumference becoming crowded together before the central ones. The manner in which the several spots corresponding to central rays blend together into one image at the focus, and those formed by the exterior ones are scattered round it, gives us a very good idea of the variation of density of the rays in the circle of aberration at or near the principal focus; and if the white screen be waved rapidly to and fro in the cone of rays, so as to pass over the focus at each oscillation, the whole cone will be seen as a solid figure in the air, and the place of the circle of least aberration will become evident to the eye, forming altogether a very pleasing and instructive experiment.

§ XI. Of the Foci for Oblique Rays, and of the Formation of Images.

318. We have hitherto considered rays as converging to, or diverging from, a single point; but as this is not the case with luminous bodies of a sensible diameter, we now proceed to examine the cases of refraction at spherical surfaces, where more than one radiant point is concerned, or where several pencils are incident at once on the surface. We shall take for our positive, or fundamental case, as we have done all along, that of converging rays incident on the convex side of a more refractive medium than the ambient one, and derive all others from it by the changes in the sign and relative magnitudes of $R$, $D$, &c.

In fig. 56, then, let $Q$ and $Q'$ be the foci of two pencils of convergent rays incident on the spherical surface $C C'$, whose centre is $E$. Draw $Q E C$, $Q' E C'$, cutting the surface in $C$ and $C'$, and, regarding $C E Q$ as the axis of the pencil $R Q$, $S Q$, $T Q$, the focus of refracted rays will be found by taking $q$, such as that $\frac{1}{C q} = f$, shall be equal to $(1 - m) R + m D$, (247, e.) Similarly, regarding $C' E Q'$ as the axis of the pencil converging to $Q'$, the focus $q'$ will be had by the equation

$$\frac{1}{C' q'} = f' = (1 - m) R + m D' .$$

Thus when $C' Q' = C Q$, $C q'$ will also equal $C q$, and, in general, when the locus of the point $Q$ is given, that of $q$ may be found.

Definition. The image of an object, in Optics, is the locus of the focus of a pencil of rays diverging from, or converging to, every point of it, and received on a refracting surface. Thus, supposing $C Q'$ to be a line, or surface, every point of which may be regarded as a focus of incident rays, $q q'$ is its image.

Problem. To find the form of the image of a straight line formed by a spherical refracting or reflecting surface.

Put $C E = r, \quad C Q = a, \quad E M = x, \quad M q' = y, \quad E q' = \sqrt{x^2 + y^2}, \quad C' Q' = a' .

Then we have

$$\frac{1}{C' q'} = \frac{1 - m}{r} + \frac{m}{a'} = \frac{(1 - m) a' + m r}{r a'} ;$$

and therefore

$$C' q' = \frac{r a'}{(1 - m) a' + m r} ; \quad E q' = \frac{m r (a' - r)}{(1 - m) a' + m r} ;$$

we have, consequently,

$$x^2 + y^2 = \frac{m^2 r^2}{(1 - m) a' + m r} .$$

But, by similar triangles, $E q' : E M : : E Q' : E Q$, or

$$x^2 + y^2 = \frac{(a' - r) a}{a^2} ,$$

equating these two values we get

$$\frac{a}{a} = \frac{(1 - m) a' + m r}{m r} ; \quad a' = \frac{m}{1 - m} \cdot \frac{r (a - x)}{x} ;$$

so that eliminating $a'$, by substituting this value for it, we get for a final equation between $x$ and $y$, or for the equation of the image

$$(1 - m)^2 (x^2 + y^2) = \left(\frac{r}{a}\right)^2 (m a - x)^2$$

which belongs to a conic section.

321. Problem. When an oblique pencil is incident on any system of spherical surfaces, to find the focus of refracted rays.
Take $E'$, (fig. 57,) the centre of the first surface, and let $Q'$ be the focus of incident rays. Join $Q'E'$ and produce it to $C'$, then will $C'$ be the vertex of the surface corresponding to the pencil whose focus is $Q'$; and taking

$$\frac{1}{C'Q'} = \frac{1 - m'}{C'E'} + \frac{m'}{C'Q'}$$

$Q''$ will be the focus of refracted rays. Again, join $Q''$ and $E''$, the centre of the second surface, produce to $C''$, and take

$$\frac{1}{C''Q''} = \frac{1 - m''}{C''E''} + \frac{m''}{C''Q''}$$

and $Q''$ will be the focus after refraction at the second surface, and so on.

**Corol.** In the case of an infinitely thin lens, when the obliquity is small, it is evident, from this construction, that the focus of oblique rays will lie at the same distance from the lens with that of rays convergent to, or divergent from, a point in the axis at the same distance with the focus of incident rays, but instead of lying in the axis, will deviate from it.

**Definition.** The centre of a lens is a point in its axis where a line joining the extremities of two parallel radii of its two surfaces cuts the axis. Thus, in the various lenses represented in fig. 58, 59, 60, and 61, $E'A$ and $E''B$ being two parallel radii; join $BA$, and produce, if necessary, till it meets the axis in $X$, and $X$ is the centre.

**Corol. 1.** The centre is a fixed point; for, since $AE'$ and $BE''$ are parallel, we have $E'X : E/E'' :: A E' : B E'' - A E'$, in which proportion three terms being invariable, the other is so also.

**Corol. 2.** If $C'C'$, the interval of the surfaces or thickness of the lens, be put equal to $t$ ($t$ being always positive) and the curvatures be respectively $R'$ and $R''$, we have, for the distance of the centre from the first surface, or for $C'X$, the following value,

$$C'X = \frac{R''}{R' - R''} \cdot t.$$
L I G H T.

The eye sees by the rays which enter it, and judges of the existence of an object, by the fact of rays diverging sensibly from some point in space. If, then, rays diverge rigorously from a point, the eye which receives them is irresistibly led to the belief (unless corrected by experience and judgment) of an object being there; the illusion is complete, and vision perfect. But if such divergence be only approximate, as when the density of the rays which reach the eye in any one direction is very much greater than in directions adjacent on either side, vision is still produced, only less distinct, in proportion to the degree of deviation from strict mathematical divergence of the rays which produce it. Suppose, now, Q to be a radiant point placed anywhere with respect to the refracting or reflecting surface A C B, (fig. 66,) and let A q F B be the caustic formed by the intersection of all the refracted or reflected rays. Let us suppose an eye placed at E, and from thence draw E q a tangent

\[ f = (1 - m) R + m D \]

be simply \( f = m D \). Now \( f \) = \( \frac{1}{C Q} \); \( D = \frac{1}{C Q} \); and \( m = \frac{1}{\mu} \). Hence this equation, translated into geometrical language, gives \( C Q = \mu \times C Q \).

Oblique vision through refracting or reflecting surfaces of any figure. Fig. 66.
to the caustic, which continue to the surface C, and join Q C. Then it is obvious, that any small pencil Q C, Q C
diverging from Q, will form a focus at q (Art. 134, &c.) from which it will afterwards diverge, and fall on the eye
at E, nearly as if the rays came from a mathematical point; and from what was said in Art. 161 and 162, it
appears that the density of rays in the cone q E is infinitely greater than in any adjacent cone having the eye for
its base; so that q will appear as an image of Q, more or less confused, in proportion to the degree of curvature
of the caustic at q; for it is evident, that if the curvature be great, the assumed concentration of any small finite
pencil Q C C' in one mathematical point q, will deviate more from truth than if the caustic approach nearly to a
straight line.

Corol. As the eye shifts its place, the apparent position of an object seen in a reflecting or refracting surface
shifts also, for as E varies, the tangent E q shifts its place on the caustic, and the point of contact q, or the
place of the image shifts.

This doctrine may be illustrated by a very familiar instance. If we look through a surface of still water, not
very deep, but having a level horizontal bottom, the bottom will not appear a plane, but will seem to rise on all
sides, and approach nearer the surface the more obliquely we look. To explain this, let Q be a point in the
bottom, and let Q P e be the course of the pencil of rays by which an eye at e sees it (fig. 39) on the visual ray.
The point in the caustic to which e P produced is a tangent, is Y; and from the form of the caustic D Y B (see
Art. 238) it is obvious, that Y is nearer the surface the more oblique e P is to it. The apparent figure of the
bottom will therefore be thus determined. From the eye E (fig. 69) draw any line E g to the point G of the
surface; and having drawn P Y parallel to E G, touching the branch D Y B of the caustic having Q, vertically
below E for a radiant point in Y, prolong E G to H, making G H = P Y, then will H be the image of the point
Q in the bottom, belonging to the caustic D Y H; and the locus of H, or the apparent form of the bottom,
will be the curve D F H, having a basin-shaped curvature at D, a point of contrary flexure at F, and an
asymptote C G K coinciding with the surface.

But, to return to the case of images formed by rays incident at very small obliquities and nearly central,
the following rules for determining their places, magnitudes, and apparent situations in all cases of spherical
surfaces, will be convenient to bear in memory, and will need no express demonstration to the reader of the fore-
going pages.

Rule 1. Any image formed, or about to be formed, by converging rays, or from which rays diverge, may be
regarded as an object.

Rule 2. In spherical reflectors the object and its image lie on the same side of the principal focus. They move
in contrary directions, and meet at the surface and centre of the reflector. The distance of the image from the
principal focus and centre is had by the proportion

\[ \frac{Q F}{F E} : \frac{E F}{F g} : \frac{Q E}{E q} \]

and the image is erect when the object and surface lie on the same side of the principal focus; but inverted when
on contrary sides. The relative magnitudes of the object and image (being as their distances from the centre)
given by the proportion

\[ \frac{Q F}{F E} : \frac{E F}{F g} : \frac{Q E}{E q} \]

Rule 3. In thin lenses, of all species, if Q be the place of the object, q of its image, E the centre of the lens,
F the principal focus of rays incident in a contrary direction, then will the object and image lie on the same, or
opposite side of the lens, according as the object and lens lie on the same or opposite sides of the principal
focus F. In the former case the image is erect, in the latter inverted, with respect to the object. The distance
of the image from the lens, or from the object, is had by the proportions

\[ \frac{Q F}{F E} : \frac{E F}{F g} : \frac{Q E}{E q} \]

and the magnitude of the object is to that of the image as the distance of the object from F is to the focal length,
or as

\[ \frac{Q F}{F E} \]

Rule 4. In all combinations of reflectors and lenses, the image formed by one is to be regarded as the object,
whose image is to be formed by the next, and so on, till we come to the last.

It has been already remarked (Art. 6) that visible objects are distinguished from optical images by this, that
from the former light emanates in all directions, whereas in the latter it emanates only in certain directions.
This is an important limitation in practical optics. A real object can be seen whenever nothing opaque is
interposed between it and the eye. An image can only be seen when the eye is placed in the pencil of rays
which goes to form it, or diverges from it. Thus in the case represented in fig. 62, except the eye be placed
somewhere in the space D q p H, it will see no part of the image, B q D and A p H being the extreme rays
refracted by the lens from the extremities of the object.

The brightness of an image is, of course, proportional to the quantity of light which is concentrated in each Brightness
point of it; and, therefore, supposing no aberration, as the apparent magnitude of the lens or mirror which forms of images.

\[ \text{brightness} \propto \frac{\text{area of object}}{\text{area of image}} \]

of object from lens : (distance)^2 of image; and since the apparent magnitude of the lens seen from the object

\[ \text{brightness} \propto \left( \frac{\text{diameter}}{\text{distance from object}} \right)^2 \]

the brightness or degree of illumination of the image is as the apparent

\[ 3 \pi 2 \]
magnitude of the lens seen from the image, alone, whatever be the distance of the object. Now the apparent
magnitude of the lens seen from the image is always much less than a hemisphere. Therefore (even supposing
no light lost by reflection or refraction) the illumination of the image is always much less than that of the object.
This is the case when the image is received on a screen which reflects all the rays, or when viewed by an
eye behind it having a pupil large enough to receive all the rays which have crossed at the image, & fortiori,
then, when the eye does not receive all the rays, must the apparent intrinsic brightness be less than that of the
object. This supposes the object to have a sensible magnitude; but when both the object and its image are
physical points, the eye judges only of absolute light; and the light of the image is therefore proportional to the
apparent magnitude of the lens, as seen from the object. In the case of a star, for instance, whose distance is
constant, the absolute light of the image is simply as the square of the aperture, and this is the reason why stars
can be seen in large telescopes which are too faint to be seen in small ones.

§ XII. Of the Structure of the Eye, and of Vision.

It is by means of optical images that vision is performed, that we see. The eye is an assemblage of lenses
which concentrate the rays emanating from each point of external objects on a delicate tissue of nerves; called
the retina, there forming an image, or exact representation of every object, which is the thing immediately per-
cceived or felt by the retina.

Fig. 70 is a section of the human eye through its axis in a horizontal plane. Its figure is, generally speaking,
spherical, but considerably more prominent in front. It consists of three principal chambers, filled with media
of perfect transparency and of refractive powers, differing sensibly inter se, but none of them greatly different from
that of pure water. The first of these media, A, occupying the anterior chamber, is called the aqueous humour,
and consists, in fact, chiefly of pure water, holding a little muriate of soda and gelatine in solution, with a trace
of albumen; the whole not exceeding eight per cent.* Its refractive index, according to the experiments of
M. Chossat,† and those of Dr. Brewster and Dr. Gordon,‡ is almost precisely that of water, viz. 1.337, that of
water being 1.336. The cell in which it is contained is bounded, on its anterior side, by a strong, horny, and
delicately transparent coat, called the cornea, the figure of which, according to the delicate experiments and
measures of M. Chossat,§ is an ellipsoid of revolution about the major axis; this axis, of course, determines the
axis of the eye; but it is remarkable, that in the eyes of oxen, measured by M. Chossat, its vertex was never
found to be coincident with the central point of the aperture of the cornea, but to lie always about 10°
(reckoned on the surface) inwardly, or towards the nose, in a horizontal plane. The ratio of the semi-axis
of this ellipse to the excentricity, he determines at 1.3; and this being nearly the same with 1.337, the index
of refraction, it is evident, from what was demonstrated in Art. 236, that parallel rays incident on the cornea in
the direction of its axis, will be made to converge to a focus situated behind it, almost with mathematical
exactness, the aberration which would have subsisted, had the external surface a spherical figure, being almost
completely destroyed.

The posterior surface of the chamber A of the aqueous humour is limited by the iris γ, which is a kind of
circular opaque screen, or diaphragm, consisting of muscular fibres, by whose contraction or expansion an
aperture in its centre, called the pupil, is diminished or dilated, according to the intensity of the light. In very
strong lights the opening of the pupil is greatly contracted, so as not to exceed twelve hundredths of an inch in
the human eye, while in feeble illuminations it dilates to an opening not exceeding twenty-five hundredths,|| or
double its former diameter. The use of this is evidently to moderate and equalize the illumination of the image on the retina, which might otherwise injure its sensibility. In animals (as the cat) which see well in
the dark, the pupil is almost totally closed in the daytime, and reduced to a very narrow slit. But in the human
eye, the form of the aperture is always circular. The contraction of the pupil is involuntary, and takes place
by the effect of the stimulus of the light itself; a beautiful piece of self-adjusting mechanism, the play of which
may be easily seen by approaching a candle to the eye while directed to its own image in a looking-glass.

Immediately behind the opening of the iris lies the crystalline lens, B, enclosed in its capsule, which forms the
posterior boundary of the chamber A. Its figure is a solid of revolution, having its anterior surface much less
curved than the posterior. Both surfaces, according to M. Chossat, are ellipsoids of revolution about their
lesser axes; but it would seem from his measures, that the axes of the two surfaces are neither exactly coincident in
direction with each other, nor with that of the cornea. This deviation would be fatal to distinct vision
were the crystalline lens very much denser than the others, or were the whole refraction performed by it. This,
however, is not the case; for the mean refractive index of this lens is only 1.384, while that of the aqueous
humour, as we have seen, is 1.337; and that of the vitreous C, which occupies the third chamber, is 1.339; so
that the whole amount of bending which the rays undergo at the surface of the crystalline is small, in compa-
rison with the inclination of the surface at the point where the bending takes place, and, since near the vertex, a

Dr. Young's Lectures on the Mechanism of the Eye, Philosophical Transactions, vol. xci.
Light.

material deviation in the direction of the axis can produce but a very minute change in the inclination of the ray to the surface, this cause of error is so weakened in its effect, as, probably, to produce no appreciable aberration.

The crystalline is composed of a much larger proportion of albumen and gelatine than the other humours of the eye, so much so as to be entirely coagulable by the heat of boiling water. It is somewhat denser towards the centre than at the outside. According to Dr. Brewster and Dr. Gordon, the refractive indices of its centre and middle of its thickness, from the centre to the outside, and the outside itself, are respectively 1.3999, 1.3786, and 1.3767, that of pure water being 1.3355. This increase of density is obviously useful in correcting the aberration, by shortening the focus of rays near the centre, according to the rule laid down in Art. 299 for finding the effect of aberration. The effect of the elliptic figure of the surfaces is, however, a matter of pretty complex calculation, and cannot be entered upon in the limits of this essay. Its use is, probably, to correct the aberration of oblique pencils.

The posterior chamber C of the eye is filled with the vitreous humour, a fluid differing (according to Chenevis) neither in specific gravity nor in chemical composition in any sensible respect from the aqueous; and, as we have already seen, having a refractive index but very little superior to it.

The refractive density of the crystalline being superior to that of either the aqueous or vitreous humour, the rays which are incident on it in a state of convergence from the cornea, are made to converge more, and exactly in their final focus is the posterior surface of the cell of the vitreous humour covered by the retina d, a network (as its name imports) of inconceivably delicate nerves, all branching from one great nerve O, called the optic nerve, which enters the eye obliquely at the inner side of the orbit, next the nose. The retina lines the whole of the cavity C up to i, where the capsule of the crystalline commences. Its nerves are in contact with, or immersed in, the pigmentum nigrum, a very black velvety matter, which covers the choroid membrane g, and whose office is to absorb and stifle all the light which enters the eye as soon as it has done its office of exciting the retina; thus preventing internal reflexions, and consequent confusion of vision. The whole of these humours and membranes are contained in a thick tough coat, called the sclerotic, which unites with the cornea, and forms what is commonly called the white of the eye.

Such is the structure by which parallel rays, or those emanating from very distant objects, are brought to a focus on the retina. But as we require to see objects near, as well as at a distance, and as the focus of a lens or system of lenses for near objects is longer than for distant ones, it is evident that a power of adjustment must reside somewhere in the eye; by which either the retina can be moved farther from the cornea, and the eye lengthened in the direction of its axis, or the curvature of the lenses themselves altered so as to give greater convergency to the rays. We know that such a power exists, and can be called into action by a voluntary effort; and, evidently, by a muscular action, producing fatigue if long continued, and not capable of being strained beyond a certain point. Anatomists, however, as well as theoretical opticians, differ as to the mechanism by which this is effected. Some assert, that the action of the muscles which move the eye in its orbit, called the recti, or straight muscles, when all contracted at once, producing a pressure on the fluids within, forces out the cornea, rendering it at once more convex, and more distant from the retina. This opinion, however, which has been advocated by Dr. Olbers, and even attempted to be made a matter of ocular demonstration by Ramsden and Sir E. Home, has been combated by Dr. Young, by experiments which show, at least, very decisively, that the increase of convexity in the cornea has little if any share in producing the effect. An elongation of the whole eye, spherical as it is and full of fluid, to the considerable extent required, is difficult to conceive, as the result of any pressure which could be safely applied, as to give distinct vision at the distance of three inches from the eye, (as we can see well,) the sphere of the eye is nearly one-seventh longer than in its natural state; and the extension of the sclerotic thus produced, would hardly seem compatible with its great strength and toughness. Another opinion, which has been defended with considerable success by the excellent philosopher last named, is, that the crystalline itself is susceptible of a change of figure, and becomes more convex when the eye adapts itself to near distances. His experiments, on persons deprived of this lens, go far to prove the total want of a power to change the focus of the eye in such cases, though a certain degree of adaptation is obtained by the contraction of the iris, which, limiting the diameter of the pencil, diminishes the space on the retina over which imperfectly converged rays are diffused, and thus, in some measure, obviates the effect of their insufficient convergence. When we consider that the crystalline lens has actually a regular fibrous structure, (as may be seen familiarly on tearing to pieces the lens of a boiled fish's eye,) being composed of layers laid over each other like the coats of an onion, and each layer consisting of an assemblage of fibres proceeding from two poles, like the meridians of a globe, the axis being that of the eye itself; we have, so far at least, satisfactory evidence of a muscular structure; and were it not so, the analogy of pelagic animals, in which no muscular fibres can be discerned, and which yet possess the power of motion, and obedience to the nervous stimulus, though nerves, no more than muscles can be seen in them, would render the idea of a muscular power resident in the crystalline easily admissible, though nerves have as yet not been traced into it. On the whole, it must be allowed, that the presumption is strongly in favour of this mechanism, though the other causes already mentioned may, perhaps, conspire to a certain extent in producing the effect, and though the subject must be regarded as still open to fuller demonstration. It is the boast of science to have been able to trace so far the refined contrivances of this most admirable organ; not its shame to find something still concealed from its scrutiny; for, however anatomists may differ on points of structure, or physiologists dispute on modes of action, there is that in what we do understand of the formation of the eye so similar, and yet so infinitely superior, to a product of human ingenuity,—such thought, such care, such refinement, such advantage taken of the properties of natural agents used as mere instruments, for accomplishing a given end, as force upon us a conviction of
The images of external objects are of course formed inverted on the retina, and may be seen there, by dissecting off the posterior coats of the eye of a newly-killed animal, and exposing the retina and choroid membrane from behind, like the image on a screen of rough glass, mentioned in Art. 351. It is this image, and this only, which is felt by the nerves of the retina, on which the rays of light act as a stimulus; and the impressions thereon are transmitted through the optic nerve to the sensorium, impressed on the optic nerve, and transmitted through the optic nerve to the sensorium, impressed thereon by the image, which is not present among the profounder mysteries of physiology, but which appears to differ in no respect from that in which the impressions of the other senses are transmitted. Thus, a paralytic of the optic nerve produces, while it lasts, total blindness, though the eye remains open, and the lenses retain their transparency; and some very curious cases of half blindness have been successfully referred to an affection of one of the nerves without the other. On the other hand, while the nerves retain their sensibility, the degree of perfection of vision is exactly commensurate to that of the image formed on the retina. In cases of cataract, where the crystalline lens loses its transparency, the light is prevented from reaching the retina, or from reaching it in a proper state of regular concentration, being stopped, confused, and scattered by the opaque or semi-opaque portions it encounters in its passage. The image, in consequence, is either altogether obliterated, or rendered dim and indistinct; and the growth of blindness is accordingly. If the opaque lens be extracted, the full perception of light returns; but one principal instrument for producing the convergence of the rays being removed, the image, instead of being formed on the retina, is formed considerably behind it, and the rays being received in their unconverted state on it, produce no regular picture, and therefore no distinct vision. But if we give to the rays, before their entry into the eye, a certain proper degree of convergence, by the application of a convex lens, so as to render the remaining lenses capable of finally effecting their exact convergence on the retina, restoration of distinct vision is the immediate result. This is the reason why persons who have undergone the operation for the cataract (which consists either in totally removing, or in putting out of the way an opaque crystalline) wear spectacles of comparatively very short focus. Such glasses perform the office of an artificial crystalline. A similar imperfection of vision to that produced by the removal of the crystalline, is the ordinary effect of old age, and its remedy is the same. In aged persons the external transparent surface of the eye, called the cornea, loses something of its convexity, and becomes flatter. The power of the eye is therefore diminished, (Art. 248 and 255,) and a perfect image can no longer be formed on the retina. The deficient power is however supplied by a convex lens, or spectacle-glass, (Art. 268,) and vision rendered perfect or materially improved.

Short-sighted persons have their eyes too convex, and this defect is, like the other, remediable by the use of proper lenses of an opposite character. There are cases, however, though rare, in which the cornea becomes so very prominent as to render it impossible to apply conveniently a lens sufficiently convex to counteract its action. Such cases would be accompanied with irremediable blindness, but for that happy boldness, justifiable only by the certainty of our knowledge of the true nature and laws of vision, which in such a case has suggested the opening of the eye and removal of the crystalline lens, though in a perfectly sound state. But these are not the only cases of defective vision arising from the structure of the organ, which are susceptible of remedy. Malconformations of the cornea are much more common than is generally supposed, and few eyes are, in fact, free from them. They may be detected by closing one eye, and directing the other to a very narrow, well-defined luminous object, not too bright, (the horns of the moon, when a slender crescent, only two or three days old, are very proper for the purpose,) and turning the head about in various directions. The line will be doubled, tripled, or multiplied, or variously distorted; and careful observation of its appearances, under different circumstances, will lead to a knowledge of the peculiar conformation of the refracting surfaces of the eye which causes them, and may suggest their proper remedy. A remarkable and instructive instance of the kind has recently been adduced by Mr. G. B. Airy, (Transactions of the Cambridge Philosophical Society,) in the case of one of his own eyes; which, from a certain defect in the figure of its lenses, he ascertained to be caused from a plane detached in a vertical plane, in a horizontal plane, so as to render the eye utterly useless. This, it is obvious, would take place if the cornea, instead of being a surface of revolution, (in which the curvature of all its sections through the axis must be equal,) were of some other form, in which the curvature in a vertical plane is greater than in a horizontal. It is obvious, that the correction of such a defect could never be accomplished by the use of spherical lenses. The strict method, applicable in all such cases, would be to adapt a lens to the eye, of nearly the same refractive power, and having its surface next the eye an exact intaglio fac-simile of the irregular cornea, while the external should be exactly spherical of the same general convexity as the cornea itself; for it is clear, that all the distortions of the rays at the posterior surface of such a lens would be exactly counteracted by the equal and opposite distortions at the cornea itself.† But the necessity of limiting the correct lens to such surfaces as can be truly ground in glass, to render it of any real and everyday use, and which surfaces are only spheres, planes, and cylinders, suggested to Mr. Airy the ingenious idea of a double concave lens, in which one surface should be spherical, the other cylindrical. The use of the spherical surface was to correct the general defect of a too convex cornea. That of the cylindrical may be thus explained. Suppose parallel rays incident on a concave cylindrical surface, A B C D, in a direction perpendicular to its axis, as in fig. 71, and let S F P Q T T', be any laminar pencil of them contained in a parallelepiped infinitely
thin, and having its sides parallel to the axis. Any of the rays SP, S'P', of this pencil lying in a plane APS perpendicular to the axis, will after refraction converge to, or diverge from, a point X, also in this plane; and, therefore, all the rays incident on PQ, P'Q', will after refraction have for their focus the line XY, in the caustic surface AFGD, and the principal focus of the cylinder will be the line FG, whose distance from the vertex C'C of the surface, or FC, is the same with the focal length of a spherical surface, formed by the revolution of A B about the axis FC. Thus we see that a cylindrical lens produces no convergency or divergency in parallel rays, incident in the plane of its axis; while it converges or diverges rays in a plane at right angles to the axis, as a spherical surface of equal curvature would do. If then such a cylindrical surface be conjoined with a spherical one, the focus of the spherical surface will remain unaltered in one plane, but in the other will be changed to that of a lens formed by it, and a spherical surface of equal curvature with the cylinder. Hence by properly placing such a cylindro-spheric lens across the defective eye, its defect will be (approximately, at least) counteracted. It would be wrong to conclude our account of this interesting application of mathematical knowledge to the increase of the comforts and improvement of the faculties of its possessor, in other than his own words. "After some ineffectual applications to different workmen, I at last procured a lens to these dimensions,* from an artist named Fuller, at Ipswich. It satisfies my wishes in every respect. I can now read the smallest print at a considerable distance with the left" (the defective) "eye as well as with the right. I have found that vision is most distinct when the cylindrical surface is turned from the eye: and as, when the lens is distant from the eye, it alters the apparent figure of objects by refracting differently the rays in different planes, I judged it proper to have the frame of my spectacles made so as to bring the glass pretty close to the eye. With these precautions, I find that the eye which I once feared would become quite useless, can be used in almost every respect as well as the other."

Blindness, partial or total, may be caused, not only by the opacity of the crystalline lens, but of any other part, or by anything extraneous to the materials of which they consist, interposed between the external transparent surface of the cornea and the retina. In all such cases, if the sensibility of the nerve be uninjured, the restoration of sight is never to be despaired of. In a recent most remarkable case, operated by Mr. Wardrop, and by him recorded in the Philosophical Transactions for 1826, blindness from infancy, accompanied with complete obliteration of the pupil, by a contraction of the irs, owing to an unsuccessful operation, performed at six months of age, was removed, and perfect sight restored after a lapse of forty-six years, by a simple removal of the obstruction, by breaking a hole through the closed membrane. The details of this case are in the highest degree interesting, but we must refer the reader to the volume of the Philosophical Transactions cited for the account.

As we have two eyes, and a separate image of every external object is formed in each, it may be asked, why do we not see double? and, to some, the question has appeared to present much difficulty. To us it appears, that we might with equal reason ask, why—having two hands, and five fingers on each, all endowed with equal sensibility of touch and equal aptitude to discern objects by that sense—we do not feel decapule? The answer is the same in both cases: it is a matter of habit. Habit alone teaches us that the sensations of sight correspond to anything external, and to what they correspond. An object (a small globe or wafer suppose) is before us on a table; we direct our eyes to it, i. e. we bring its images on both retinas to those parts which habit has ascertained to be the most sensible and best situated for seeing distinctly; and having always found that in such circumstances the object producing the sensation is one and the same, the idea of unity in the object becomes irresistibly associated with the impression. But while looking at the globe, squeeze the upper part of one eye downwards, by pressing on the eyelid with the finger, and thereby forcibly throw the image on another part of the retina of that eye, and double vision is immediately produced, two globes or two wafers being distinctly seen, which appear to recede from each other as the pressure is stronger, and approach, and finally blend into one as it is relieved. The same effect may be produced without pressure, by directing the eyes to a point nearer to, or farther from than the wafer; the optic axis in this case being both directed away from the object seen. When the eyes are in a state of perfect rest, their axes are usually parallel, or a little diverging. In this state all near objects are seen double; but the slightest effort of attention causes their images to coalesce immediately. Those who have one eye distorted by a blow, see double, till habit has taught them anew to see single, though the distortion of the optic axis subsists.

The case is exactly the same with the sense of touch. Lay hands on the globe, and handle it. It is one, nothing can be more irresistible than this conviction. Place it between the first and second fingers of the right hand in their natural position. The right side of the first and left of the second finger feel opposite convexities; but as habit has always taught us that two convexities so felt belong to one and the same spherical surface, we never hesitate or question the identity of the globe, or the unity of the sensation. Now cross the two fingers, bringing the second over the first, and place the globe on the table in the fork between them, so as to feel the left side of the globe with the right side of the second finger, and the right with the left of the first. In this state of things the impression is equally irresistible, that we have two globes in contact with the fingers, especially if the eyes be shut, and the fingers placed on it by another person. A pea is a very proper object for this experiment. The illusion is equally strong when the two fore fingers of both hands are crossed, and the pea placed between them.

So forcible is the power of habit in producing single vision, that it will bring the two images to apparent coalescence, when the rays which form one of them are really turned far aside from their natural course. To prove of habit in producing single vision illustrated by experiment.

* Radius of the spherical surface 3½ inches, of the cylindrical 4½.
before it a prism, with a variable refracting angle, (an instrument to be described hereafter, see Index,) and, first, let the angle be adjusted to zero, then will the prism produce no deviation, and the object will appear single. Now vary the prism, so as to produce a deviation of $3^\circ$ or $5^\circ$ of the rays in a horizontal plane to the right. The candle will immediately be seen double, the image deviated by the prism being seen to the left of the other; but the slightest motion, such as winking with the eyelids, blends them immediately into one. Again, vary the prism a few degrees more in the same direction; the candle will again be doubled, and again rendered single by winking, and directing the attention more strongly to it; and thus may the optic axes be, as it were, invigiled to an inclination of $20^\circ$ or $30^\circ$ to each other. In this state of things, if a second candle be placed exactly in the direction of the deviated image of the first, but so screened, that its rays shall not fall on the left eye, and the prism be then suddenly removed in the act of winking, the two candles appear as one. If the deviation of the image seen with the right eye be made to the apparent right, the range within which it is possible to bring them to coalesce is much more limited, as it is much more usual for us to direct by an effort the optic axes towards, than from each other. If the deviation be made but a very little out of the horizontal plane, no effort will enable us to correct it. It is probable that some cases of squinting might be cured by some such exercise in the act of directing the optic axes, if continued perseveringly.

Such is, undoubtedly, a sufficient explanation of single vision with two eyes; yet Dr. Wollaston has rendered it probable that a physiological cause has also some share in producing the effect, and that a semi-decussation of the optic nerves takes place immediately on their quitting the brain, half of each nerve going to each eye, the right half of each retina consisting wholly of fibres of one nerve, and the left wholly of the other, so that all images of objects out of the optic axis are perceived by one and the same nerve in both eyes, and thus a powerful sympathy and perfect unison kept up between them, independent of the mere influence of habit. Immediately in the optic axis, it is probable, that the fibres of both nerves are commingled, and this may account for the greater acuteness and certainty of vision in this part of the eye.

Another point, on which much more discussion has been expended than it deserves, is the fact of our seeing objects erect when their images on the retina are inverted. Erect, means nothing else than having the head farther from the ground, and the feet nearer, than any other part. Now, the earth, and the objects which stand on it, preserve the same relative situation in the picture on the retina that they do in nature. In that picture, men, it is true, stand with their heads downwards; but then, at the same time, heavy bodies fall upwards; and the mind, or its deputy, the nerve, which is present in every part of the picture, judges only of the relation of its parts to one another. How these parts are related to external objects, is known only by experience, and judged of at the instant only by habit.

There is one remarkable fact which ought not to escape mention, even in so brief an abstract of the doctrine of vision as the present, it is, that the spot $O$, at which the optic nerve enters the eye, is totally insensible to the stimulus of light, for which reason it is called the punctum cecum. The reason is obvious: at this point the nerve is not yet divided into those almost infinitely minute fibres, which are fine enough to be either thrown into fetectors, or otherwise changed in their mechanical, chemical, or other state, by a stimulus so delicate as the rays of light. The effect, however, is curious and striking. On a sheet of black paper, or other dark ground, place two white wafers, having their centres three inches distant. Vertically above that to the left, hold the right eye, at 12 inches from it, and so that when looking down on it, the line joining the two eyes shall be parallel to that joining the centre of the wafers. In this situation closing the left eye, and looking full with the right at the wafer perpendicularly below it, this wafer is seen, the other being completely invisible. But if removed ever so little from its place, either to the right or left, above or below, it becomes immediately visible, and starts, as it were, into existence. The distances here set down may perhaps vary slightly in different eyes.

It will cease to be thought singular, that this fact, of the absolute invisibility of objects in a certain point of the field of view of each eye, should be one of which not one person in ten thousand is apprized, when we learn, that it is not extremely uncommon to find persons who have for some time been totally blind with one eye without being aware of the fact. One instance has fallen under the knowledge of the writer of these pages.

In the eyes of fishes, the humours being nearly of the refractive density of the medium in which they live, the refraction at the cornea is small, and the work of bringing the rays to a focus on the retina is almost wholly performed by the crystalline. This lens, therefore, in fishes is almost spherical, and of small radius, in comparison with the whole diameter of the eye. Moreover, the destruction of spherical aberration not being producible in this case by mere refraction at the cornea, the crystalline itself is adapted to execute this necessary part of the process, which it does by a very great increase of density towards the centre. (Brewster, Treatise on New Philosophical Instruments, p. 268.) The fibrous and coated structure of the crystalline lens is beautifully shown in the eye of a fish coagulated by boiling.

The same scientific principles which enable us to assist natural imperfections of sight, can be employed in giving additional power to this sense, even in individuals who enjoy it naturally in the greatest perfection. It being once understood, that the image on the retina is that which we really see, it follows, that if by any means we can render this image brighter, larger, more distinct than in the natural state of the organ, we shall see objects brighter than in their natural state, enlarged in dimension, and, therefore, capable of being examined more in detail, or more sharply defined and clearly outlined. The means which the principles already detailed put in our power, for the accomplishment of such ends, are the concentration of more rays than enter the natural eye by lenses; the enlargement of the image on the retina, by substituting for the object seen an image of it, either larger than the object itself, or capable of being brought nearer to us; and the destruction of aberration, by properly adapting the figure and materials of our instruments to the end proposed.

Proposition. The apparent magnitude of a rectilinear object is measured by the angle subtended by it at
Light.

The centre of the eye, in its optical sense, is a point nearly in the centre of the pupil in the plane of the iris, and the image of any external object PQ, being formed at the bottom of the eye at pq, by rays crossing there, Fig. 72.

must subtend the same angle; so that \( pq = PQ \).

\[ \frac{pE}{PE} \]

Corol. If the object be so distant that the rays from each point of it may be regarded as parallel, the angular diameter of the object is measured by the inclination of rays of its extreme pencils to each other. Whenever, therefore, the eye sees by parallel, or very nearly parallel, rays, the apparent magnitude of the object seen, is measured by the inclination of its extreme pencils, and the object itself is referred to an infinite distance, or to the concave surface of the heavens.

Prop. When a convex lens is placed between the eye and any object, so as to have the object at a distance from the lens equal to its focal length, it will be distinctly seen by an eye capable of converging parallel rays, and will appear enlarged beyond its natural size.

Let \( PQ \) be the object, \( C \) the lens, and \( E \) the centre of the eye. Since the object is in the focus of the lens, Fig. 73. the rays of a pencil diverging from any point \( P \) in it, will emerge parallel to \( PE \), and to each other; they will, therefore, after refraction in the eye, be brought to converge on the retina to a point \( p \), such that \( EP \) parallel to \( PC \). Similarly, rays from \( Q \) will, after refraction through the lens and eye, converge to \( q \); such that \( EQ \) parallel to \( QC \). Thus, a distinct image will be formed at \( pq \) on the retina, and the apparent angular magnitude of the object seen through the lens will be the angle \( qE \).

Now this is equal to \( PC \), or the angle subtended by the object at the centre of the lens, and is, therefore, greater than \( PE \), or that subtended by it at the centre of the eye, because the lens is between the eye and object.

Hence, the nearer the eye is to the lens, the less will be the difference between the apparent magnitudes of the object, as seen with and without the lens interposed. But if the lens be of shorter focus than the least distance at which the eye can see distinctly, there will be this essential difference between vision with and without the lens, that in the former case the object is seen distinctly, and well-defined; while in the latter, or with the naked eye, it will be indistinct and confused, and the more so the nearer it is brought.

Hence, by the use of a convex lens of short focus, objects may be seen distinct, and magnified to any extent we please: for let \( L \) be the power, or reciprocal focal length of the lens, and \( D \) the greatest proximity of the object to the centre of the eye at which it can be seen distinctly without a lens. Then we shall have \( L : D :: \angle P \) angle subtended by the object at the proximity \( D \); and, therefore, : apparent linear magnitude of objects are magnified.

\[ \frac{L}{D} \]

the ratio of these magnitudes, or, as it is called, the magnifying power of the lens, beyond that of the naked eye, Magnifying power.

Corol. \( D \) being given, the magnifying power is as \( L \), or as \( \frac{1}{R} \) \( \times \) \( \frac{1}{R'} \). This explains the use of the word power in the foregoing sections. Whatever we have demonstrated of the powers of lenses in the foregoing pages, is true of magnifying powers. Thus the sum of the magnifying powers of two convex lenses is the magnifying power of the two combined. If one be concave, its magnifying power is to be regarded as negative, and instead of their sum we must take their difference.

Prop. To express, generally, the visual angle under which a small object placed at any distance from a lens, and seen by an eye any how situated, appears, supposing it seen distinctly. Let \( PQ \), fig. 74, 75, 76, 77, be the object, \( E \) the lens, \( O \) the eye, and \( pq \) the image. Put \( \frac{1}{E} = D, \frac{1}{E} = \frac{1}{E} \) putting \( O \) for \( Q \) the linear magnitude of the object; and, moreover, \( OE = EQ = \frac{1}{f} = \frac{f}{e} \), therefore we have,

\[ A = O \cdot D \cdot \frac{f}{f - e} = O \cdot \frac{f}{f - e} \]

when \( L \), as all along, represents the power of the lens. Now \( O \cdot D \) is the visual angle of the object, as seen from the centre of the lens; therefore, putting \( O \cdot D \) or \( EQ \) = \( \frac{A}{L + D - e} \) we get

\[ A = (\frac{e}{L + D - e}) \]

(a)

Vol. IV.
402 LIGHT.

In concave lenses, the images of distant objects are formed erect, and on the same side of the lens with the object. If, therefore, such a lens be held between the eye and distant objects at a sufficient distance from the eye for distinct vision, the objects will be seen erect, and diminished in magnitude. In this case, $e$ is positive, and $L$ and $D$ both negative; therefore $L + D - e$ is a negative quantity, greater (without regard to the sign) than $e$, and, consequently, $A$ is negative, and less than $A$. In reflectors, $f = 2R - D$, and, therefore,

$$A = (A) \cdot \frac{e}{2R - D - e}.$$  

In a convex reflector, $e$ is necessarily negative, at least if the mirror be made of metal, because the eye must be on the side of the surface towards the incident light; and, therefore, $2R - e$ is positive, and $\frac{e}{2R - D - e}$ will be greater or less than unity, according to the value of $2R - D - e$. In concave reflectors, $R$ is negative, and $e$ is also negative for the same reason as in concave; therefore the sign and magnitude of $A$ in this, as well as the former case, may vary indefinitely, according to the place of the eye, the image, and the object. The varieties of these cases are represented in fig. 78 and 79.

If the image, instead of being seen directly by the naked eye, be seen through the medium of another general lensor reflector, so placed as to cause the pencils diverging primarily from each point of the object, to emerge finally, either exactly parallel, or within such limits of convergence or divergence as the eye can accommodate itself to, the object will be seen distinctly, and either larger or smaller than it would be seen by the unassisted eye, according to the magnitude of the image, and the power of the lens or reflector used to view it. This is the principle of all telescopes and microscopes. As most eyes can see with parallel rays, they are so constructed as to make parallel pencils emerge parallel; and a mechanical adjustment allows such a quantity of motion of the lenses or reflectors with respect to each other, as to give the rays a sufficient degree of convergence or divergence as may be required.

In the common refracting, or, as it is sometimes called, the astronomical telescope, the image is first formed by a convex lens, and is viewed through a convex lens, placed at a distance from the other nearly equal to the sum of their focal lengths. The lens which forms the image is called the object-glass, and that through which it is viewed, the eye-glass of the telescope. If the latter be concave, the telescope is said to be of the Galilean construction, such having been the original arrangement of Galileo's instruments. The situation of the lenses, and the course of the rays in these two constructions, are represented in fig. 80 and 81.

In the former construction, let $PQ$ be the object. Draw $QOG$ through the centres of the object and eye-glass, and this line will be the axis of the telescope. From any point in the object draw $ROp$ through the centre $O$ of the object-glass, and meeting $pq$, a line through $q$, the focus of the point $Q$, perpendicular to the axis in $p$, then will $pq$ be the image of $PQ$. Let $PA, PB$ be the extreme rays of the pencil diverging from $P$, and incident on the object-glass, and they will be refracted to and cross at $p$. Hence, unless the diameter of the eye-glass $bG$ is such, that the ray $Ap$ shall be received on it, the point $p$ will be seen less illuminated than the point $p$ in the centre of the object; and if it be so small that the line $Bp$ produced does not meet it, then none of the rays from $P$ can reach the eye at all. Thus, the field of view, or angular dimensions of the object seen, is limited by the aperture of the eye-glass. To find its extent, then, join $Bb, Aa$, opposite extremities of the object and eye-glass, meeting the image in $r$ and $p$, and the axis in $X$, then $rp$ is the whole extent of the image which is seen at all, and the angle $pO r$, which is equal to $pO R$, is the angular extent of the field of view. Now we have $AB : a b : : OX : GX$, and, therefore, $A B + a b : : O G : O X$, whence we get $OX = \frac{AB}{A B + a b} \cdot O G; GX = \frac{a b}{A B + a b} \cdot O G$. But we have, moreover, $Xq = Oq - OX; p r = a b \cdot \frac{Xq}{OX}$, and angle $rOp = \frac{rp}{Oq}$. To express this algebraically, put

$$Diameter \ of \ object-glass = a; \ Power \ of \ object-glass = L.$$

$$Diameter \ of \ eye-glass = \beta; \ Power \ of \ eye-glass = l.$$

Then

$$OX = \frac{a}{a + \beta} \left(\frac{1}{L} + \frac{1}{l}\right); \ GX = \frac{\beta}{a + \beta} \left(\frac{1}{L} + \frac{1}{l}\right)$$

$$QX = \frac{1}{a + \beta} \left(\frac{\beta}{L} - \frac{a}{l}\right); \ and \ pr = \frac{\beta l - aL}{L + l};$$

This last is the linear magnitude of the visible portion of the image; and it is, as we see, symmetrical both with respect to the eye-glass and object-glass.

Now from this it is easy to deduce both the field of view and magnifying power of the telescope; for the former is equal to the angle subtended by $pr$, at the centre of the object-glass, and the latter is obtained from the former, when the angle $rGp$ subtended at the centre of the eye-glass is obtained. But we have
Hence we see, that the greater the power of the eye-glass is, compared with that of the object-glass, the greater the magnifying power of the telescope; or, in other words, the greater the focal length of the object glass compared with that of the eye-glass.

The pencils of rays after refraction at the eye-glass will emerge parallel, and therefore proper for distinct vision to an eye properly placed to receive them. Now the eye will receive both the extreme rays $bR$ and $aP$ Distance of the pencils diverging from $r$ and $p$, if it be placed at their point of concourse $E$; but since $bE$ is parallel to eye, $rG$, and $aE$ to $pG$, we have

$$GE = G_q \times \frac{b}{Pr} \quad \text{or} \quad GE = \frac{\beta (L + l)}{\beta l - aL}.$$ (c)

If the eye be placed nearer to, or farther off from, the eye-glass than this distance, it will not receive the extreme rays, and the field of view, or visible area of the object, will be lessened. In the construction of convex single eye-pieces, therefore, care must be taken to prolong the tube which carries them, (as in the figure,) so that when the eye is applied close to its end, it shall still be at this precise distance from the glass.

If the telescope be inverted, and the eye applied behind the object-glass, it is evident that it will remain a telescope, but its magnifying power will be changed to $\frac{L}{l}$; so that, if it magnified before, it will diminish objects now, and the field of view will be proportionally increased. In this way, beautiful miniature pictures of distant objects may be seen.

If the telescope, instead of being turned on objects so distant as that the pencils flowing from them may be regarded as parallel, be directed to near objects, the distance between the object-glass and eye-glass must be lengthened so as to bring the image exactly into the focus of the latter. To accomplish this, the eye-glass is generally set in a sliding tube movable by a rack-work, or by hand. The same mechanism serves also to adjust the telescope for long or short-sighted persons. The former require parallel or slightly divergent rays, the latter very divergent; and to obtain the necessary divergence for the latter, the eye-glass must be brought nearer the object-glass.

The same theory and formulae apply to the second, or Galilean, construction, only recollecting that in this case $L$, the power of the eye-glass, is negative. In this case, therefore, the value of $GE$ is negative, or the eye should be placed between the object-glass and eye-glass; but, as that is incompatible with the other conditions, in order to get as great a field of view as possible, the eye must be brought as near to its proper place as possible, and therefore close to the eye-glass.

In the astronomical telescope objects are seen inverted, in the Galilean, erect; for, in the former, the rays from the extremities of the object have crossed before entering the eye, in the latter, not.

If the object be brought nearer the object-glass, the magnifying power is increased; because in this case (calling $D$ the proximity of the object) $\frac{l}{L-D}$ expresses the magnifying power, as is easily seen from what has been said Art. 382. Thus a telescope used for viewing very near objects becomes a microscope. The ordinary construction of the compound microscope is nothing more than that of the astronomical telescope modified for the use it is intended for. The object-glass has in this instrument a much greater power than the eye-glass, so that, when employed for viewing distant objects, it acts as a telescope inverted, and requires to be greatly shortened. But for near objects, as $D$ increases, $l-D$ diminishes, and the fraction $\frac{l}{l-D}$ may be increased to any amount, by bringing the object nearer to the object-glass, and at the same time lengthening the interval between the lenses, which is expressed by $\frac{1}{L-D} + \frac{1}{l}$. But as this requires two operations, it is usual to leave the latter distance unaltered, and vary, by a screw or rack-work, only the former. Fig. 82 is a section of such an instrument. It is, however, convenient to have the power of lengthening and shortening the distance between the glasses, as by this means any magnifying power between the limits corresponding to the extreme distances may be obtained; and if a series of object-glasses be so selected, that the greatest power attainable by one within the limits of the adjustment in question, shall just surpass the least obtainable by the next, and so on, we may command any power we please. Such a series is usually comprised in a small revolving plate containing cells, each of which can be brought in succession into the axis of the microscope by a simple mechanism.

In the reflecting telescope, of the most simple construction, the image is formed by a concave mirror, and viewed by a convex or concave eye-glass, as in refracting telescopes; but since the head of the observer would intercept the whole of the incident light in small telescopes, and a great part of it in large ones, the axis of the telescope reflector itself is turned a little obliquely, so as to throw the image aside, by which it can be viewed with little or no loss of light. The inconvenience of this is a little distortion of the image, caused by the obliquity of the rays;
but as such telescopes are only used of a great size, and for the purpose of viewing very faint celestial objects, in which the light diffused by aberration is insensible, little or no inconvenience is found to arise from this cause.

Such is the construction of the telescopes used by Sir William Herschel in his sweeps of the heavens.

To obviate the inconvenience of the stoppage of rays by the head, Newton, the inventor of reflecting telescopes, employed a small mirror, placed obliquely, as in fig. 83, opposite the centre of the large one. Thus parallel rays P A, P B, emanating from a point in the axis of the telescope, are received, before their meeting, on a plane mirror C D inclined at 45° to the axis, and thence reflected through a tube projecting from the side of the telescope to the lens G, and by it refracted to the eye E. It is manifest, that if the image formed by the mirror A B behind C D be regarded as an object, an image equal and similar to it (Art. 335) will be formed at F, at an equal distance from the plane mirror; and this image will be seen through the glass G, just as if it were formed by an object-glass of the same focal length placed in the prolongation of the axis of the eye-tube, beyond the small mirror, (supposed away.) Hence the same propositions and formulae will hold good in the Newtonian telescope, as in the astronomical and Galilean, for the magnifying power, field of view, and position of the eye, substituting only 2 R for L, and 2 R – D for L – D, and recollecting that R is negative, as the mirror has its concavity turned towards the light.

The Gregorian telescope, instead of a small plain mirror turned obliquely, has a small convex mirror with its concavity turned towards that of the large one, as in fig. 84; but instead of being placed at a distance from the large one equal to the sum of the focal lengths, the distance is somewhat greater; hence the image p q, formed in the focus of the great mirror, being at a distance from the vertex of the small one greater than its focal length, another image is formed at a distance, viz. at or near the surface of the great mirror, at r s. In the centre of the large mirror there is a hole which lets pass the rays to an eye-lens g. The adjustment to parallel or diverging rays, or for imperfect eyes, is performed by an alteration of the distance between the mirrors made by a screw.

The Cassegrainian construction differs in no respect from the Gregorian, except that the small mirror is convex and receives the rays before their convergence to form an image. The magnitude of the field, the distance of the eye and of the mirrors from each other, are easily expressed in these constructions; the latter being derived from the former by a mere change of sign in the curvature of the small mirror. Let then R' and Rº be the curvatures of the two mirrors, then in the Gregorian telescope R' is negative and Rº positive; and if we put t for the distance between their surfaces, (t being negative, because the second reflecting surface lies towards the incident light) we shall have for an object whose proximity is D

\[ D' = D; \quad f' = 2 R' - D' = 2 R' - D; \quad f'' = 2 Rº - Dº; \quad Dº = \frac{f'}{1 - f' t} \]

adopting the formula and notation of Art. 251. Now these give, by substitution,

\[ D'' = \frac{2 R' - D}{1 - t (2 R' - D)}; \quad f'' = 2 Rº - \frac{2 R' - D}{1 - t (2 R' - D)} = \frac{2 Rº - 2 R' + D}{1 - t (2 R' - D)}. \]

This is the reciprocal distance of the second image from the second reflecting surface. If we wish that the image to be viewed by the eye-lens should fall just on the surface of the large mirror, we have only to put \( f'' = \frac{1}{1 - t} \) (because \( f'' \) is positive, and \( t \) negative.) For parallel rays this gives

\[ R' Rº. tº + (4 R' - 2 Rº) t - 1 = 0; \]

whence \( t \) may be found when \( R' \) and \( Rº \) are given, or vice versa.

The description of other optical instruments, and of the more refined construction of telescopes, &c. must be deferred till we are farther advanced in our account of the physical properties of light, and especially of the different refrangibility of its rays and their colours, which will form the object of the next part.
PART II.

CHROMATICS.

§ I. Of the Dispersion of Light.

Hitherto we have regarded the refractive index of a medium as a quantity absolutely given and the same for all rays refracted by the medium. In nature, however, the case is otherwise. When a ray of light falls obliquely on the surface of a refracting medium, it is not refracted entirely in one direction, but undergoes a separation into several rays, and is dispersed over an angle more or less considerable, according to the nature of the medium and the obliquity of incidence. Thus if a sunbeam SC be incident on the refracting surface AB, and be afterwards received on a screen RV, (fig. 85,) it will, instead of a single point on the screen as R, illuminate a space RV of a greater extent the greater is the angle of incidence. The ray SC, then, which, before refraction was single, is separated into an infinite number of rays CR, CO, CY, &c. each of which is refracted differently from all the rest.

The several rays of which the dispersed beam consists, are found to differ essentially from each other, and from the incident beam, in a most important physical character. They are of different colours. The light of the sun is white. If a sunbeam be received directly on a piece of paper, it makes on it a white spot; but if a piece of white paper (that is, such as by ordinary daylight appears white) be held in the dispersed beam, as RV, the illuminated portion will be seen to be differently coloured in different parts, according to a regular succession of tints, which is always the same, whatever be the refracting medium employed.

To make the experiment in the most striking and satisfactory manner, procure a triangular prism of good flint-glass, and having darkened a room, admit a sunbeam through a small round hole OP in the window shutter. If this be received on a white screen D at a distance, there will be formed a round white spot, or image of the sun, which will be larger as the paper is farther removed. Now in the beam before the screen place the prism ABC, having one of its angles C downwards and parallel to the horizon, and at right angles to the direction of the sunbeam, and let the beam fall on one of its sides BC obliquely. It will be refracted and turned out of its course, and thrown upwards, pursuing the course FGR, and may be received on a screen E properly placed. But on this screen there will no longer be seen a white round spot, but a long streak, or, as it is called in Optics, a spectrum RV of most vivid colours, (provided the admitted sunbeam be not too large, and the distance of the screen from the prism considerable.) The tint of the lower or least refracted extremity R is a brilliant red, more full and vivid than can be produced by any other means, or than the colour of any natural substance. This dies away first into an orange, and this passes by imperceptible gradations into a fine pale straw-yellow, which is quickly succeeded by a pure and very intense green, which again passes into a blue, at first of less purity, being mixed with green, but afterwards, as we trace it upwards, deepening to the purest indigo. Meanwhile, the intensity of the illumination is diminishing, and in the upper portion of the indigo tint is very feeble, but it is continued still beyond, and the blue acquires a pallid cast of purplish red, a livid hue more easily seen than described, and which, though not to be exactly matched by any natural colour, approaches most nearly to that of a fading violet: "tinctus viola pallor."

If the screen on which the spectrum be received have a small hole in it, too small to allow the whole of the spectrum to pass, but only a very narrow portion of it, as X, (fig. 87,) the portion of the beam which goes to form that particular spot X may be received on another screen at any distance behind it, and will there form a spot d of the very same colour as the part X of the spectrum. Thus if X be placed in the red part of the spectrum the spot d will be red; if in the green, green; and in the blue, blue. If the eye be placed at d, it will see through the hole an image of the sun of dazzling brightness; not, as usually, white, but of the colour which goes to form the spot X of the spectrum. Thus we see, that the joint action of all the rays is not essential to the production of the coloured appearance of the spectrum, but that one colour may be insulated from the rest, and examined separately.

If, instead of receiving the ray Xd, transmitted through the hole X, on a screen immediately behind it, it be intercepted by another prism abc, it will be refracted, and bent from its course, as in Xfghx; and after this second refraction may be received on a screen e. But it is now observed to be no longer separated into a coloured spectrum like the original one RV, of which it formed a part. A single spot x only is seen on the screen, the colour of which is uniform, and precisely that which the part X of the spectrum would have had, were it intercepted on the first screen. It appears, then, that the ray which goes to form any single point of the spectrum is not only independent of all the rest, but having been once insulated from them, is no longer capable of further separation into different colours by a second refraction.

This simple, but instructive experiment, then, makes us acquainted with the following properties of light:
1. A beam of white light consists of a great and almost infinite variety of rays differing from each other in colour and refrangibility.

For the ray $SF$ from any one point of the sun’s disc, which if received immediately on the screen would have occupied only a single point on it, or (supposing the hole in the screen to have a sensible diameter) only a space equal to its area, is dilated into a line $VR$ of considerable length, every point of which (speaking loosely) is illuminated. Now the rays which go to $V$ must necessarily have been more refracted than those which go to $R$, which can only have been in virtue of a peculiar quality in the rays themselves, since the refracting medium is the same for all.

2. White light may be decomposed, analyzed, or separated into its elementary coloured rays by refraction. The act of such separation is called the dispersion of the coloured rays.

3. Each elementary ray once separated and insulated from the rest, is incapable of further decomposition or analysis by the same means. For we may place a third, and a fourth, prism in the way of the twice refracted ray $g$, and refract it in any way, or in any plane; it remains undispersed, and preserves its colour quite unaltered.

4. The dispersion of the coloured rays takes place in the plane of the refraction; for it is found that the spectrum $VR$ is always elongated in this plane. Its breadth is found, on the other hand, by measurement, to be precisely the same as that of the white image $D$, (fig. 86,) of the sun, received on a screen at a distance $OD$ from the hole, equal to $OF + FG + GH$, the whole course of the refracted light, which shows that the beam has undergone no contraction or dilation by the effect of refraction in a plane perpendicular to the plane of refraction.

To explain all the phenomena of the colours produced by prismatic dispersion, or of the prismatic colours, as they are called, we need only suppose, with Newton, that each particular ray of light, in undergoing refraction at the surface of a given medium, has the sine of its angle of incidence to that of refraction in a constant ratio, so long as the medium and the ray are the same; but that this ratio varies not only, as we have hitherto all along assumed, with the nature of the medium, but also with that of the ray. In other words, that there are as many distinct species, or at least varieties of light, as there are distinct illuminated points in the spectrum into which a single ray of white light is dispersed. This amounts to regarding the quantity $\mu$, for any medium, not as one and invariable, but as susceptible of all degrees of magnitude between certain limits: one, the least of which, corresponds to the extreme, or least refracted red ray; the other, the greatest value of $\mu$, to the extreme or most refracted violet. Each of these varieties separately conforms to the laws of reflection and refraction we have already laid down. As in Geometry we may regard a whole family of curves as comprehended under one equation, by the variation of a constant parameter; so in Optics we may include under one analysis all the doctrine of the reflexions, refractions, and other modifications of a ray of white or compound light, by regarding the refractive index $\mu$ as a variable parameter.

To apply this, for instance, to the experiment of the prism just related: A single ray of white light being supposed incident on the first surface, must be regarded as consisting of an infinite number of coincident rays, of all possible degrees of refrangibility between certain limits, any one of which may be indifferently expressed by the refractive index $\mu$. Supposing the prism placed so as to receive the incident ray perpendicularly on one surface, then the deviation will be given by the equation

$$\mu \cdot \sin I = \sin (I + D)$$

I being the refracting angle of the prism. $D$ therefore is a function of $\mu$, and if $\mu$ vary by the infinitely small increment $\delta \mu$, i.e. if we pass from any one ray in the spectrum to the consecutive ray, $D$ will vary by $\delta D$, and the relation between these simultaneous changes will be given by the equation resulting from the differentiation of the above with the characteristic $\delta$: thus we get

$$\delta \mu \cdot \sin I = \delta D \cdot \cos (I + D)$$

It is evident, then, that as $\mu$ varies, $D$ also varies; and, therefore, that no two of the refracted and coloured rays will coincide, but will be spread over an angle, in the plane of refraction, the greater, the greater is the total variation of $\mu$ from one extreme to the other.

In order to justify the term analysis, or decomposition, as applied to the separation of a beam of white light into coloured rays, we must show by experiment that white light may be again produced by the synthesis of these elementary rays. The experiment is easy. Take two prisms $ABC$, $abc$ of the same medium, and having equal refracting angles, and lay them very near together, having their edges turned opposite ways, as in fig. 87. With this disposition, a parallel beam of white light intromitted into the face $AC$ of the first prism, will emerge from the face $bc$ of the last, undeviated, and colourless, as if no prisms were in the way. Now the dispersion having been fully completed by the prism $ABC$, the rays in passing through the thin lamina of air $BAC$ must have existed in their coloured and independent state, and been dispersed in their directions; but being refracted by the second prism so as to emerge parallel, the colour is destroyed by the mixture and confusion of the rays.

To see more clearly how this takes place in fig. 88, let $SR$ and $SV$ be two parallel white rays, incident on the first prism, and separated by refraction; the former into the coloured pencil $Rc$, the latter into a pencil exactly similar to $Vrc$. Let $Rc$ be the least refracted ray of the former pencil, and $Vc$ the most refracted of the latter. These, of course, must meet; let them meet in $c$, and precisely at $c$ apply the vertex of the second prism, having its side $ca$ parallel to $CB$, but its edge turned in the opposite direction; then will the rays $RC$ and $VC$, each for itself, and independent of the other, be refracted so as to emerge parallel to its original direction.
light, and the emergent rays will therefore be coincident and superimposed on each other as c's. Thus the emergent ray c will contain an extreme red and an extreme violet ray. But it will also contain every intermediate variety; for draw c f anywhere between c R and c V. Then, since the angle which c f makes with the surface B C is greater than that made by the extreme violet ray C B, but less than that made by the extreme red, there must exist some value of μ intermediate between its extreme values, which will give a deviation equal to the angle between c f and S Y parallel to S R. Consequently, if S Y be a white ray, separated into the pencil Y S Y' by refraction, the coloured ray Y f c of that particular refrangibility will fall on c, and be refracted along c. Every point then of the surface g f h will send to c a ray of different refrangibility, comprehending all the values of μ from the greatest to the least. Thus all the coloured elements, though all belonging originally to different white rays, will, after the second refraction, coincide in the ray c, and experience proves that so reunited they form white light. White light, then, is re-composed when all the coloured elements, even though originally belonging to separate white rays, are reunited in place and direction. In the reflection of light, regarded as a case of refraction, μ has a specific numerical value, and cannot vary without subverting the fundamental law of reflection. Thus, there is no dispersion into colours produced by reflection, because all the coloured rays after reflection pursue one and the same course. There is one exception to this, more apparent than real, when light is reflected from the base of a prism internally, of which more hereafter. The recomposition of white from coloured light may be otherwise shown, by passing a small circular beam of solar light through a prism A B C, (fig. 89,) and receiving the dispersed beam on a lens E D at some distance. If a white screen be held behind the lens, and removed to a proper distance, the whole spectrum will be reunited in a spot of white light. The way in which this happens will be evident by considering the figure, in which T E and T D represent the parallel pencils of rays of any two colours (red and violet, for instance) into which the incident white beam S T is dispersed. These will be collected after refraction, each in its own proper focus; the former at F, the latter at G; after which each pencil diverges again, the former in the cone F H, the latter in G H. If the screen then be held at H, each of these pencils will paint on it a circle of its own colour, and so of course all the intermediate ones; but these circles all coinciding, the circle H will contain all the latter in G H. If the screen then be held at H, each of these pencils will paint on it a circle of its own colour, and so of course all the intermediate ones; but these circles all coinciding, the circle H will contain all the rays of the spectrum confounded together, and it is found (with the exception of a trifling coloured fringe about the edges, arising from a slight overlapping of the several coloured images) to be of a pure whiteness. That the reunion of all the coloured rays is necessary to produce whiteness, may be shown by intercepting a portion of the spectrum before it falls on the lens. Thus, if the violet be intercepted, the white will acquire a tinge of yellow; if the blue and green be successively stopped, this yellow tinge will grow more and more ruddy, and pass through orange to scarlet and blood red. If, on the other hand, the red end of the spectrum be stopped, and more and more of the less refrangible portion thus successively abstracted from the beam, the white will pass first into pale and then to vivid green, blue-green, blue, and finally into violet. If the middle portion of the spectrum be intercepted, the remaining rays, concentrated, produce various shades of purple, crimson, or plum-colour, according to the portion by which it is thus rendered deficient from white light; and by varying the intercepted rays, any variety of colours may be produced; nor is there any shade of colour in nature which may not thus be exactly imitated, with a brilliancy and richness surpassing that of any artificial tints of the prismatic. Now, if we consider that all these shades are produced on white paper, which receives and reflects to our eyes whenever light happens to fall on it; and that the same paper placed successively in the red, green, and blue portion of the spectrum, will appear indifferently red, or green, or blue, we are naturally enough led to conclude, that the colours of natural bodies are not qualities inherent in the bodies themselves, by which they immediately affect our sense, but are mere consequences of that peculiar disposition of the particles of each body, by which it is enabled more copiously to reflect the rays of one particular colour, and to transmit, or stifle, or, as it is called in optics, absorb the others. Such is the Newtonian doctrine of the origin of colours. Every phenomenon of optics conspires to prove its justice. Perhaps the most direct and satisfactory proof of it is to be found in the simple fact, that every body, indiscriminately, whatever be its colour in white light, when exposed in the prismatic spectrum, appears of the colour experimentally appropriate to that part of the spectrum in which it is placed; but that its tint is incomparably more vivid and fall when laid in a ray of a tint analogous to its hue in white light, than in any other. For example, vermillion placed in the red rays appears of the most vivid red; in the orange, orange; in the yellow, yellow, but less bright. In the green rays, it is green; but from the great insusceptibility of vermillion to reflect green light, it appears dark and dull; still more so in the blue; and in the indigo and violet it is almost completely black. On the other hand, a piece of dark blue paper, or Prussian blue, in the indigo rays has an extraordinary richness and depth of blue colour. In the green its hue is green, but much less intense; while in the red rays it is almost entirely black. Such are the phenomena of pure and intense colours; but bodies of mixed tints, as pink or yellow paper, or any of the lighter shades of blue, green, brown, &c., when placed in any of the prismatic rays, reflect them in abundance, and appear, for the time, of the colour of the ray in which they are placed. Refraction by a prism affords us the means of separating a ray of white light into the rays of different refrangibility of which it consists, or of analyzing it. But to make the analysis complete, and to insulate a ray of any particular refrangibility in a state of perfect purity, several precautions are required, the chief of which are as follows: 1st. The beam of light to be analyzed must be very small, as nearly as possible approaching to a mathematical ray; for if A B, a b be a beam of parallel rays of any sensible breadth (fig. 89) incident on the prism P, the extreme rays A B, a b will each be separated by refraction into spectra G B H and g b h: B G, b g Fig. 89. being the violet, and B H, b h the red rays of each respectively; and since A B, a b are parallel, therefore C G
and $cg$ will be so, and also $DH$ and $da$. Hence the red ray $DH$ from $B$ will intersect the violet $cg$ from $b$, in some point $F$ behind the prism; and a screen $EFF$ placed at $F$ will have the point $F$ illuminated by a red ray from $B$, and a violet one from $b$, and therefore (as is easily seen) by all the rays intermediate between the red and violet, from points between $B$ and $F$. $F$ therefore will be white. If the screen be placed nearer the prism than $F$, as at $KLk$, it is clear that from any point between $L$ and $k$ lines drawn parallel to $KC, DL$, to any intermediate direction, will fall between $C$ and $c, D$ and $d$, &c., respectively; and therefore that every point between $L$ and $k$ will receive from some other of the surface $CD$ of the prism a ray of each colour, and will therefore be white. Again, any point as $x$ between $k$ and $l$ can receive no violet ray, nor any ray of the spectrum whose angle of deviation is greater than $180° - ax$; for such ray to reach $x$ must come from a part of the prism below $b$, which is contrary to the supposed limitation of $AB, ab$; but all rays whose angle of deviation is less than $180° - ax$, will reach $x$ from some part or other of the surface $BD$. Hence the entire portion of the spectrum on the screen $EF$ will be white at $k$, pure red at $f$, and intermediate between white and red, or a mixture of the least refrangible rays of the spectrum at any intermediate point; and, in the same manner, the portion $KL$ will be white at $L$, violet at $K$, and at any intermediate point will have a colour formed by a mixture of a greater or less portion of the more refrangible end of the spectrum. If the screen be removed beyond $F$, as into the situation $GgHh$, the white portion will disappear, no point between $g$ and $H$ being capable of receiving any ray whose angle of deviation is between $180° - gb$ and $180° - a b H$.

We may regard the whole image $Gh$ as consisting of an infinite number of spectra formed by every elementary ray of which the beam $ABab$ is composed, overlapping each other, so that the end of each in succession projects beyond that of the foregoing. The fewer, therefore, there are of these overlapping spectra, or the smaller the breadth of the incident beam, the less will be the mixture of rays so arising, and the purer the colours. Removal of the screen to a greater distance from the prism, evidently produces the same effect as diminution of the size of the beam; for while each colour occupies constantly the same space on the screen (for $Gg = Kk$) the whole spectrum is diffused over a larger space as the screen is removed, by the divergence of its component rays of different colours, and therefore the individual colours must of necessity be continually more and more separated from each other.

2ndly. Another source of confusion and want of perfect homogeneity in the colours of the spectrum is the angular diameter of the sun or other luminary, even when the aperture through which the beam is admitted is ever so much diminished. For let $ST$ (fig. 90) be the sun, whose rays are admitted to the prism $ABC$ through a very small hole $O$ in a screen placed close to it. The beam will be dilated by refraction into the spectrum $vr$. Now, if we consider only the rays of one particular kind, as the red, and regard all the rest as suppressed, it is clear that a red image $r$ of the sun will be formed by them alone on the screen; the rays from every point of the sun's disc crossing at $O$, and pursuing (after refraction) different courses. If the prism be placed in its situation of minimum deviation, which at present we will suppose, this image will be a circle, and if the sun and the screen subtend equal angles at $O$. In like manner, the violet rays (considered apart from the red) will form a circular violet image of the sun, at $v$, by reason of their greater refrangibility; and every species of ray, of intermediate refrangibility, will form, in like manner, a circular image between $r$ and $v$. The constitution of the spectrum whose angle of deviation is greater than $180° - abr$; for such ray to reach $r$ from $a$ must come from a part of the prism below $b$, which is contrary to the supposition of a limited beam $AB$, $ab$; but all rays whose angle of deviation is less than $180° - abr$, will reach $r$ from some part or other of the surface $BD$. Hence the entire portion of the spectrum on the screen $EF$ will be white at $k$, pure red at $f$, and intermediate between white and red, or a mixture of the least refrangible rays of the spectrum at any intermediate point; and, in the same manner, the portion $KL$ will be white at $L$, violet at $K$, and at any intermediate point will have a colour formed by a mixture of a greater or less portion of the more refrangible end of the spectrum. If the screen be removed beyond $F$, as into the situation $GgHh$, the white portion will disappear, no point between $g$ and $H$ being capable of receiving any ray whose angle of deviation is between $180° - gb$ and $180° - a b H$.

There are several ways by which the angular diameter, or the degree of divergence of the incident beam may be diminished. Thus, first, we may admit a sunbeam through a small hole, as $A$, in a screen, and receive the divergent cone of rays behind it on another screen $B$, (fig. 7.) at a considerable distance, having another small hole $B$ to let pass, not the whole, but only a small portion of the sun's image. The beam $BC$, so transmitted, will manifestly have a degree of divergence less than that of the beam immediately transmitted from $A$ in the proportion of the diameter of the aperture $B$ to the diameter of the sun's image on the screen $B$.

Another and much more commodious method is to substitute for the sun its image formed in the focus of a convex lens of short focus. This image is of very small dimensions, its diameter being equal to focal length of the lens $x$ sine of sun's angular diameter, or $30'$, which is about one 114th part of radius,$)$ so that a lens of an inch focus placed all the rays which fall on it within a circle of about the 114th of an inch in diameter, which, for this purpose, may be regarded as a physical point. The disposition of the apparatus is as represented in fig. 92. The rays converged by the lens $L$ to $F$, afterwards diverge as if they emanated from an intensely bright luminous point placed at $F$, and a screen with a small aperture $O$ being placed at a distance from it, and close behind it the prism $ABC$, the spectrum $vr$ may be received on a screen again placed at a considerable distance behind the prism, each of whose points will be illuminated by rays of a very high degree of purity and homogeneity, and by diminishing the focal length of the lens, and the aperture $O$, and increasing the distance $FO$, or $Or$, this may be carried to any extent we please. It should, however, be remarked, that the intensity of the purified ray, and the quantity of homogeneous light so obtained, are diminished in the same ratio as the purity of the ray is increased.

A third method of obtaining a homogeneous beam is to repeat the process of analysis on a ray as nearly pure as can be conveniently obtained by refraction through a single prism. Thus, in fig. 93, $VR$, the spectrum formed by a first refraction at the prism is reflected on a screen which intercepts the whole of it, except that particular colour we wish to insulate and purify, which is allowed to pass through an aperture $MN$; behind this is placed another prism $B$, so as to reflect this beam a second time. If then the portion
Light.

MN were already perfectly pure, it would pass the second prism without undergoing any further separation; but if there be (as there always will) other rays mixed with it, these will be dilated by the subsequent refraction into a second spectrum. v. r of faint light, with a much brighter portion mn in the midst; and if the rest of the rays be intercepted, and this portion only allowed to pass through an aperture, the emergent beam mp will be much more homogeneous than before its incidence on the second prism,—and in proportion as the distance between the second prism and the screen is increased, the purity of the ray obtained will be greater.

Another source of impurity in the prismatic rays is the imperfection of the materials of our ordinary prisms, which are full of striae and veins, which disperse the light irregularly, and thus confound together in the spectrum rays which properly belong to different parts of it. Those who are not fortunate enough to possess glass prisms free from this defect, (which are very rare, and indeed hardly to be procured for any price) may obviate the inconvenience by employing hollow prisms full of water, or, rather, any of the more dispersive oils. A great part of the inconvenience arising from a bad prism may, however, be avoided by transmitting the rays as near the edge of it as possible, so as to diminish the quantity of the material they have to pass through, and therefore their chance of encountering veins and striae in their passage.

When every care is taken to obtain a pure spectrum; when the divergence of the incident beam is extremely small, and its dimensions also greatly reduced; when the prism is perfect, and the spectrum sufficiently elongated to allow of a minute examination of its several parts, some very extraordinary facts have been observed respecting its constitution. They were first noticed by Dr. Wollaston, in a Paper published by him in the Phil. Trans., 1802; and have since been examined in full detail, and with every delicacy and refinement which the highest talents and the most unlimited command of instrumental aids could afford, by the admirable and ever-to-be-lamented Fraunhofer. It does not appear that the latter had any knowledge of Dr. Wollaston's previous discovery, so that he has, in this respect, the full merit of an independent inventor. The facts are these: The solar spectrum, in its utmost possible state of purity and tenuity, when received on a white screen, or when viewed by admitting it at once into the eye, is not an uninterrupted line of light, red at one end and violet at the other, and shading away by insensible gradations through every intermediate tint from one to the other, as Newton conceived it to be, and as a cursory view shows it. It is interrupted by intervals absolutely dark; and in those parts where it is luminous, the intensity of the light is extremely irregular and capricious, and apparently subject to no law, or to one of the utmost complexity. In consequence, if we view a spectrum formed by a narrow line of light parallel to the refracting edge of the prism, (which affords a considerable breadth of spectrum without impairing the purity of the colours, being, in fact, an assemblage of infinitely narrow linear spectra arranged side by side,) instead of a luminous fascia of equable light and graduating colours, it presents the appearance of a striped ribbon, being crossed in the direction of its breadth by an infinite multitude of black, and by some totally black bands, distributed irregularly throughout its whole extent. This irregularity, however, is not a consequence of any casual circumstances. The bands are constantly in the same parts of the spectrum, and preserve the same order and relations to each other; the same proportional breadth and degree of obscurity, whenever and however they are examined, provided solar light be used, and provided the prisms employed be composed of the same material: for a difference in the latter particular, though it causes no change in the number, order, or intensity of the bands, or their places in the spectrum, as referred to the several colours of which it consists, yet causes a variation in their proportional distances titer se, of which more hereafter. By solar light must be understood, not merely the direct rays of the sun, but any rays which have the sun for their ultimate origin; the light of the clouds, or sky, for instance; of the rainbow; of the moon, or of the planets. All these lights, when analyzed by the prism, are found deficient in the identical rays which are wanting in the solar spectrum; and the deficiency is marked by the same phenomenon, viz. by the occurrence of the same dark bands in the same situations in spectra formed by these several lights. In the light of the stars, one of other hand, in electric light, and that of flames, though similar bands are observed in their spectra, yet they are differently disposed; and the spectrum of each several star, and each flame, has a system of bands peculiar to itself, and characteristic of its light, which it preserves unalterably at all times, and under all circumstances.

Fig. 94 is a representation of the solar spectrum as laid down minutely by Fraunhofer, from micrometrical measurement, and as formed by a prism of his own incomparable flint glass. Only the great number of small bands observed by him (upwards of 500 in number) have been omitted, to avoid confusing the figure. Of these bands, or, as he terms them, “fixed lines” in the spectrum, he has selected seven, (those marked B, C, D, E, F, G, H,) as terms of comparison, or as standard points of reference in the spectrum, on account of their distinctness, and the facility with which they may be recognised. Of these, B lies in the red portion of the spectrum, near the end; C is farther advanced in the red; D lies in the orange, and is a strong double line easily recognised; E is in the green; F in the blue; G in the indigo, and H in the violet. Besides these, there are others very remarkable; thus b is a triple line in the green, between E and F, consisting of three strong lines, of which two are nearer each other than the third, &c.

The definiteness of these lines, and their fixed position, with respect to the colours of the spectrum,—in other words, the precision of the limits of those degrees of refrangibility which belong to the deficient rays of solar light,—renders them invaluable in optical inquiries, and enables us to give a precision hitherto unheard of to optical measurements, and to place the determination of the refractive powers of media on the several rays almost on the same footing, with respect to exactness, with astronomical observations. Fraunhofer, in his various essays, has made excellent use of them in this respect, as we shall soon have occasion to see.
which the rays diverge, as from a fine luminous line, in the manner described in Art. 415 for a lens. If now the
eye be applied close behind the prism, the line will be seen dilated into a broad coloured band, consisting of the
prismatic colours in their order; and if the prism be good, and carefully placed in its situation of minimum
deformation, and of sufficiently large refracting angle to give a broad spectrum, some of the more remarkable of
the fixed lines will be seen arranged parallel to the edges of the spectrum, especially the lines D and F, the
former of which appears, in this way of viewing it, to form a separation between the red and the yellow. If
the light of the sun be too bright, so as to dazzle the eye, any narrow line of common daylight (as the slit
between two nearly closed window-shutters) may be substituted. This was the mode in which the fixed lines
were first discovered by Dr. Wollaston.

But it is difficult and requires acute sight to perceive, in this manner, any but the most conspicuous lines.
The reason is, their very small angular breadth; which, in the largest of them, can scarcely, under any
circumstances, exceed half a minute, and in the smaller not more than a few seconds. They require, therefore, to
be magnified. This may be done by a telescope interposed between the eye and the prism, in the manner repre-
sented in fig. 95, in which L' L is the line of light, from which rays, diverging in all directions, fall on the prism
A B C, are refracted by it, and after refraction are received on the object-glass D of the telescope. This object-
glass, it should be observed, must be of that kind denominated achromatic, to be presently described, (see Index,
and of which it need only be here said, that it is so constructed as to be capable of bringing rays of all colours to foc-
us at one and the same distance from the glass. Now, if we consider only rays of any one degree of refrangibility
(the extreme red, for instance) the pencils diverging from every point of L' L will, after refraction at the two
surfaces of the prism, diverge from corresponding points of an image L' L' situated in the direction from the
base towards the vertex of the prism. Rays of any greater refrangibility will, after refraction at the prism, diverge
from a linear image L'' L'' parallel to L' L', but farther from the original line L L. Thus the white line L L will,
after refraction at the prism, have for its image the coloured rectangle L'' L'' L'' L'', which will be viewed through
the telescope as if it were a real object. Now every vertical line of this parallelogram will form in the focus of
the object-glass a corresponding vertical image of its own colour; and the object-glass being achromatic, all
these images are equidistant from it, so that the whole image of the parallelogram L'' L'' L'' L'' will be a similar coloured
parallelogram, having its plane perpendicular to the axis of the telescope. This will be viewed as a real object
through the eye-glass, and the spectrum will thus be magnified as any other object would be, according to the
power of the telescope, (Art. 362.) With this disposition of the apparatus (which is that employed by Fraun-
hofer) the fixed lines are beautifully exhibited, and (if the prism be perfect) may be magnified to any extent.
The slightest defect of homogeneity in the prism, however, as may be readily imagined, is fatal. With glass
prisms of our manufacture it would be quite useless to attempt the experiment; and those who would repeat it
in this country should employ prisms of highly refractive liquids, enclosed in hollow prisms of good plate glass.
The eye-pieces of telescopes, not being usually achromatic, a slight change of focus is still required, when the
lines in the red and violet portions of the spectrum are to be viewed. This (if an inconvenience) might be obvi-
ated by the use of an achromatic eye-piece.

That an actual image of the spectrum, with its fixed lines, is really formed in the focus of the object-glass,
as described, may be easily shown, by dismounting the telescope, and receiving the rays refracted by the object-
glass on a screen in its focus. This, indeed, affords a peculiarly elegant and satisfactory mode of exhibiting the
phenomena to several persons at once. An achromatic object-glass of considerable focal length (6 feet, for
instance) should be placed at about twice its focal length from the line of light, and (the prism being placed
immediately before the glass) the image will be formed at about the same distance, 12 feet behind it, (f = L +
D; L = s ; D = — s; f = s + ( s+ s) and being received on a screen of white paper or emerald glass
may be examined at leisure, and the distances of the lines from each other, &c. measured on a scale. But by
far the best methods of performing these measurements are those practised by Fraunhofer, viz. the adaptation
of a micrometer to the eye-end of the telescope, (see Micrometer, in a subsequent part of this Article,) for ascer-
taining the distances of the closer lines; and the giving the axis of the telescope, together with the prism which
is connected with it, a motion of rotation in a horizontal plane, the extent of which is read off by verniers and
microscopes on an accurately graduated circle, in the same way as in astronomical observations. The apparatus
employed by him for this purpose, and which is applicable to a variety of useful purposes in optical researches,
is represented in fig. 96.

The fixed lines in the spectrum do not mark any precise limits between the different colours of which it
consists. According to Dr. Wollaston, (Phil. Trans., 1802.) the spectrum consists of only four colours, red,
green, blue, and violet; and he considers the narrow line of yellow visible in it in his mode of examination
already described (looking through a prism at a narrow line of light with the naked eye) as arising from a
mixture of red and green. These colours, too, he conceives to be well defined in the spaces they occupy, not
graduating insensibly into each other, and of, sensibly, the same tint throughout their whole extent. We confess
we have never been able quite satisfactorily to verify this last observation, and in the experiments of Fraunhofer,
(which we had the good fortune to witness, as exhibited by himself at Munich,) where, from the perfect distinctness
of the finest lines in the spectrum, all idea of confusion of vision, or intermixture of rays is precluded, the tints
are seen to pass into each other by a perfectly insensible gradation; and the same thing may be noticed in the
coloured representations of the spectrum published in the first essay of that eminent artist, and executed by
himself with extraordinary pains and fidelity. The existence of a pale straw yellow, not of mere linear breadth,
but occupying a very sensible space in the spectrum, is there very conspicuous, and may also be satisfactorily
shown by other experiments to be hereafter described, when we come to speak of the absorption of light. In
short, (with the exception of the fixed lines, which Newton's instrumental means did not enable him to see,) the
spectrum is, what that illustrious philosopher originally described it, a graduated succession of tints, in which all
the seven colours he enumerates can be distinctly recognised, but shading so far insensibly into each other that a positive limit between them can be nowhere fixed upon. Whether these colours be really compound or not, whether some other mode of analysis may not effect a separation depending on some other fundamental difference between the rays than that of the degree of their refrangibility, is quite another question, and will be considered more at large hereafter. At present it may be enough to remark, that all probability, drawn from everyday experience, is in favour of this idea, and leads us to believe that orange, green, and violet are mixed colours; and red, yellow, and blue, original ones; the former we everyday see imitated by mixtures of the latter, but never vice versa. This doctrine has been accordingly maintained by Mayer, in a curious Tract published among his works. (See the Catalogue of Optical Writers at the end of this Article.) A very different doctrine has, however, been advanced by Dr. Young, (Lectures on Natural Philosophy, i. 441,) in which he assumes red, green, and violet, as the fundamental colours. The respective merits of these systems will be considered more at large hereafter. (See Index, Composition of Colours.)

Media, as we have seen, differ very greatly in their refractive power, or in the degree in which prisms of one and the same refracting angle composed of different substances, deflect the rays of light. This was known to the optical philosophers who preceded Newton. This great man, on establishing the general fact, that one and the same medium refracts differently the differently coloured rays, might naturally have been led to inquire experimentally whether the amount of this difference of action were the same for all media. He appears to have been misled by an accidental circumstance in the course of an experiment, in which the varieties of media in this respect ought to have struck him,* and in consequence adopted the mistaken idea of a proportional action of all media on the several homogeneous rays. Mr. Hall, a gentleman of Worcestershire, was the first to discover Newton's mistake; and having ascertained the fact, of the different dispersive powers of different kinds of glass, applied his discovery successfully to the construction of an achromatic telescope. His invention, however, was unaccountably suffered to fall into oblivion, (though it is said that he made several such telescopes, some of which still exist,) and the fact was re-discovered and re-applied to the same great purpose by Mr. Dollond, a celebrated optician in London, on the occasion of a discussion raised on the subject by some à priori and paradoxical opinions broached by Euler.

If a prism of flint glass and one of crown, of equal refracting angles, be presented to two rays of white light, as A B C, a b c. (fig. 97;) S C and s c being the incident rays, C R, C V the red and violet rays refracted by the flint, and c r, c v those refracted by the crown; it is observed, first, that the deviation produced in either the red or violet ray by the flint glass, is much greater than that produced by the crown; secondly, that the angle R C V, over which the coloured rays are dispersed by the flint prism, is also much greater than the angle r c v, over which they are dispersed by the crown; and, thirdly, that the angles R C V, r c v, or the angles of dispersion, are not to each other as Newton supposed them to be, in the same ratio with the angles of deviation T C R, t c r, but in a much higher ratio; the dispersion of the flint prism being much more than in proportion to the deviation produced by it. And if, instead of taking the angles of the prism equal, the refracting angle of the crown prism be so increased as to make the deviation of the red ray equal to that produced by the flint prism, the deviation of the violet will fall considerably short of such equality. In consequence of this, if the two prisms be placed close together, with their edges turned opposite ways, as in fig. 98, so as to oppose each other's action, the red ray, being equally refracted in opposite directions, will suffer no deviation; but the violet ray, being more refracted by the flint than by the crown prism, will, on the whole, be bent towards the thicker part of the flint prism, and thus an uncorrected colour will subsist, though the refraction (for one ray, at least) is corrected. *Vice versa, if the dispersion be corrected, that is, if the refracting angle of the crown prism, acting in opposition to the flint, be so further increased as to make the difference of the deviations of the red and violet rays produced by it equal to the difference of their deviations produced by the flint, the deviation produced by it will now be greater than that produced by the flint; and the total deviation, produced by both prisms acting together, will now be in favour of the crown.

By such a combination of two prisms of different media a ray of white light may therefore be turned aside considerably from its course, without being separated into its elementary coloured rays. It is manifest, that (supposing the angles of the prisms small, and that both are placed in their positions of minimum deviation) the deviations to produce this effect must be in the inverse ratio of the dispersive powers of the two media; for supposing $\mu, \mu'$ to be the refractive indices of the prisms for extreme red rays, and $\mu + \delta \mu, \mu' + \delta \mu'$ for extreme violet, A and A' their refracting angles, and D and D' their deviations, we have, generally, in the position of minimum deviation

$$\mu \cdot \sin \frac{A}{2} = \sin \frac{A + D}{2}, \text{whence } \delta \mu \cdot \sin \frac{A}{2} = \frac{1}{2} \delta D \cdot \cos \frac{A + D}{2};$$

$$\mu' \cdot \sin \frac{A'}{2} = \sin \frac{A' + D'}{2}, \text{whence } \delta \mu' \cdot \sin \frac{A'}{2} = \frac{1}{2} \delta D' \cdot \cos \frac{A' + D'}{2};$$

whence, since the prisms oppose each other,

---

* He counteracted the refraction of a glass, by a water prism. There ought to have been a residuum of uncorrected colour; but, unluckily, he had mixed sugar of lead with the water to increase its refraction, and the high dispersive power of the salts of lead (of which, of course, he could not have the least suspicion) thus robbed him of one of the greatest discoveries in physical optics.
Putting this equal to zero, we have

\[ \frac{\delta \mu}{\delta \mu'} \cdot \sin \frac{1}{2} A = \cos \frac{1}{2} (A + D) \]

and, eliminating \( \sin \frac{1}{2} A \) and \( \sin \frac{1}{2} A' \) from this, by means of the two original equations from which we set out, we get

\[ \frac{\delta \mu}{\delta \mu'} \cdot \frac{\sin \frac{1}{2} (A + D)}{\cos \frac{1}{2} (A + D')} = \frac{\sin \frac{1}{2} (A' + D')}{\cos \frac{1}{2} (A' + D')} \]

Now if we call \( p, p' \) the dispersive powers of the media, or the proportional parts of the whole refractions of the extreme red ray, to which the dispersion is equal, we shall have

\[ p = \frac{\delta \mu}{\mu - 1} \quad \text{and} \quad p' = \frac{\delta \mu'}{\mu' - 1} \]

so that

\[ \frac{p}{p'} = \frac{\mu'}{\mu} \cdot \frac{\mu - 1}{\mu' - 1} \cdot \frac{\tan \frac{1}{2} (A + D')}{\tan \frac{1}{2} (A + D)} = \frac{\mu - 1}{\mu' - 1} \cdot \frac{\sin \frac{1}{2} A'}{\sin \frac{1}{2} A} \cdot \sqrt{1 - \mu^2} \cdot \frac{\sin \frac{1}{2} A}{1 - \mu^2} \cdot (\sin \frac{1}{2} A')^2 \]

Such is the strict formula, which, when \( A \) and \( A' \) are very small, becomes

\[ \frac{p}{p'} = \frac{\mu - 1}{\mu' - 1} \cdot \frac{A'}{A} \quad \text{or}, \quad \text{since} \quad (\mu - 1) A = D, \quad \text{and} \quad (\mu' - 1) A' = D' \]

428. The formula just obtained, furnishes us with an experimental method of determining the ratio of the dispersive powers of two media. For if we can by any means succeed in forming them into two prisms of such refracting angles, that, when placed in their respective positions of minimum deviation, a well defined bright object, viewed through both, shall appear well defined and free from colour at its edges; then, by measuring their angles, and knowing also from other experiments their refractive indices, the equation \((a)\) gives us immediately the ratio in question.

When we view through a prism any well defined object, either much darker or much lighter than the ground against which it is seen projected, as, for instance, a window bar seen against the sky, its edges appear fringed with colours and ill defined. The reason of this may be explained as follows:

Let \( A B \), fig. 99, be the section of a horizontal bar seen through the prism \( P \) held with its refracting edge downwards, and first let us consider what will be the appearance of the upper edge \( B \) of the object. Since we see by light, and not by darkness, the thing really seen is not the dark object, but the bright ground on which it stands, or the bright spaces \( B C, A D \) above and below. Now the bright space \( B C \) above the object being illuminated with white light, will, after refraction at the prism, form a succession of coloured images \( b, c, b', c' \), \( b'' c'', \&c. \), superposed on and overlapping each other. They are represented in the figure as at different distances from \( P \), but this is only to keep them distinct. In reality, they must be supposed to lie upon and interfere with each other. The least refracted \( b c \) of these is red, and the most refracted \( b'' c'' \) violet, and any intermediate one (as \( b' c' \)) of some intermediate colour, for instance. Beyond \( b' \) no image exists, so that the whole space below \( b' \) will appear dark to an eye situated behind the prism. On the other hand, above \( b \) the images of every colour in the spectrum coexist, the bright space \( b c \) being supposed to extend indefinitely above \( B \). Therefore the space above \( b \) in the refracted image will appear perfectly white. Between \( b \) and \( b' \) there will be seen, first, a general diminution of light, as we proceed from \( b \) towards \( b' \), because the number of superposed luminous images continually decreases; secondly, an excess in all this part, of the more refrangible rays in the spectrum above what is necessary to form white light, for beyond \( b \) no red image exists, beyond \( b' \) no yellow, and so on; the last which projects beyond all, at \( b'' \), being a pure unmixed violet. Thus the light will not only decrease in intensity, but by the successive subtraction of more and more of the less refrangible end of the spectrum will acquire a bluer and bluer tint, deepening to a pure violet, so that the upper edge of the dark object will appear fringed with a blue border, becoming paler and paler till it dies away into whiteness. The reverse will happen at the lower edge \( A \). The bright space \( A D \) forms, in like manner, a succession of coloured images, \( a, d, d', a'' d' \), of which the least deviated \( a d \) is red, the most \( a'' d'' \) violet, and the intermediate ones of the intermediate colours. Therefore the point \( a \), which contains only the extreme red, will appear of a sombre red; \( a' \), which contains all the rays from red to yellow (suppose), of a lively orange red; and in proportion as the other images belonging to the more refrangible end of the spectrum come in, this tendency to an excess of red will be neutralized, and the portion beyond \( a'' \), containing all the colours in their natural proportions, will be purely white. Hence, the lower edge of the dark object will appear bordered with a red fringe, whose width fades away into whiteness, in the same way as the blue fringe which borders the upper edge. These fringes, of course, destroy the distinctness of the outlines of objects, and render vision through a prism confused. The confusion ceases, and objects resume their natural well defined outlines, if illuminated with homogeneous light, or if viewed through coloured glasses which transmit only homogeneous rays.
The eye can judge pretty well, by practice, of the destruction of colour, and indistinctness in the edges of objects, when prisms are made to act in opposition to one another, as above described; but (owing to causes presently to be considered) the compensation is never perfect, and there always remains a small fringe of uncorrected purple on one side, and green on the other, when the eye is best satisfied; so that observations of dispersive powers by this method are liable to a certain extent of error, and, indeed, precision in this department of optical science is very difficult to obtain.

To determine the dispersive power of a medium, having formed it into a prism, and measured by the goniometer, or otherwise, its refracting angle, and ascertained its refractive index, the next step is to find the refracting angle of a prism of some standard medium, which shall exactly compensate its dispersion, so as to produce a refraction as nearly as possible from colour. But as it is impossible to have a series of standard prisms with every refracting angle which may be requisite, it becomes necessary to devise some means of varying the refracting angle of one and the same prism by insensible gradations. Many contrivances may be had recourse to for this. Thus, first, we may use a prism composed of two plates of parallel glass, united by a hinge, or otherwise, and enclosing between them a fluid, which may be prevented from escaping either by capillary attraction, if in very small quantity, or by close-fitting metallic cheeks, forming a wedge-shaped vessel, if in larger. This contrivance, however, is liable to a thousand inconveniences in practice. Secondly, we may use two prisms of the same kind of glass, one of which has one of its faces ground into a convex, and the other into a concave cylinder, of equal curvatures, having their axes parallel to the refracting edges. These being applied to each other, and one of them being made to revolve round the common axes of the two cylindric surfaces upon the other, the plane faces will evidently be inclined to each other in every possible angle within the limits of the motion, (see fig. 100, a, b, exhibiting two varieties of this construction.) The idea, due, we believe, to Boscovich, is ingenious, but the execution difficult, and liable to great inaccuracies.

The following method succeeds perfectly well, and we have found it very convenient in practice. Take a prism of good flint glass, whose section is a right angled triangle, A B C, having the angle A about 30° or 35°, C being the right angle, and whose length is twice the breadth of the side A C; and, having ground and polished the side A C, and the hypotenuse of the prism to true planes, cut it in half, so as to form two equal prisms with one face in each a square, and whose refracting angles (A, A') cannot, of course, be otherwise than equal. Cement the square faces together very carefully with mastic, so that the edges A, A', shall be on opposite sides of the square surface, which is common to both; and then, making the whole solid to revolve round an axis perpendicular to the common surface, and passing through its centre, grind off all the angles of the squares in the lathe, and the whole will be formed into a cylindrical solid, with oblique, parallel, elliptical, plane ends, as in fig. 101. Then separate the prisms, (by warming the cement,) and set each of them in a separate brass mounting, as in fig. 102, so as to have their circular faces in contact, and capable of revolving freely upon each other about their common centre. The lower one is fixed in the centre of the divided circle D E, while the mounting of the upper or moveable one carries an arm with an adjustable vernier reading off to tenths of degrees, or, if necessary, to minutes. The whole apparatus is set in a swing frame between plates, which grasp the divided plate by a groove in its edge, allowing a motion in its own plane, and a capability of adjusting it to any required position, so as to admit of the compound prism deviating an incident ray in every possible plane, and under every possible situation, with respect to the faces of the prisms. It is evident, that in the position here represented, where the prisms oppose each other, and at which the vernier must be set to read off zero, the refracting angle is rigorously nothing; and when turned round 180°, since the prisms then conspire, their combined angle must be double that of each. In intermediate situations, the angle between the planes of their exterior faces must, of course, pass through every intermediate state, and (by spherical trigonometry) it is readily shown, that if $\theta$ be the reading off of the vernier, or the angle of rotation of the prisms on each other from the true zero, the angle of the compound prism will be had by the equation

$$\sin \frac{A}{2} = \sin \frac{\theta}{2} \cdot \sin (A)$$

where (A) is the refracting angle of each of the simple prisms, and A the angle of the compound one.

To use this instrument, place the prism $A'$, whose dispersive power is to be compared with the medium of which the standard prism (A) is formed, with its edge downwards and horizontal, before a window, and, selecting one of the horizontal bars properly situated, fix it so that the refraction of this bar shall be a minimum, or till, on slightly inclining the prism backwards and forwards, the image of the bar appears stationary. Then take the standard compound prism, adjust it to zero, and set it vertically on its frame behind the first prism. Move its index a few degrees from zero, and turn the divided circle in its own plane, till the refraction so produced by the second prism is contrary to that produced by the first. The colour will be found less than before; continue this till the colour is nearly compensated, then, by means of the swing motion, and of the motion round the vertical axis, adjust the apparatus so that two of the window bars, a horizontal and a vertical one, seen through both prisms, shall appear to make a right angle with each other, (an adjustment, at first, rather puzzling, but which a little practice renders very easy.) Then complete the compensation of the colour; verify the position of the standard prism, (by the same test,) and finally read off the vernier, and the required angle A of the compensating prism is easily calculated by the equation (b). This calculation may be saved by tabulating the values of A corresponding to those of $\theta$, (the value of (A) being supposed known by previous exact measures,) or, by graduating the divided circle at once, not into equal parts of $\theta$, but according to such computed values of A, so as to read off at once the value of the angle required.
A simpler, perhaps, on the whole, a better, method of comparing the dispersions of two prisms, is one proposed and applied extensively by Dr. Brewster, in his ingenious Treatise On New Philosophical Instruments, a work abounding with curious contrivances and happy adaptations. It consists in varying, not the refracting angle of the standard prism, but the direction in which its dispersion is performed. It is manifest, that if we can produce from a line of white light, by means of a standard prism any how disposed, a coloured fringe, in which the colours occupy the same angular breadth as in that produced by a prism of unknown dispersion; then, the latter, being made to refract this fringe in a direction perpendicular to its breadth, and opposite to the order of its colours, must destroy all colour and produce a compensated refraction; and therefore if the position of the standard prism which produces such a fringe be known, the dispersion of the other may be calculated.

To accomplish this, let A B be a horizontal luminous line of considerable length, and let it be refracted downwards, but obliquity in the direction A a, B b, by a standard prism whose dispersion is greater than that of the prism to be measured. Then it will form an oblique spectrum a b b' a', a b being the red, and a' b' the violet; and the angular breadth of this coloured fringe will be a m = a a' \times \sin inclination of the plane of refraction to the horizon. Now, let the prism whose dispersion is to be measured be made to refract this coloured band vertically upwards; then, if the plane of the first refraction be so inclined to the horizon that the angle subtended by a m at the eye shall be just equal to the angle of dispersion of the other prism, all the colours of the rectangular portion b c a' d will be made to coincide in the horizontal line A' B', which will appear therefore free from colour, except at its extremities A' B', where the coloured triangles a c a', b d b' will produce a red termination A' A'' and a blue one B' B'' at the respective ends of the line to which they correspond. Hence, if the second prism remaining fixed, with its edge downwards and parallel to the horizon, the other or standard prism be turned gradually round in the plane perpendicular to its principal section, a position must necessarily be found where the twice refracted line A' B' will appear free from colour both above and below. In this position let it be arrested, and the angle of inclination of its edge to the horizon read off; its complement is the angle a a' m, which we will call \( \theta \). Let us now suppose each prism adjusted to its position of minimum deviation, and (as it is a matter of indifference which is placed first) let the prism to be examined or the fixed prism be placed next the object.* Then, D' and D being the total deviations produced by the fixed and revolving prisms on the extreme red ray, we must have

\[
\delta D' - \delta D \cdot \sin \theta = 0; \quad \text{or} \quad \delta \mu = \frac{\sin \frac{1}{2} (A + D)}{\sin \frac{1}{2} A},
\]

whence we obtain

\[
\frac{p'}{p} = \frac{\delta \mu}{\delta \mu'} \cdot \frac{\mu - 1}{\mu' - 1} = \frac{\mu}{\mu'} \cdot \frac{\mu - 1}{\mu' - 1} \cdot \tan \frac{1}{2} (A + D) \cdot \sin \theta;
\]

where the angles \( \frac{1}{2} (A + D) \) and \( \frac{1}{2} (A' + D') \) are given by the equations

\[
\sin \frac{1}{2} (A + D) = \mu \cdot \sin \frac{1}{2} A; \quad \sin \frac{1}{2} (A' + D') = \mu' \cdot \sin \frac{1}{2} A';
\]

from which formula, \( \theta \) being known, and also the angles and refractive indices of the two prisms, the ratio of their dispersions is found.

By these, or other similar methods, may the dispersions of any media be compared with those of any other taken as a standard. If the media be solid, they must be formed into prisms; if fluid, they must be enclosed in hollow prisms of truly parallel plates of glass, whose angles must be accurately determined, (and one of which will serve for any number of fluids.) But to ascertain directly the dispersion of that standard prism, we must pursue a different course. The first method which obviously presents itself, is to measure the spectrum on finitely at both ends, and its visible extent varies so enormously with the brightness of the sun, and the more.

The eye being guarded as above described, let the slits be refracted by the prism (in its minimum position) from the longer towards the shorter. Then will a red and violet image of each a, b, and a', b' be seen. Now let the prism be removed from the slits, (or vice versd.) still preserving its position of minimum deviation, till the violet image of the longer slit exactly falls upon and covers the red image of the shorter, as in the position a' b' of the figure. Then it is obvious, that the distance between the slits, divided by their distance from the prism, is the sine of the total angle of dispersion, or is equal to \( \delta D \), and this being known

\[
\delta \mu = \frac{\delta D}{2} \cdot \cos \frac{1}{2} (A + D) \cdot \sin \frac{1}{2} A,
\]

and therefore \( \delta \mu \) or \( p \), the dispersive power, is obtained.

* Dr. Brewster has chosen a somewhat different position, (Treatise, &c. p. 296,) with a view to simplify the formulae; but it does not appear to us that any advantage is gained in that respect by his arrangement.
But all these methods are only rude approximations, as the great discrepancies of the results hitherto obtained by them abundantly prove; thus, the dispersions of various specimens of flint glass, obtained by the method last described, come out no less than one-sixth larger than those previously given by Dr. Brewster. The only method which can really be relied on is that practised by Fraunhofer, (where the media can be procured in a state of sufficient purity and quantity for its application;) and consists in determining, with astronomical precision, by direct measures, the values of \( \mu \) for the several points of definite refrangibility in the spectrum, marked, either by the fixed lines, or by the phenomena of coloured flames or absorbent media. (See Index, Flames—Absorption.) By taking advantage of the properties of the latter, a red ray, of a refrangibility strictly definite, may be insulated with great facility; and as it lies so near the extremity of the spectrum as not to be perceptible till all the brighter rays are extinguished, it is invaluable as a fixed term in optical researches, and will always be understood by us in future, when speaking of the commencement of the spectrum, or the extreme red, even though a red ray still less refrangible should be capable of being discerned by careful management, and in favourable circumstances. In like manner, by the simple artifice of putting a little salt into a flame, a yellow ray of a character perfectly definite is obtained, which, it is very remarkable, occupies precisely the place in the scale of refrangibility where in the solar spectrum the dark line D occurs, (Art. 418, 419.) These, and the fixed lines there mentioned, leave us at no loss for rays identifiable at all times and in all circumstances, (with a good apparatus,) and enable us to place the doctrine of refractive and dispersive powers on the footing of the most accurate branches of science.

The following table, extracted from Fraunhofer's Essay on the Determination of Refractive and Dispersive Powers, &c. contains the absolute values of the index of refraction \( \mu \) for the several rays whose places in the spectrum correspond to the seven lines B, C, D, E, F, G, H, assumed by him as standards (see Art. 419, &c.) for several different glasses of his own manufacture, and for certain liquids. These values, for distinction's sake, we may designate by the signs \( \mu (B), \mu (C), \mu (D), &c. \)

</table>

The above table renders very evident a circumstance which has long been recognised by experimental opticians, and which is of great importance in the construction of telescopes, viz. the irrationality, (as it has been termed,) or want of proportionality of the spaces occupied in spectra formed by different media by the several coloured rays, or by those whose refrangibilities, by any one standard medium, lie between given limits. If we fix upon water, for example, as a standard medium, (and we see no reason why it should not be generally adopted as a term of reference in this, as in other physical inquiries—of course at a given temperature—that of its maximum density, for instance,) it is obvious, that any ray may be identified by stating its index of refrangibility by water; thus, a scale of refrangibilities, which, for brevity, we shall term the water scale, is established; and so soon as we know the refractive index of a ray from vacuum into water, we have its place in the water spectrum, its colour,
and its other physical properties (so far as they depend on the refrangibility of the ray) determined. Thus Part II.

1.333577 being known to be the refractive index for a ray in water, that ray can be no other than the particular ray D, whose colour is pale orange-yellow, and which is totally deficient in solar light, and peculiarly abundant in the light of certain flames. Now let x be the refractive index of any ray whatever for water, or its place in the water scale. Then it is evident, that its refractive index for any other medium must of necessity be a function of x, because the value of x determines this and all the other properties of the ray. Hence we must have between μ and x some equation which may be generally represented by γ = F(x); F(x) denoting a function of x.

To determine the form of this function, we must consider, that if A be the very small angle of a prism, and D the deviation produced by it at the minimum, we have μ/A = A + D/2, or D = (μ - 1) A. Hence, supposing A the refracting angle constant, the deviation is proportional to A - 1. Now, since in all media, as well as in water, the deviations observe, at least, the same order, being always least for the red and greatest for the violet, it follows, that in all media μ - 1 increases as x increases; so that, supposing x0 to be the index of refraction in the water scale for the first visible red ray, or the commencing value of x, and μ0 the index for the same ray in the other medium, (μ - 1) - (μ0 - 1), or μ - μ0 must increase with x - x0; and since they vanish together, we may represent the one in a series with indeterminate coefficients, and powers of the other, thus

μ - μ0 = A (x - x0) + B (x - x0)^2 + C (x - x0)^3 + &c.;

or, which comes to the same thing, a, β, γ, &c., representing other indeterminate coefficients, (x0 - 1 being constant.)

μ - μ0 = a . (x - x0) + b . (x - x0)^2 + &c.

The simplest hypothesis we can form respecting the values of a, β, γ, &c. is that which makes a = 1, and b, and all the other coefficients vanish. This gives μ - μ0 = x - x0.

We have before used δμ to denote what is here signified by μ - μ0, viz. the difference between the refractive indices of any ray in the spectrum, and that at its commencement; and we have denoted by δμ/μ - 1 the same quantity which is here expressed by μ - μ0/μ0 - 1. This then is the expression, in our present notation, of the dispersive power of the medium; and the equation now under consideration therefore indicates, that, on the hypothesis made, the dispersive power of the medium must necessarily be the same with that of water; and of course (supposing this hypothesis to be founded in the nature of light) all media must have the same dispersive power. This, as we have already seen, is not the case.

The next simplest hypothesis is that which admits a as an arbitrary constant determined by the nature of the medium, but still makes b, c, &c. = 0. This reduces the equation to

μ - μ0 = a . x - x0/x0 - 1;

consequently (if μ' and x' be any other corresponding values of μ and x) we must have also

μ' - μ0 = a . x' - x0/x0 - 1, and therefore μ' - μ/μ0 - 1 = a . x' - x/x0 - 1; whence we have μ'/μ = a = μ0 - 1/x0 - 1.

Hence, if this hypothesis be correct, and μ, x and μ', x' be any two pairs of corresponding refractive indices for rays however situated, the fraction μ'/μ = μ/x' - x must be invariable. The foregoing table, however, shows very distinctly that this is far from being the case. Thus, if we take the flint glass, No. 18, the comparison of the two rays B and C gives for the value of the fraction in question 2.562; and if we compare in like manner the rays C and D, D and E, E and F, F and G, G and H respectively, we obtain the values 2.871, 3.075, 3.193, 3.469, 3.726; the great deviation of which from equality, and their regular progression, leaves no doubt of the incompatibility of the hypothesis in question, as a general law, with nature. If we institute the same comparison for the other media in the table, we shall find the greatest diversity prevail; and if, instead of water, we assume any other as a standard, the same incompatibility will be found. Thus if the flint glass, No. 13, be compared with oil of turpentine, we find for the values of the series of fractions in question, 1.586, 1.844, 1.783, 1.843, 1.861, 1.809, which first diminish to a minimum and then increase again, &c.

It follows from this, that the proportion which the several coloured spaces (or the intervals BC, CD, DE, &c.) bear to each other in spectra formed by different media, is not the same in all. Thus taking the green ray E for the middle colour, and calling all that part of the spectrum which lies on the red side of E the red,
Light, and all on the other side the blue portions, the ratio of the spaces occupied by the red and blue in any spectrum will be represented by the fraction \( \frac{\mu (H) - \mu (E)}{\mu (E) - \mu (B)} \). Now the values of this in the several media of the foregoing table are set down in the following list:

<table>

Here we see that the same coloured spaces which in the flint No. 23 are in the ratio of 21:10, in the water spectrum are only in the ratio of 17:10 (nearly), so that the blue portion of the spectrum is considerably more extended in proportion to the red in the flint glass than in the water spectrum.

From this it follows, that if two prisms be formed of different media (such as flint glass and water) of such refracting angles as to give spectra of equal total lengths, and these be made to refract in opposition to each other, although the red and violet rays will, of course, be united in the emergent beam, yet the intermediate rays will still be somewhat dispersed, the water prism refracting the green, or middle rays more than in proportion to the extremes; consequently, if a white luminous line be the object examined through such a combination, instead of being seen after refraction colourless, it will form a coloured spectrum of small breadth compared with what either prism separately would form, and having one side of a purple and the other of a green tint. Any dark object viewed against the sky (as a window bar) will be seen fringed with purple and green borders, the green lying on the same side of the bar with the vertex of the flint prism; because in such a combination, green must be considered as the most, and purple as the least, refrangible tint, and the flint prism, of necessity, having the least refraction in this case, the most refrangible fringe will lie towards its vertex, that being the least refracted side of the bar; for the same reason that, when seen through a single prism, a dark object on a white ground appears fringed with blue on its least refracted edge. (Art. 429.)

This result accords perfectly with observation. Clairaut, and, after him, Boscouvich, Dr. Blair, and Dr. Brewster, have severally drawn the attention of opticians to these coloured fringes, or, as they may be termed, secondary spectra, and demonstrated their existence in the most satisfactory manner. Dr. Brewster, in particular, has entered into a very extensive and highly valuable series of experiments, described in his Treatise on new philosophical instruments, and in his paper on the subject in the Edinburgh Transactions; from which it follows, that when a compound prism, consisting of any of the media in the following list refracting in opposition to each other, unites the red and violet rays, the green will be deviated from their united course by the combination, in the direction of the refraction of that medium which stands before the other in order:

4. Phosphorus acid. 34. Oil of ambergris. 64. Amber.
13. Nitrous acid. 43. Fenugreek. 73. Muriate of antimony.
15. Malic acid. 45. Nut oil. 75. Sweet fennel seeds.
17. Fluor spar. 47. Rue. 77. Orange-coloured glass.
22. Tourmaline. 52. Gum copal. 82. Cummin.
27. Gum Arabic. 57. Marjoram. 87. Sulphuret of carbon.
29. Oil of almonds. 59. Peppermint. 89. Oil of cassia.
30. Tartrate of potash and soda.
It is evident from this table, that (generally speaking) the more refractive a medium is, the greater is the extent of the blue portion of its spectrum compared with the red.

If two prisms of the proper refracting angles, composed of media not very remote from each other in this list, be made to oppose each other, the secondary spectrum will be small, and the refraction almost perfectly colourless. Such a combination is said to be achromatic, (a-χρωμάτως.)

The existence of the secondary spectrum, while it renders the attainment of perfect achromacity impossible, by the use of two media only, shows, also, that in a theoretical point of view we are not entitled to neglect the coefficients \( b, c, \ldots \) of the equation (1), Art. 439. The law of nature probably requires the series to be continued to infinity; and if, by way of uniting three rays, we employ prisms of three media, tertiary spectra, and after them still others in succession, would doubtless be found to arise. These, however, will be small in comparison of each other.

The table (Art. 437) gives us the means of computing the coefficients on which they depend for the particular media there stated. If we put \( \frac{x - x_0}{x_0 - 1} = y \) and suppose \( P, P', P'' \), \( p, p', p'' \), \&c. to be the values of \( P \) and \( p \) corresponding to the several values of \( \mu \) and \( x \) set down in the table, we shall have, for determining \( a, b, c, \&c. \) in any one of those media, the equations

\[
\begin{align*}
P &= a p + b p^2 + c p^3 + \ldots \quad P' &= a p' + b p'^2 + c p'^3 + \ldots \\
P'' &= a p'' + b p''^2 + c p''^3 + \ldots
\end{align*}
\]

and as many such equations must be used as there are coefficients to determine. Confining ourselves, at present to two, we find \( P = a p + b p^2; \quad P' = a p' + b p'; \) whence

\[
a = \frac{P p'^2 - P' p^2}{p p' (p' - p)}; \quad b = \frac{P p' - P' p}{p p' (p' - p)};
\]

and, since it is desirable to select rays as far removed from each other in the spectrum as possible, we shall take \( \mu_0 \) and \( x_0 \) from the column \( \mu \) (B); and determine \( P \) and \( p \) by the values in the column \( \mu \) (E), and \( P', p' \) by those under \( \mu \) (H). The results will be as follows:

Problem. To determine the analytical relation which must hold good in order that two prisms may form an achromatic combination; that is, may refract a white ray without separating the extreme colours.

Resuming the equations and notation of Art. 215, since the prisms are placed in vacuo, we have to substitute \( \mu, \frac{1}{\mu'}, \mu', \mu'' \), in those equations respectively, and we shall have

\[
\begin{align*}
\mu \cdot \sin \rho &= \sin a \\
\sin a' &= 1 + \rho \sin a \\
\sin a'' &= \mu \sin a' \sin a''
\end{align*}
\]

and

\[
\begin{align*}
a' &= I + \rho; \quad D = a + I + I' + I'' - \rho'' \\
a'' &= I' + \rho'; \quad \delta \mu = \sin \rho + \mu \delta \rho \cdot \cos \rho = 0
\end{align*}
\]

Now, since by hypothesis the incident and emergent rays are both colourless, we must have \( \delta \rho = 0, \) and \( \delta D = 0, \) that is \( \delta \rho'' = 0, \) the sign \( \delta \) being supposed to refer to the variation of the place of the ray in the spectrum. Hence the two systems of equations (1) and (2) are exactly similar, in their form; the former as relates to \( \rho, a, a', \rho', \) and the latter as to \( a''', \rho''', \rho', a'''. \) Now, the first system gives

\[
\begin{align*}
\delta \mu \cdot \sin \rho + \mu \delta p \cdot \cos \rho &= 0; & \delta a' &= \delta \rho; & \delta \rho' \cos \rho' &= \delta \mu \cdot \sin a' + \mu \delta a' \cdot \cos a';
\end{align*}
\]

whence, by elimination and reduction, we find

\[
\begin{align*}
\rho &= \frac{\sin I}{\cos \rho \cdot \cos \rho'} \delta \mu;
\end{align*}
\]
and, consequently, by reason of the analogy of the two systems of equations pointed out above,

$$\frac{\partial \alpha'}{\partial I'} = -\frac{\sin I'}{\cos \alpha' \cdot \cos \alpha''} \frac{\partial \rho'}{\partial I'}$$

But, since $$\alpha' = I + \rho'$$, we have $$\frac{\partial \rho'}{\partial I'} = \frac{\partial \alpha'}{\partial I'}$$, so that we finally get

$$\frac{\cos \rho \cdot \cos \rho'}{\cos \alpha'' \cdot \cos \alpha'''} = -\frac{\sin I}{\sin I'} \cdot \frac{\partial \mu}{\partial \rho'}$$

The property expressed by this equation may be thus stated. Conceive the ray to pass both ways outwards from a point in its course between the two prisms; then, in order that the combination may be achromatic, the products of the cosines of its incidences on the surfaces of each prism must be to each other in the ratio compounded of that of the sines of their respective refracting angles, and the differences of their refractive indices for red and violet rays; besides which, they must refract in opposition to each other, or $$I$$ and $$I'''$$ their refracting angles must have opposite signs.

The combination of this equation with the system of equations above stated, expressing the conditions of refraction by the prism, and their relative position with regard to each other (which is included in the equation $$\alpha'' = I + \rho''$$) suffice, algebraically speaking, to resolve every problem which can occur, of this kind; but the final equations are for the most part too involved to allow of direct solution. Nevertheless, the results we have arrived at will furnish occasion for remarks of moment; and, first, since $$\rho'$$ is the angle of refraction from the second surface of the first prism, $$2\rho'$$ is the angular breadth of the spectrum produced by it; this is, therefore, proportional, ceteris paribus, to the product of the sines of the angles of refraction at its two surfaces. Let us trace the progress of the variation of this, as the incident ray changes its inclination to the first surface, beginning with the case when it just grazes the surface from the back towards the edge. In this case

$$a = 90°, \sin \rho = \frac{1}{\rho},$$

consequently $$\rho$$, and therefore $$I + \rho$$ or $$\alpha'$$, and therefore $$\rho'$$ are all finite, and at their maximum. Hence $$\cos \rho \cdot \cos \rho'$$ is finite, and at its minimum; and therefore $$2\rho'$$, or the breadth of the spectrum, is also finite, but a maximum. As the incident ray becomes more inclined to the surface $$\rho$$, and therefore $$\alpha'$$ and $$\rho'$$ diminish, and the denominator of $$2\rho'$$ increases, so that the breadth of the spectrum diminishes, and reaches a minimum when $$\cos \rho \cdot \cos \rho'$$ attains its maximum; that is, when $$d \rho \cdot \tan \rho + d \rho' \cdot \tan \rho' = 0$$. Now this equation, substituting and reducing gives, for determining the values of $$\rho'$$, and therefore of $$a$$, or the incidence when the spectrum is a minimum,

$$\rho^2 \cdot \sin (I + \rho') \cdot \cos (I + 2 \rho') + \sin \rho = 0.$$  

Hence we see that the position which gives a minimum of breadth to the spectrum is very different from that which gives a minimum of deviation, being given by the above equation, which is easily resolved by a table of logarithms, and which shows at once that $$\rho'$$ must be greater than $$45° - \frac{1}{2}$$.  

After attaining the position so determined, the breadth of the spectrum again increases, and continues to do so till the rays can be no longer transmitted through the prism. At this limit the emergent ray just grazes the posterior face of the prism from its thinner towards its thicker part $$\rho' = 90°, \cos \rho' = 0$$. At this limit, therefore, the dispersion becomes infinite. All these stages are easily traced by turning a prism round its edge between the eye and a candle; or, better, between the eye and the narrow slit between two nearly closed window-shutters. Hence, as the incident ray varies from the position $$S E$$ (Fig. 105) to $$S'E$$, and therefore the refracted from $$F G$$ to $$F' G'$$, the breadth of the spectrum commences at a maximum, but finite value, diminishes to a minimum and then increases to infinity. The distribution of the colours in the spectrum, or the breadths of the several coloured spaces in any state of the data, will moreover differ according to the values of $$\rho, \rho'$$ and $$\sin I$$; for the equation (e), by assigning to $$\Delta \mu$$ the values which correspond in succession to the intervals between red and orange, orange and yellow, yellow and green, &c. will give the corresponding values of $$2\rho'$$, or the apparent breadths of these spaces. Now the denominator $$\cos \rho \cdot \cos \rho'$$ is an implicit function of $$\mu$$, and therefore varies when the initial ray is taken in different parts of the spectrum. The variation is trifling when the angles $$\rho, \rho'$$ are considerable; but near the limit, when the ray can barely be transmitted, it becomes very great, the spectrum is violently distorted, and the violet extremity greatly lengthened in proportion to the red. The effect is the same as if the nature of the medium changed and descended lower in the order of substances in the table Art. 443.

From what has just been said, we see the possibility of achromatising any prism, however large its refracting angle, by any other of the same medium, however small may be its angle; for since, by properly presenting a prism to the incident ray, its dispersion may be increased to infinity; if made to refract in opposition to another whose dispersion has any magnitude, however great, it may be made to counteract, or even overcome it. Thus in Fig. 106 the dispersion of the second prism $$\alpha$$, of small refracting angle, being increased by the effect of its inclined position, is rendered equal and opposite to that of the prism $$A$$, whose refracting angle is large.

When the prisms differ greatly in their angles, however, the second must be very much inclined, so as to bring it near to the limit of transmission. In this case, its law of dispersion, as just shown, will be greatly disturbed, and rendered totally different from what obtains in the other prisms; so that perfect achromatically...
cannot be produced; but when the extreme red and violet rays are united, the green will be too little refracted by the second prism, and a purple and green spectrum will arise, as in the case of prisms of different media. To this spectrum Dr. Brewster (who was the first to place it in evidence) has given the name of a tertiary spectrum; but it appears to us, that this term had better be reserved for the spectra mentioned in Art. 446, and those now in question may be called subordinate spectra.

If a small rectangular object be viewed through such a combination as above described, in which the prism \( A \) is placed in its position of minimum deviation, and chromatised by a second prism, whose angle is less than that of \( A \), but not so small as to introduce this cause of colour, it will appear distorted in figure; for the sides parallel to the edges of the prisms will undergo no change in their apparent length, while the breadth of the rectangle will appear magnified. For the first prism, by reason of its position, does not alter the angular dimensions of objects seen through it; but the second changes their angular breadth in the ratio of \( \frac{d \alpha''}{d \alpha'} \), that is (by differentiation) in the ratio of \( \frac{\cos \alpha' \cos \alpha''}{\cos \beta' \cos \beta''} \) to unity, a ratio which increases rapidly as the inclination of the prism increases, and \( \beta' \) approaches a right angle.

M. Amici has taken advantage of these properties to construct a species of achromatic telescope, which, at first sight, appears very paradoxical, being composed merely of four prisms of the same kind of glass, with plane surfaces. To understand its construction, conceive a small square object \( o'p' \) placed with the side \( o' \) parallel to the refracting edges of a pair of prisms so adjusted, and perpendicular to their principal sections, i.e. to the plane of the paper. Then, after refraction through both, it will be seen by an eye at \( E \), as a real object \( o'p' \), having its length \( o \) unaltered, but magnified in breadth. Now, if we add a second pair of prisms, similar to the first, and similarly disposed with respect to each other, so as to form a second achromatic combination, but having the plane of their principal sections at right angles to the former, producing a refraction perpendicular to the plane of the paper, or parallel to the length of the distorted square, this will be in like manner seen as a real and colourless object, but again distorted, its side \( o'p' \) remaining unaltered, but \( o' \) being magnified. Thus, by the effect of the first distortion, the breadth of the square is magnified, and, by that of the second, its length, and in the same ratio; and therefore the final result will be an image undistorted, achromatic, and magnified.

The writer of these pages had the pleasure of witnessing the very good performance of one of these singular telescopes, magnifying about four times in the hands of its inventor, at Modena, in 1826. It is evident, that, by superposing several such telescopes on each other, the magnifying power may be increased in geometrical progression. It is equally clear, that, by using prisms of two different media to form the several binary combinations, the spectra of distortion may be made to counteract the secondary spectra, arising from the difference in the scales of dispersion in the two media; and thus an achromaticity, almost mathematically perfect, might be obtained. It is worthy of consideration, whether, for the purpose of viewing very bright objects, as the sun, for instance, this species of telescope might not prove of considerable service. It would have the advantage of being its own darkening glass, of not bringing the rays to a focus, and therefore of requiring no extraordinary care in the figuring of the surfaces; and, in short, of being exempt from all those inconveniences which oppose the perfection of telescopes of the usual constructions, as applied to this particular object.

Proposition. To find the conditions of achromaticity when several prisms of different media refract a ray of white light, supposing all their refracting angles very small, and the ray to pass nearly at right angles to the principal section of each.

The refracting angles being \( A, A', A'', \&c. \), and the refractive indices \( n, n', n'', \&c. \), the several partial deviations will be \( D = (n - 1) A; \ D' = (n' - 1) A'; \ &c. \); and their sum, or the total deviation, will be \( (n - 1) A + (n' - 1) A' + (n'' - 1) A'' + \&c. \). In order that the emergent ray may be colourless, this must be the same for rays of all colours; and its variation, when \( n, n', n'', \&c. \) are made to vary, must vanish, or

\[
A \beta + A' \beta' + A'' \beta'' + \&c. = 0.
\]

Now, by equation \((d)\) of Art. 439, we have \( \beta \), (or, in the notation of that article, \( \beta - \beta_o \))

\[
\beta = (n_0 - 1) \left\{ a_0 \cdot \frac{1}{x_0 - 1} + b \left( \frac{1}{x_0 - 1} \right)^2 + \&c. \right\}
\]

Therefore the above equation gives, when arranged according to powers of \( \frac{1}{x_0} \),

\[
0 = \left\{ A (n_0 - 1) a + A' (n_o' - 1) a' + A'' (n_o'' - 1) a'' + \&c. \right\} \cdot \frac{1}{x_0 - 1}
\]

+ \left\{ A (n_0 - 1) b + A' (n_o' - 1) b' + A'' (n_o'' - 1) b'' + \&c. \right\} \left( \frac{1}{x_0 - 1} \right)^2
\]

+ \&c.

taking \( a', b', \&c. \) to represent the dispersive powers of the various orders for the second prism, \( a'', b'', \&c. \) for the third, and so on. Hence, in order that this may vanish for all the rays in the spectrum, we must have (putting, for brevity, \( \mu \) for \( n_o, \mu' \) for \( n_o' \), \&c.)

\[
A \beta + A' \beta' + A'' \beta'' + \&c. = 0.
\]
and so on. Generally speaking, the number of these equations being infinite, no finite number of prisms can satisfy them all; but if we attempt only to unite as many rays in the spectrum as there are prisms, which is the greatest approach to achromaticity we can attain, we have as many equations as unknown quantities, minus one, and the ratios of the angles to each other become known. Thus, to unite two rays two media suffice, and we can only take into consideration the first order of dispersions, which give

\[
(\mu - 1) a + (\nu - 1) A' a' + (\nu'' - 1) A'' a'' + \&c. = 0
\]

To unite three rays we have

\[
(\mu - 1) A a + (\nu - 1) A' a' + (\nu'' - 1) A'' a'' = 0
\]

whence by elimination

\[
\frac{A'}{A} = - \frac{\mu - 1}{\mu' - 1} \frac{a'}{a}
\]

and so on for any number.

In the case of two media, if the quantities \( b, c, \&c. \) be not known, the dispersive powers of the first order, \( a, a', \) should be determined, not by comparison of the extreme red and violet rays, which are too little luminous, but to render their strict union a matter of importance; we should rather endeavour to unite those rays which are at once powerfuly illuminating, and differing much in colour, such as the rays D and E. The exact union of these will insure the approximate union of all the rest better, on the whole, than if we aimed at uniting the extremes of the spectrum, and a far greater concentration of light will be produced. This should be carefully borne in mind in all experiments on the dispersions of glass to be used in the construction of telescopes.

If we would produce the greatest possible achromaticity by three prisms, the rays to be selected for determining the values of \( a, b, a', b', \) should be C, E, and G; or, which would, perhaps, be still better, C, E, and a ray midway between D and E; but the want of a sufficiently well marked line in that part of the spectrum throws some slight difficulty in the way of this latter combination, when solar light is used, and would oblige us to have recourse to some other method of measurement, of which a variety might be suggested.

In the case of three media, if the numerators and denominators of the expressions (k) vanish, or nearly so, the solutions become illusory, or at least inapplicable in practice. This happens whenever either of the fractions

\[
\frac{a}{a'}, \frac{a'}{a''}, \frac{a''}{a'''}
\]

becomes equal to either of the corresponding fractions \( \frac{b}{b'}, \frac{b'}{b''}, \) or \( \frac{b''}{b'''} \). Hence, to obtain practicable combinations, it is necessary to employ media which differ as much as possible in their scales of dispersive powers, i.e., in which the coloured spaces differ as far as possible from proportionality; such, for instance, as flint glass, crown glass, and muriatic acid; or, still better, oil of cassia, crown glass, and sulphuric acid, &c.

§ II. Of the Achromatic Telescope.

In the refracting telescopes described in Art. 380, &c. the different refrangibility of the differently coloured rays presents an obstacle to the extension of their power beyond very moderate limits. The focus of a lens being shorter as the refractive index is greater, it follows, that one and the same lens refracts violet rays to a focus nearer to its surface than red. This is easily seen by exposing a lens to the sun’s rays, and receiving the converging cone of rays on a paper placed successively at different distances behind it. At any distance nearer to the lens than its focus for mean rays, the circle on the paper will have a red border, but beyond it a blue one; for the cone of red rays whose base is the lens, envelopes that of violet within the focus, its vertex lying beyond the other, but is enveloped by it without, for the converse reason. Hence, if the paper be held in the focus for mean rays, or between the vertices of the red and violet cones, these will then form a distinct image, being collected in a point: but the extreme, and all the other intermediate rays, will be diffused over circles of a sensible magnitude, and form coloured borders, rendering the image indistinct and hazy. This deviation of the several coloured rays from one focus is called the “chromatic aberration.”

The diameter of the least circle within which all the coloured rays are concentrated by a lens supposed free from spherical aberration is easily found. Thus, in fig. 107, if \( v \) be the focus for violet, and \( r \) for red rays, \( n m o \) Least circle of chromatic aberration, is explained.

The diameter of the least circle within which all the coloured rays are concentrated by a lens supposed free from spherical aberration is easily found. Thus, in fig. 107, if \( v \) be the focus for violet, and \( r \) for red rays, \( m n o \) Least circle of chromatic aberration, Fig. 107.
therefore equating these \( \frac{m\nu}{C\nu} = \frac{m\nu}{C\nu} \) and \( m\nu = m\nu \cdot \frac{C\nu}{C\nu} \). \( m\nu + m\nu = m \cdot \frac{C\nu}{C\nu} \). \( \frac{C\nu + C\nu}{2} = \frac{r\nu}{2} \) very nearly, since the dispersion is small in comparison with the whole refraction. Therefore \( n\phi = \frac{AB}{2} \cdot \frac{r\nu}{C\nu} \). Now, \( f \) being the reciprocal focal distance \( (\AA + D = (\mu - 1) (R' + R'') + D) \) we have \( r\nu = \delta \frac{1}{f} = \frac{\delta f}{f^2} = \frac{\delta \mu (R' - R'')}{f^2} \) \( = \frac{\delta \mu}{\mu - 1} \cdot \frac{L}{f^2} \) and \( C\nu = \frac{1}{f} \), supposing \( \mu \) to represent the index of refraction for extreme red rays.

Hence we get diameter of least circle of chromatic aberration = semi-aperture \( \times \frac{L}{f} \cdot \frac{\mu}{\mu - 1} \) and for parallel rays, when \( L = f \), simply semi-aperture \( \times \) dispersive index \( \times \frac{L}{f} \).

458. Use of very long telescopes.

459. Principle of the achromatic telescope.

These equations afford all the relations necessary to insure achromaticity; and when satisfied, since they do not contain \( D \), they show that an object-glass which is achromatic for any one distance of the object is so for all distances. It is evident, that the same system of equations may be obtained directly from the expression in Art. 265 for the joint power of a system of lenses whose individual powers are \( L', L'' \), \&c. For the condition of achromaticity gives \( \frac{3}{2} L = 0 \), that is \( 3L' + 3L'' + 3L''' + \&c. = 0. \)

But since \( L' = (\mu' - 1) (R' - R'') \&c. \) (according to the system of notation there adopted)

\[ \frac{3}{2} L' = (R' - R'') \cdot \frac{3}{2} \mu' = L'. \]

But in the equation (\( d \)) if we put in succession for \( \mu_o \) the values \( \mu', \mu'', \&c., \) for \( \mu - \mu_o \) respectively, \( \frac{3}{2} \mu', \frac{3}{2} \mu'', \&c., \) and for \( a, b, \&c. \) the systems of coefficients \( a', b', \&c. ; a'', b'', \&c. ; \) \( a''', b''', \&c. ; \) and suppose \( \frac{x - x_o}{x_o - 1} = p \), we shall have

\[ \frac{3}{2} \mu' = a' p + b' p^2 + \&c.; \]

\[ \frac{3}{2} \mu'' = a'' p + b'' p^2 + \&c.; \]
which, being made to vanish independently of $p$, gives the very same system of equations as (a.)

To satisfy all these equations at once with any finite number of lenses being impossible, we must rest content with satisfying as many of the most important as the number of lenses will permit. Thus, if we have two lenses of different media, such as flint and crown glass, for instance, one only of them can be satisfied, and this must of course be the first, viz.

$$L' a' + L'' a'' = 0,$$

or

$$\frac{L''}{L'} = -\frac{a'}{a''};$$

which shows that the powers of the lenses must oppose each other, and be to each other inversely (and of course their focal lengths directly) as the dispersive powers. In such a combination, the values of $a'$, $a''$, the dispersive powers, however, ought not to be obtained from the relative refractions for the extreme red and violet rays of the spectrum, (according to the remark in Art. 453,) but rather from the strongest and brightest rays whose colours are in decided contrast; such, for instance, as the rays $C$ and $F$ in Fraunhofer's scale.

With three lenses of different media, two of the equations of achromaticity can be satisfied, and the secondary spectrum corrected, thus we have

$$0 = L' a' + L'' a'' + L''' a''' = 0,$$

or

$$0 = \left(\frac{L' a'}{L''} - \frac{L'' a''}{L''} - \frac{L''' a'''}{L'''}\right);$$

and in determining the values of $a'$, $a''$, &c. the rays to be employed should be the brightest yellow for a middle ray, and a pretty strong red and blue for the extremes. The rays $B$, $E$, $H$ are perhaps inferior to $C$, $E$, $G$ for this purpose.

Hence in a double object-glass having a positive focus the least dispersive lens must be of a convex or positive, and the most so of a negative, or concave character. The order in which they are placed is of no consequence, as far as aplanatism is concerned.

A single lens, as we have seen, neither admits of the destruction of the spherical, nor chromatic aberration, (Art. 396 and 457;) but if we combine two or more lenses of different media, the equations $s$, $t$, $u$, $v$ of Art. 399, 310, 312, and 313, combined with the equations just derived (a), Art. 459, or so many of them as are not incompatible, afford us the means of annihilating both species of aberration at once; and what is curious, and must be regarded as singularly fortunate, the relations afforded by the destruction of the chromatic aberration, which, at first sight, would appear likely greatly to complicate the inquiry, tend, on the contrary, remarkably to simplify it, being in fact the very relations the analyst would fix upon to limit his symbols, and give his final equations the greatest simplicity their nature admits, if left at his disposal. For, it will be remarked, that in the general equation for the destruction of the spherical aberration, $\Delta \phi = 0$, or

$$0 = \frac{L}{\phi} (a' - \beta' D' + \gamma' D'^2) + \frac{L''}{\beta''} (a'' + \beta'' D'' + \gamma'' D'^2) + \&c.;$$

the expressions within the parentheses are all of the second degree when expressed in terms of the curvatures of the surfaces, and of $D' = D$ the proximity of the radiant point to the first lens; and as $L'$, $L''$, &c. are respectively of the first degree, in terms of the curvatures, the whole is, in its general form, of the third degree, and the equation of a cubic form. But the conditions of aplanatism, which assign relations only between $L$, $L''$, &c. without involving $R$, $R''$, &c. enable us to eliminate these quantities and replace them in the above equation, by giving combinations of $a'$, $a''$, $b'$, $b''$, &c., so that it becomes reduced to a quadratic form, and its treatment simplified accordingly.

Let us proceed now to develop the equation (d), in which, according to the foregoing remark, the conditions of aplanatism are introduced, $L$, $L''$, &c. may be regarded as given quantities; for, taking $L = L + L'' + \&c. =$ the power of the compound lens, (which we may suppose given, or, if we please, assume equal to unity) this, combined with the equations (a), determines the values of $L$, &c. Thus, in the case of two lenses, if we put $\pi$ for the ratio of the dispersive powers, or $\zeta = \frac{a'}{a''}$ we have $L' = \frac{L}{1 - \zeta}$, $L'' = \frac{-\pi L}{1 - \zeta}$; and similarly for three or more lenses. Suppose then we represent by $r'$, $r''$, $r'''$, &c. the respective curvatures of the first, or anterior surfaces of the first, second, third, &c., lens, in order; the first being that on which the rays first fall. Then we have $L' = (a' - 1) (R' - R'') = (\mu' - 1) (r' - R'')$ so that $R'' = r' - \frac{L}{\mu' - 1}$; and similarly $R'' = r'' - \frac{L''}{\mu'' - 1}$, &c. We must therefore put in the foregoing expressions

$$R' = r'; \quad R'' = r' - \frac{L'}{\mu' - 1}; \quad R''' = r''; \quad R'''' = r'' - \frac{L''}{\mu'' - 1}, \&c.
466. For brevity, let us represent by $X$, the terms of this expression, independent of the quantity $D$; by $Y$, the assemblage of terms multiplied by $D'$; and by $Z$, those multiplied by $D''$, and we shall have

$$\Delta f = \frac{Y}{2} \{ X + Y \cdot D + Z \cdot D' \} ;$$

and if this vanish the aberration is destroyed. Now, first, if we regard only parallel rays, or suppose $D = 0$, this reduces itself to $X = 0$, so that the condition $X = 0$ being satisfied, the telescope will be perfect when used for astronomical purposes, or for viewing objects so distant that $D'$ may be disregarded.

The equation $X = 0$ is of the second degree in each of the quantities $r', r''$, &c., whose number is that of the lenses. Consequently, this condition alone is not sufficient to fix their values; and, without assuming some further relations between them, or some other limitations, the problem is indeterminate, and the aberration may be destroyed in an infinite variety of ways. Confining ourselves at present to the consideration of two lenses only, since $X = 0$ contains only two unknown quantities, one other equation only is required, and we have only to consider what other condition will be attended with the greatest practical advantages. Clairaut has proposed to adjust the two lenses so as to have their adjacent surfaces in contact throughout their whole extent, to allow of their being cemented together, and thus avoid the loss of light by reflection at these surfaces. This certainly would be a great advantage were it possible so to cement two glasses of large size together, as to bring neither of them into a state of strain as the cement cools, or otherwise fixes; and were it not for the further inconvenience, that the media being of course differently expandable by heat, every subsequent change of temperature would necessarily distort their figure, as well as strain their parts, when thus forcibly held together, just as we see a compound lamina of two differently expandable metals assume a greater or less curvature, according to the temperature it is exposed to. Meanwhile the condition in question is algebraically expressed by $L'' = (\mu - 1) (r'' - r')$; for in this case $R'' = r'$, and $R'''' = r''$, and this being of the first degree only in $r'$, $r''$ affords a final equation of a quadratic form by elimination with $X = 0$, which latter, in the case before us of two lenses, is the same as the equation (v), Art. 312, writing only $r'$ for $R'$, and $r''$ for $R''$. 

$$\alpha' = (2 + \mu') r'^{\prime} - (2 \mu' + 1) \cdot \frac{r'}{\mu' - 1} \cdot L' + r' \cdot \left( \frac{\mu}{\mu' - 1} \right)^{2} L'' ,$$

$$\beta' = (4 + 4 \mu') r' - (3 \mu' + 1) \cdot \frac{r'}{\mu' - 1} \cdot L' ,$$

$$\gamma' = 2 + 3 \mu' ,$$

and similarly for $\alpha''$, $\beta''$, $\gamma''$, &c. So that, substituting again these expressions, and putting for $D''$ its equal $L' + D'$, for $D'''$ its equal $L' + L'' + D'$, and so on, we have, finally, for the general equation $\Delta f = 0$, as follows:

$$0 = \left\{ \left( \frac{2}{\mu'} + 1 \right) L' + r' \cdot \left( \frac{2}{\mu' - 1} \right)^{2} L'' + r' \cdot \left( \frac{2}{\mu'' - 1} \right)^{2} L''' + \ldots \right\}$$

$$- \left\{ \left( \frac{2}{\mu' - 1} \right)^{2} L' + r' \cdot \left( \frac{2}{\mu'' - 1} \right)^{2} L'' + r' \cdot \left( \frac{2}{\mu''' - 1} \right)^{2} L''' + \ldots \right\}$$

$$- 4 \left\{ \left( \frac{2}{\mu} + 3 \right) L'' + \left( \frac{2}{\mu''} + 3 \right) (L' + L') \right\}$$

$$+ \left\{ \left( \frac{2}{\mu'} + 3 \right) L' + \left( \frac{2}{\mu''} + 3 \right) L'' + \left( \frac{2}{\mu'''} + 3 \right) L''' + \ldots \right\}$$

$$- D \cdot \left\{ \left( \frac{2}{\mu'} + 3 \right) L' + \left( \frac{2}{\mu''} + 3 \right) L'' + \left( \frac{2}{\mu'''} + 3 \right) L''' + \ldots \right\}.$$
But this condition of Clairaut’s has another and much greater inconvenience, which is, that the resulting quadratic has its roots imaginary, when the refractive and dispersive powers of the glasses are such as are by no means unlikely to occur in practice; and without the limits of refraction and dispersion, for which they are real, the resulting curvatures change so rapidly on slight variations of the data, as to make their computation delicate, and interpolation between them, so as to form a table, very troublesome. D’Alembert, in his Opuscules, tom. iii., has proposed a variety of other limitations, such, for instance, as annihilating the spherical aberration for rays of all colours, (which comes to the same as supposing at once \( X = 0 \) and \( \frac{6}{2} \mu' + \frac{1}{2} \mu'' = 0 \), and which leads to biquadratic equations, and affords no practical advantage,) &c. But, without going into useless refinements of this kind, the very form of the general equation \( X^2 + Y^2 = 0 \) points out a condition combining every advantage the case is susceptible of. This consists in putting \( Y = 0 \). By this supposition, the term depending on \( Y \) is destroyed, without assuming \( Y = 0 \); so that the telescope is not only perfect for parallel rays, but admits of as considerable a proximity of the object without losing its aplanatic character, as the nature of the case will allow. The term \( Z \cdot D'' \) indeed, or

\[
D'' \cdot \left\{ \left( \frac{2}{\mu''} + 3 \right) L' + \left( \frac{2}{\mu''} + 3 \right) L'' \right\},
\]

cannot vanish when two lenses only are used, being composed wholly of given functions of the refractive and dispersive powers, unless by \( D'' \) itself vanishing, or by an accidental adjustment of the values of \( \mu', \mu'', L', \) &c. But except the object be brought within a comparatively small distance from the telescope, (such as ten times its own length,) the square of \( D'' \) is always so small as to allow of our disregarding this term, and considering the instrument as perfectly aplanatic when \( Y = 0 \). Now this equation, being of the first degree in \( r', r'' \), adds no new algebraic difficulty to the problem, but leads by elimination to a final quadratic; and, what is of most consequence, for such values of \( \mu', \mu'', \) and the dispersive ratio \( w \) as occur in practice, the roots of this quadratic are always real, and the resulting curvatures of all the surfaces are moderate, and well adapted for practice; more so, indeed, than in any construction hitherto proposed. They are, moreover, such as to afford remarkable and peculiar facilities for interpolation, as we shall presently see. These reasons seem to leave no room for hesitation in fixing on the condition \( Y = 0 \), as that which ought to be introduced to limit the problem of the construction of a double object-glass, and to render it, so far as it can be rendered, aplanatic.

This equation, in the case in question, is

\[
0 = 4 \left( 1 + \frac{1}{\mu'} \right) L' r' + 4 \left( 1 + \frac{1}{\mu''} \right) L'' r'' - \frac{3}{\mu' - 1} L' L'' - \left( 6 + \frac{4}{\mu''} \right) L' L'' - \frac{3}{\mu'' - 1} L' L''; \quad (f)
\]

which is to be combined with \( (r) \), Art. 412, in which \( R' = r' \) and \( R'' = r'' \). To reduce these to numbers, \( \mu', \mu'', \) and the dispersive ratio \( w \) must first be known. The readiest and most certain way in practice, for the use of the optician, is to form small object-glasses from specimens of the glasses intended to be employed, and by trial work them till the combination is as free from colour as possible, by the test usually had recourse to in practice. This is, to examine with a high magnifying power the image of a well defined white circle, or circular annulus on a black ground. If its edges are totally free from colour, the adjustment is perfect, but (owing to the secondary spectrum) this will seldom be the case; and there will generally be seen on the interior edge of the annulus a faint green, and on the exterior a purplish border, when the telescope is thrown a little out of focus by bringing the eye-glass near to the object-glass, and vice versa. The reason is, that while the great mass of orange and blue rays is collected in one focus, the red and violet are converged to a focus farther from, and the green to one nearer to the object-glass; the refraction of the green rays being in favour of the convex or crown glass, and of the red and violet (which united form purple) in favour of the flint (see table, Art. 443) or concave lens. The focal lengths of the lenses are then to be accurately determined, and the ratio of the dispersions \( (w) \) will then be known, being the same with that of the focal lengths (454). The refractive indices will be best ascertained by direct observation, forming portions of each medium into small prisms. Now, \( w \) being known, if we take unity for the power of the compound lens, we have \( L' = \frac{1}{1 - w} \) and \( L'' = - \frac{w}{1 - w} \), so that \( L' \) and \( L'' \) are known, and we have therefore only to substitute their values and those of \( \mu', \mu'', \) in the algebraic expressions, and proceed to eliminate by the usual rules. The following compendious table contains the result of such calculations for the values of \( \mu', \mu'', w \) therein stated, together with the amount of variation produced by varying either of the refractive indices independently of the other, for the sake of interpolation by proportional parts. Fig. 108 is a representation of the resulting object-glass.
Table for finding the Dimensions of an Aplanatic Object-glass.

Refractive index of crown, or convex lens = \( \mu' = 1.524 \).
Refractive index of flint, or concave lens = \( \mu'' = 1.585 \).
Compound focal length = 10.000.

To apply this table to any other proposed state of the data, we have only to consider that to compute the radius of any one of the surfaces, as the first or fourth, we have only to regard each element as varying separately, and take proportional parts for each. The following example will elucidate the process: Required the dimensions for an object-glass of 30 inches focus, the refractive index of the crown glass being 1.519, and that of the flint 1.589; the dispersive powers being as 0.567: 1, or 0.567 being the dispersive ratio. Here \( \mu' = 1.519 \), \( \mu'' = 1.589 \), and \( \omega = 0.567 \). The computation must first be instituted for a compound focus = 10.000, as in the table, and we proceed thus:

1st. Subtract the decimal (0.567) representing the dispersive ratio from 1.000, and 10 times the remainder (= 10 \times 0.433 = 4.330) is the focal length of the crown lens.

2nd. Divide unity by the decimal above mentioned, \((0.567,)\) subtract 1.000 from the quotient \( \frac{1}{0.567} - 1.7685 \), minus 1 = 0.7685 and the remainder multiplied by 10 (or 7.685) is the focal length of the flint lens. We must next determine by the tables the radii of the first and fourth surfaces for the dispersive ratios there set down (0.55 and 0.60) next less and next greater than the given one. For this purpose we have

Refractive powers given.

1.519 and 1.589

Refractive powers in table

1.524 and 1.585

Differences

- 0.005

+ 0.004

The given refraction of the crown being less, and of the flint greater, than their average values on which the table is founded. Looking out now opposite to 0.55 in the first column for the variations in the two radii corresponding to a change of + 0.010 in the two refractions, we find as follows:

<table>
<thead>
<tr>
<th>First surface.</th>
<th>Fourth surface.</th>
</tr>
</thead>
<tbody>
<tr>
<td>For a change = + 0.010 in the crown</td>
<td>+ 0.0740 + 1.0080</td>
</tr>
<tr>
<td>For a change = + 0.010 in the flint</td>
<td>- 0.0011 - 0.5033</td>
</tr>
</tbody>
</table>

But the actual variation in the crown instead of + 0.010 being - 0.005, and of the flint + 0.004, we must take the proportional parts of these, changing the sign in the former case; thus we find the variations in the first and last radii to be.
If we interpolate, by a process exactly similar, the same two radii for a dispersive ratio 0.60, we shall find, respectively,

<table>
<thead>
<tr>
<th></th>
<th>First surface</th>
<th>Fourth surface</th>
</tr>
</thead>
<tbody>
<tr>
<td>For a variation of -0.005 in the crown</td>
<td>-0.0338</td>

<tr>
<td>Radii in table</td>
<td>6.7069</td>
<td>14.2937</td>
</tr>
<tr>
<td>Interpolated radii</td>
<td>6.6746</td>
<td>13.5149</td>
</tr>
</tbody>
</table>

Having thus got the radii corresponding to the actual refractions for the two dispersive ratios 0.55 and 0.60, it only remains to determine their values for the intermediate ratios 0.567 by proportional parts; thus

<table>
<thead>
<tr>
<th></th>
<th>in.</th>
<th>in.</th>
<th>in.</th>
</tr>
</thead>
<tbody>
<tr>
<td>First radius</td>
<td>6.6746</td>
<td>13.5149</td>
<td></td>
</tr>
<tr>
<td>For ....</td>
<td>0.600</td>
<td>6.6746</td>
<td>13.5149</td>
</tr>
<tr>
<td>For ....</td>
<td>0.550</td>
<td>6.6810</td>
<td>13.8300</td>
</tr>
<tr>
<td>Differences + 0.050</td>
<td>-0.0064</td>
<td>-0.3151</td>
<td></td>
</tr>
</tbody>
</table>

So that 6.6810 - 0.0064 = 6.6746, and 13.8300 - 0.3151 = 13.5149, are the true radii corresponding to the given data. Thus we have, for the crown lens, focal length = 4.330 = \( \frac{1}{L} \), radius of first surface = 6.6796

\[ \frac{1}{R} \text{, index of refraction} = 1.519 = \mu', \text{whence by the formula} \quad L' = (\mu' - 1) (R' - R'') \frac{1}{R''} \text{ radius of the other surface is} - 3.3868. \]

Again, for the flint lens, the focal length = \( \frac{1}{L''} = -7.635 \), radius of the posterior surface = \( \frac{1}{R''} = -13.7729 \), index of refraction \( \mu'' = 1.589 \), whence we find \( \frac{1}{R''} = -3.3871 \) for the radius of the other surface. The four radii are thus obtained for a focal length of 10 inches, and multiplying by 3 we have for the telescope proposed

radius of first surface = + 20.0364; of second, -10.1604; of third, -10.1613; of fourth, -41.1687.

Here, then, we see that the radii of the two interior surfaces of the double lens (fig. 108) differ by scarcely more than a thousandth part of an inch; so that, should it be thought desirable, they may be cemented together. This is not merely a casual coincidence, for the particular state of the data; if we cast our eyes down the table we shall find this approximate equality of the interior curvatures (those of the second and third surfaces) maintained in a singular manner throughout the whole extent of the variation of \( \mu \). Thus the construction, here proposed in reality for glasses of the ordinary materials, approaches considerably to that of Clairaut already mentioned.

In order to put these results to the test of experience, Mr. South procured an achromatic telescope to be executed on this construction by Mr. Tulley, one of the most eminent of our British artists, which is now in the possession of J. Moore, Esq. of Lincoln. Its focal length was 45 inches, and aperture 3\( \frac{1}{2} \), and its performance was found to be fully adequate to the expectation entertained of it, bearing a magnifying power of 300 with perfect distinctness, and separating easily a variety of double stars, &c. A more minute account of its performance will be found in the Journal of the Royal Institution, No. 26. Should the splendid example set by Fraunhofer be followed up, and the practice of the optician be in future directed by a rigorous adherence to theory, grounded on exact measurements of the refractive powers of his glasses on the several coloured rays, it will become necessary to develop the above table more in detail.

When three media are employed in the construction of object-glasses, it should be our object to obtain as great a difference as possible in their scales of action on the differently coloured rays. Dr. Blair, to whom we are indebted for the first extensive examination of the dispersive powers of media as a physical character, and glasses of three media who first perceived the necessity of destroying the secondary spectrum, and pointed out the means of doing it, is the only one hitherto who has bestowed much pains on this important part of practical optics; which, considering the extraordinary success he obtained, and the perfection of the telescopes constructed on his principles, is to be regretted. We have no idea, indeed, for the reasons already mentioned, that very large object-
glasses, enclosing fluids, can ever be rendered available; but to render glasses of moderate dimensions more perfect, and capable of bearing a higher degree of magnifying power, is hardly less important as an object of practical utility. His experiments are to be found in the *Transactions of the Royal Society of Edinburgh*, 1791. We can here do little more than present a brief abstract of them.

Dr. Blair having first discovered that the secondary fringes are of unequal breadths, when binary achromatic combinations, having equal total refractions, are formed of different dispersive media, was immediately led to consider, that by employing two such different combinations to act in opposition to each other, if the total refractions were equal, the ray would emerge of course undeviated, and with its primary spectrum destroyed; but a secondary spectrum would remain, equal to the difference of the secondary spectra in the two combinations. Therefore, by a reasoning precisely similar to that which led to the correction of the primary spectrum itself, (Art. 426 and 427,) if we increase the total refraction of that combination A which, *ceteris paribus*, gives the least secondary spectrum, its secondary colour will be increased accordingly, till it becomes equal to that of the other B; so that the emergent beam will be free from the secondary spectra altogether, and will be deviated on the whole in favour of the combination A. Reasoning on these grounds, Dr. Blair formed a compound, or binary achromatic convex lens A, (fig. 109,) of two fluids a and b, (two essential oils, such as naphtha and oil of turpentine, differing considerably in dispersion,) which, when examined alone, was found to have a greater refractive power on the green rays than on the united red and violet. He also formed a secondary binary lens B, of a concave character, and also achromatic, (i. e. having the primary spectrum destroyed,) consisting of the more dispersive oil (b) and glass, and in which the green rays are also more refracted than the united red and violet, but in a greater degree, in proportion to the whole deviation, than in the other combination; and in precisely the same degree was the focal length of this lens increased or its refraction diminished, when compared with that of the combination A. When, therefore, these two lenses were placed together, as in fig. 109, an excess of refraction remained in favour of the convex combination; but the secondary spectra of each being equal and opposite (by reason of the opposite character of the lenses) were totally destroyed. In fact, he states, that in a compound lens so constructed, he could discover no colour by the most rigid test; and hence concluded, not only the red, violet, and green to be united, but also all the rest of the rays, no outstanding colour of blue or yellow being discernible. In placing the lenses together, the intermediate plane glasses may be suppressed altogether, as in fig. 110.

It was in the course of these researches that Dr. Blair was led to the knowledge of the possibility of forming binary combinations, having secondary spectra of opposite characters; that is, in which (the total refraction lying the same way) the order of the colours in the secondary spectra should be inverted. In other words, that while in some combinations the green rays are more refracted than the united red and violet, in others they are less so. He found, for instance, that while in most of the highly dispersive media, including metallic solutions, the green lay among the less refrangible rays of the spectrum, there yet exist media considerably dispersive, in which the reverse holds good. The muriatic acid, among others, is in this predicament. Hence, in binary combinations of glass with this acid, the secondary spectrum consists of colours oppositely disposed from that formed by glass and the oils, or by crown and flint glass. In consequence of this, to form an object-glass of two binary combinations, as described in the last article, they must both be of convex characters. But this affords no particular advantage. Dr. Blair, however, considered the matter in another and much more important light, as offering the means of dispensing with a third medium altogether, and producing by a single binary combination a refraction absolutely free from secondary colour. To this end he considered, that it appears to depend entirely on the chemical nature of the refracting medium, what shall be the order and distribution of the colours in the spectrum, as well as what shall be the total refraction and dispersive powers of the medium; and that therefore by varying properly the ingredients of a medium, it may be practicable, without greatly varying the total refraction and dispersion, still to produce a considerable change in the internal arrangement (if we may use the phrase) of the spectrum; and therefore, perhaps, to form a compound medium in which the seven colours shall occupy spaces regulated by any proposed law, (within certain limits.) Now if a medium could be so compounded as to have the same scale of dispersions, or the same law of distribution of the colours as crown glass with a different absolute dispersion, as we have already seen, nothing more would be required for the perfection of the double object-glass. The property of the muriatic acid just mentioned puts this in our power.

It is observed, that the presence of a metal (antimony, for instance) in a fluid, while it gives it a high refractive and dispersive power, at the same time tends to dilate the more refrangible part of the spectrum beyond its due proportion to the less. On the other hand, the presence of muriatic acid tends to produce a contrary effect, contracting the more refrangible part and dilating the less, beyond that proportion which they have in glass. Hence, Dr. Blair was led to conclude, that by mixing muriatic acid with metallic solutions, in proportions to be determined by experience, a fluid might be obtained with the wished for property; and this on trial he found to be the case. The metals he used were antimony and mercury; and to ensure the presence of a sufficient quantity of muriatic acid, he employed them in the state of muriates, in aqueous solution; or, in the case of mercury, in a solution of salt ammoniac, which is a compound of ammonia and muriatic acid, and which is capable of dissolving a considerably greater quantity of corrosive sublimate (muriate, or chloride of mercury) than water alone. By adding liquid muriatic acid to the compound known by the name of butter of antimony, (an oxide of antimony) or sal ammoniac to the mercurial solution, he succeeded completely in obtaining a spectrum in which the rays followed the same law of dispersion as in crown glass, and even in over-correcting the secondary spectrum, so as to place its exact destruction completely in his power. It only remained to form an object-glass on these principles. Fig. 111 is such an one, in which, though there are two refractions at the confines of the glass and fluid, yet the chromatic aberration, as Dr. Blair assures us, was totally destroyed, and the rays of different colours were bent from their rectilinear course with the same equality as in reflexion.
To such an extent has Dr. Blair carried these interesting experiments, that he assures us he has found it practicable to construct an object-glass of nine inches focal length, capable of bearing an aperture of three inches, a thing which assuredly no artist would ever dream of attempting with glass lenses; and we cannot close this account of his labours without joining in a wish expressed on a similar occasion by Dr. Brewster, whose researches on dispersive powers have so worthily filled up the outline sketched by his predecessor, that this branch of practical optics may be resumed with the attention it deserves, by artists who have the ready means of executing the experiments it would require. Could solid media of such properties be discovered, the telescope would become a new instrument.

These experiments of Dr. Blair lead to the remarkable conclusion, that at the common surface of two media a white ray may be refracted without separation into its coloured elements. In fact, \( \mu \) and \( \mu' \) being the refractive indices of the media for any ray as the extreme red, \( \frac{\mu'}{\mu} \) will be their relative refractive index for that ray, and \( \frac{\mu' + \mu''}{\mu + \mu'} \) will be the relative index for any other ray. If, then, the refractive and dispersive powers of the media be such that \( \frac{\mu' + \mu''}{\mu + \mu'} = \frac{\mu'}{\mu} \) or \( \mu' \mu'' = \mu' \mu \), that is, if \( \frac{\mu'}{\mu''} = \frac{\mu}{\mu'} \) and if, moreover, this relation hold good throughout the spectrum, i.e. if the increments of the refractive indices, in proceeding from the red to the violet end of the spectrum, be proportional to the refractive indices themselves, then the relative index is the same for all rays, and no dispersion will take place. Now this gives a relation between the dispersive and refractive indices of the two media, viz. \( \frac{\mu'}{\mu} = \frac{\mu' - 1}{\mu'' - 1} = \frac{1 - \frac{1}{\mu'}}{1 - \frac{1}{\mu''}} \); and, in addition to this condition, the scale of dispersions must be the same in both media. According as the dispersions differ one way or the other from this precise adjustment, the violet ray may be either more or less refracted than the red at the common surface of the two media.

We shall terminate the theory of achromatic object-glasses with a problem of considerable practical importance, as it puts it in our power, having obtained an approximate degree of achromatism in an object-glass, to Achromatic complete the destruction of the colour without making any alteration in the focal lengths or curvatures of the object-glass lenses, by merely placing them at a greater or less distance from one another.

**Problem.** To express the condition of achromatism, when the two lenses of a double object-glass are placed at a distance from each other, (= t.)

Resuming the notation of Art. 251 and 268, we have

\[
f'' = L' + D; \quad f' = L'' + \frac{f''}{1 - f'' t}; \quad f'' = L';
\]

and

\[
f' = L'' + \frac{f''}{(1 - f'' t)^2} = L'' + \frac{L'}{1 - t (L' + D)}.
\]

Now, that the combination may be achromatic, we must have \( f'' = 0 \); and, since \( t \) and \( D \) are constant, and \( L' \) and \( L'' \) only vary by the variations of \( \mu' \) and \( \mu'' \) the refractive indices, we have \( L' = (R' - R') \mu' = \frac{1}{\mu' - 1} L' = p'L' \), and similarly \( L'' = p'' L'' \), so that substituting we get

\[
\{ 1 - t (L' + D) \} \mu'' + \frac{p''}{L''} \cdot L' = 0.
\]

Such is the condition of achromatism. Since it depends on \( D \), it appears that if the lenses of an object-glass be not close together, it will cease to be achromatic for near objects, however perfectly the colour be corrected for distant ones. The eye therefore cannot be achromatic for objects at all distances, its lenses being of great thickness compared to their focal lengths; and, therefore, although in contact at their adjacent surfaces, yet having considerable intervals between others.

For parallel rays the equation becomes

\[
p'' L'' (1 - t L') = -p'L';
\]

hence, the dispersions and powers of the lenses being given their interval \( t \) may be found by the expression

\[
t = \frac{1}{L'} \left\{ 1 - \sqrt{\frac{p'}{L'}} \cdot \frac{L'}{L''} \right\}.
\]

The condition of achromacity, were the lenses placed close together, would be, as we have already shown,
§ III. Of the Absorption or Extinction of Light by uncrystallized Media.

Transparency is the quality by which media allow rays of light freely to pass through their substance, or, it may be, between their molecules; and is said to be more or less perfect, according as a more or less considerable part of the whole light which enters them finds its way through. Among media, consisting of ponderable matter, we know of none whose transparency is perfect. Whether it be that some of the rays in their passage encounter bodily the molecules of the media, and are thereby reflected; or, if this supposition be thought too coarse and unrefined for the present state of science, be stopped or turned aside by the forces which reside in the ultimate atoms of bodies, without actual encounter, or otherwise detained or neutralized by them; certain it is, that even in the most rare and transparent media, such as air, water, and glass, a beam of light intromitted, is gradually extinguished, and becomes more and more feeble as it penetrates to a greater depth within them, and ultimately becomes too faint to affect our organs. Thus, at the tops of very high mountains, a much greater multitude of stars is visible to the naked eye than on the plains at their feet; the weak light of the smallest of them being too much reduced in its passage through the lower atmospheric strata to affect the sight. Thus, too, objects cease to be visible at great depths below water, however free from visible impurities, &c. Dr. Olbers has even supposed the same to hold good with the imponderable media (if any) of the celestial spaces, and conceives this to be the cause why so few stars (not more than about five or ten millions) can be seen with the most powerful telescopes. It is probable that we shall be long without means of confirming or refuting this singular doctrine.

On the other hand, though no body in nature be perfectly, all are to a certain degree, transparent. One of the densest of metals, gold, may actually be beaten so thin as to allow light to pass through it; and that it passes through the substance of the metal, not through cracks or holes too small to be detected by the eye, is evident from the colour of the transmitted light, which is green, even when the incident light is white. The most opaque of bodies, charcoal, in a different state of aggregation, (as diamond,) is one of the most perfectly transparent; and all coloured bodies, however deep their hues, and however seemingly opaque, must necessarily be rendered visible by rays which have entered their substance; for if reflected at their surfaces, they would all appear white alike. Were the colours of bodies strictly superficial, no variation in their thickness could affect their hue; but, so far is this from being the case, that all coloured bodies, however intense their tint, become paler by diminution of thickness. Thus the powders of all coloured bodies, or the streak they leave when rubbed on substances harder than themselves, have much paler colours than the same bodies in mass.

This gradual diminution in the intensity of a transmitted ray in its progress through imperfectly transparent media, is termed its absorption. It is never found to affect equally rays of all colours, some being always absorbed in preference to others; and it is on this preference that the colours of all such media, as seen by transmitted light, depend. A white ray transmitted through a perfectly transparent medium, ought to contain at its emergence the same proportionate quantity of all the coloured rays, because the part reflected at its anterior and posterior surfaces is colourless; but, in point of fact, such perfect want of colour in the transmitted beam is never observed. Media, then, are unequally transparent for the differently coloured rays. Each ray of the spectrum has, for every different medium in nature, its own peculiar index of transparency, just as the index of refraction differs for different rays and different media.

The most striking way in which this different absorptive power of one and the same medium on differently coloured rays can be exhibited, is to look through a plain and polished piece of small-blue glass, (a rich deep blue, very common in the arts—such as sugar-basins, finger-glasses, &c. are often made of,) at the image of any narrow line of light (as the crack in a window-shutter of a darkened room) refracted through a prism whose edge is parallel to the line, and placed in its situation of minimum deviation. If the glass be extremely thin, all the colours are seen; but if of moderate thickness (as \( \frac{1}{4} \) inch) the spectrum will put on a very singular and striking appearance. It will appear composed of several detached portions separated by broad and perfectly black
Light.

Curvesrepresentingthequantitiesof theraystransmittedby thethicknesses2,3,&c.of the medium, and so for
thatthe raysin the actof traversingone stratumof a medium acquireno additionalfacilityto penetratethe
remainder.In this doctrine, y is necessarily a fraction smaller than unity, and dependingon the nature bothof
the ray and the medium. Hence, if C representthe number of equally illuminatingrays of the extreme red
in a beam of white light, C' that of the next degree of refrangibility, and so on ; the beam of white light willbe
representedby C + C' + C"+ &c.; and thetransmitted beam, aftertraversing the thickness t, willbe properly
expressed by
C. y' + C'. y'' + C". y"'+ &c.
Each term representingthe intensity of the particular ray to which it corresponds, or its ratio to what it is in
theoriginal white beam.

It is evident from this, that, strictly speaking, total extinction can never take place by any finite thickness
of the medium ; but if the fraction y for any ray be at all small, a moderate increase in the thickness, (which enters
as an exponent,) willreduce the fraction y' to a quantity perfectly insensible., Thus, in the case taken above,
where a tenth of an inch of green glass destroys one-tenth only of the red rays, a whole inch will allow to pass
only
\( \left( \frac{9}{10} \right)^{10} = 0.00000866, \) or less than three rays out of 100,000 to pass, which amounts to almost absolute
opacity.

If x be the index of refraction of any ray in the water spectrum, we may regard y as a function of x; and if on
the line R V, (fig.112,) representing the whole length of the water spectrum, we erect ordinates, Rr, MN, V v equal
to unity and to each other; and also other ordinates R r, M P, V v representing the values of y for the rays at
the corresponding points; the curve r P v, the locus of P, will be, as it were, a type, or geometrical picture of
the action of the medium on the spectrum, and the straight line R N V will be a similar type of a perfectly
transparent medium. Now if this be supposed the case when the thickness of the medium is 1, if we take
always M P': M P : M N, and M P": M P': M P: &c. and so on, the loci of P" P", &c. will be
curves representing the quantities of the rays transmitted by the thicknesses 2, 3, &c. of the medium, and so for
intermediate thicknesses, or for a thickness less than 1, as in the curve e n r.

Hence, whatever be the colour of a medium, if its thickness be infinitely diminished, it will transmit all the
raysindifferently; for when t = 0, y' = 1, whatever be y; and the curve e n v approaches infinitely near to the
line R N V'. Thus all coloured glasses blown into excessively thin bubbles are colourless, and so is the foam
of coloured liquids.

Again, if there be any, the least, preference given by the medium to the transmission of certain rays beyond
others, the thickness of the medium may be so far increased as to give it any assignable depth of tint; for if y
beever so little less than unity, and if between the values of y for different rays there be ever so little difference,
t may be so increased as to make y' as small as we please, and the ratio of y' to y' as different from unity as
we please.

In very deep coloured media all the values of y are small. If they were equal, the medium would merely
stoplight, without colouring the transmitted beam, but no such media are at present known.

If the curve e P", or the type of an absorbent medium have a maximum in any part of the spectrum, as in the
green, for instance, (fig. 113;) then, whatever be the proportion in which the other rays enter, by a sufficient
increase of thickness, that colour will be rendered predominant; and the ultimate tint of the medium, or the
last ray it is capable of transmitting, will be a pure homogeneous light of that particular refrangibility to which
the maximum ordinate corresponds. Thus green glasses, by an increase of thickness, become greener and
greener, their type being as in fig. 113; while yellow ones, whose type is as in fig. 114, change their tint by
reduplication, and pass through brown to red.

This change of tint by increase of thickness is not uncommon phenomenon; and though at first sight para-
doxical, yet is a necessary consequence of the doctrine here laid down. If we enclose a pretty strong solution
of sap-green, or, still better, of muriate of chromium in a thin hollow glass wedge, and if we look through the
edge where it is thinnest, at white paper, or at the white light of the clouds, it appears of a fine green; but if
we slide the wedge before the eye gradually so as to look successively through a greater and greater thickness
of the medium, it becomes of a deeper green; then, as the thickness is still increased, it becomes a dark green;
and if we bring it up to the eye, it appears of a deep black.
of the liquid, the green tint grows livid, and passes through a sort of neutral, brownish hue, to a deep blood-
red. To understand this, we must observe, that the curves expressing the types of different absorbent media
admit the most capricious variety of form, and very frequently have several maxima and minima corresponding
to as many different colours. The green liquids in question have two distinct maxima, as in fig. 115; the one
corresponding to the extreme red, the other to the green, but the absolute lengths of the maximum ordinates
are unequal, the red being the greater. But as the extreme red is a very feebly illuminating ray, while on the
other hand the green is vivid, and affects the eye powerfully, the latter at first predominates over the former, and
entirely prevents its becoming sensible; and it is not till the thickness is so far increased as to leave a very great
preponderance of those obscure red rays, and subdue their rivals, as in the case represented by the lowest of
the dotted curves in the figure, that we become sensible of their influence on the tint. Suppose, for instance,
to illustrate this by a numerical example, the index of transparency, or value of y, in muriate of chromium, to
be for extreme red rays, 0.9; for the mean red, orange, and yellow, 0.1: for green, 0.5; and for blue, indigo,
and violet, 0.1 each; and suppose, moreover, in a beam of white light, consisting of 10,000 rays, all equally
illuminative, the proportions corresponding to the different colours to be as follows:

<table>
<thead>
<tr>
<th>Extreme red</th>
<th>Red and orange</th>
<th>Yellow</th>
<th>Green</th>
<th>Blue</th>
<th>Indigo</th>
<th>Violet</th>
</tr>
</thead>
<tbody>
<tr>
<td>200</td>
<td>1300</td>
<td>3000</td>
<td>2800</td>
<td>1200</td>
<td>1000</td>
<td>500</td>
</tr>
</tbody>
</table>

Then, after passing through a thickness equal to 1 of the medium, the proportions in the transmitted beam
would be

<table>
<thead>
<tr>
<th>Extreme red</th>
<th>Red and orange</th>
<th>Yellow</th>
<th>Green</th>
<th>Blue</th>
<th>Indigo</th>
<th>Violet</th>
</tr>
</thead>
<tbody>

</tbody>
</table>

Thus we see, that in the first of these transmitted beams the green greatly preponderates, after the second
transmission, it is still the distinguishing colour: but after the third, the red bears a proportion to it large
enough to impair materially the purity of its tint. The fourth transmission may be regarded as totally extin-
guishing all the other colours, and leaving a neutral tint between red and green; while, in all the tints
produced by further successive transmissions, the red preponderates continually more and more, till at length
the tint becomes no way distinguishable from the homogeneous red of the extremity of the spectrum.

Whether we suppose the obscurer parts of the spectrum to consist of fewer rays equally illuminative, or of
the same number of rays of less intrinsic illuminating power with the brighter, obviously makes no difference in
the conclusion, but the former supposition has the advantage of affording a hold to numerical estimation which
the latter does not. In the instance here taken, the numbers are assumed at random. But Fraunhofer has made a
series of experiments expressly to determine numerically the illuminating power of the different rays of the spectrum.

According to which, he has constructed the curve fig. 116, whose ordinate represents the illuminating power
of the ray in that part of the spectrum on which it is supposed erected, or the proportional number of equally
illuminative rays of that refrangibility in white light. If we would take this into consideration in our geo-
metrical construction, we must suppose the type of white light, instead of being a straight line, as in fig. 112... 114, to be a curve similar to fig. 116, and the other derivative curves to be derived from it by the same rules
as above. But as the only use of such representations is to express concisely to the eye the general scale of action
of a medium on the spectrum, this is rather a disadvantageous than a useful refinement.

To take another instance. If we examine various thicknesses of the small-blue glass above noticed, it will
be found to appear purely blue in small thicknesses. As the thickness increases, a purple tinge comes on, which
becomes more and more ruddy, and finally passes to a deep red; a great thickness being, however, required, to
produce this effect. If we examine the tints by a prism, we shall find the type of this medium to be as in
fig. 117, having four maximum ordinates, the greatest corresponding to a ray at the very farthest extremity of the
red, and diminishing with such rapidity as to cause an almost perfect insulation of this ray; the next correspon-
da to a red of mean refrangibility, the next to the mean yellow, and the last to the violet, the ordinate increasing
continually to the end of the spectrum. Thus, when a piece of such glass of the thickness 0.042 inch was used, the
red portion of the spectrum was separated into two, the least refracted being a well defined band of per-
fectly homogeneous and purely red light, separated from the other red by a band of considerable breadth, and
totally black. This red was nearly homogeneous; its tint, however, differing in no respect from the former,
and being free from the slightest shade of orange. Its most refracted limit came very nearly up to the dark line
D in the spectrum. A small, sharp, black line separated this red from the yellow, which was a pretty well defined
band of great brilliancy and purity of colour, of a breadth exceeding that of the first red, and bounded on the,
light.  

Among transparent media of most ordinary occurrence, we may distinguish, first, those whose type has its ordinate decreasing regularly, with more or less rapidity from the red to the violet end of the spectrum, or which absorb the rays with an energy more or less nearly in some direct ratio of their refrangibility. In red and scarlet media the absorbent power increases very rapidly, as we proceed from the red to the violet. In yellow, orange, and brown ones, the yellow, orange, and brown ones, less so; but all of them act with great energy on the violet rays, and produce a total obliteration of them. In consequence of this, by an increase of thickness, all these media finally become red. Examples: red, scarlet, brown, and yellow glasses; port wine, infusion of saffron, permanganates of iron, muriate of gold, brandy, India soy, &c.

Among green media, the generality have a single maximum of transmission corresponding to some part of the green rays, and their hue in consequence becomes more purely green by increase of thickness. Of this kind are green glasses, green solutions of copper, nickel, &c. They absorb both ends of the spectrum with great energy; the red, however, more so, if the tint verges to blue; the violet, if to yellow. Besides these, however, are to be remarked media in which the type has two maxima; such may be termed dichromatic, having really two distinct colours. In most of these, the green maximum is less than the red; and the green tint, in consequence, loses purity by increase of thickness, and passes through a livid neutral hue to red, though this is not always the case. Examples: muriate of chrome, solution of sap-green, manganousate of potash, alkaline infusion of the petals of the peonia officinalis and many other red flowers, and mixtures of red and blue or green media.

Blue media admit of great variety, and are generally dichromatic, having two or even a great many maxima and minima in their types; but their distinguishing character is a powerful absorption of the more luminous red rays and the green, and a feeble action on the more refrangible part of the spectrum. Among those whose energy of absorption appears to increase regularly and rapidly from the violet to the red end of the spectrum, we may place the blue solutions of copper. The best example is the magnificent blue liquid formed by supersaturating sulphate of copper with carbonate of ammonia. The extreme violet ray seems capable of passing through almost any thickness of this medium; and this property, joined to the unalterable nature of the solution, and the facility of its preparation, render it of great value in optical researches. A vessel, or tube, of some inches in length, closed at two ends with glass plates, and filled with this liquid, is the best resource for experiments on the violet rays. Ammonio-oxalate of nickel transmits the blue and extreme red, but stops the violet.

Purple media act by absorbing the middle of the spectrum, and are therefore necessarily always dichromatic, some of them having red and others violet for their ultimate or terminal tint. Example: solution of archil; purple, plum-coloured, and crimson glasses; acid and alkaline solutions of cobalt, &c. They may be termed red-purple and violet-purple, according to their terminal tint.

In combinations of media, the ray finally transmitted is the residuum of the action of each. If $x$, $y$, $z$ be the indices of transmissibility of a given ray $C$ in the spectrum for the several media, and $r$, $s$, $t$ their thicknesses, the transmitted portion of this ray will be $C \cdot x^r y^s z^t$ and the residuum of a beam of white light (supposing none lost by reflexion at the surfaces) after undergoing the absorptive action of all the media, will be

$$C \cdot x^{r'} y^{s'} z^{t'} + C' \cdot x^r y^s z^t + \&c.$$

An expression which shows that it is indifferent in what order the media are placed. They may therefore be mixed, unless a chemical action take place. Thus also, by the same construction as that by which the type 1 of the first medium is derived from the straight line representing white light, may another type 2 be derived from it, and so on; and thus an endless variety of types will originate, having so many tints corresponding to them.

This circumstance enables us to insulate, in a state of considerable homogeneity, various rays. Thus, by combining with the small-blue glass, already mentioned, any brown or red glass of tolerable fulness and purity of colour, a combination will be formed absolutely impermeable to any but the extreme red ray, and the refrangibility of this is so strictly definite as to allow of its being used as a standard ray in all optical inquiries, which is the more valuable, as the coloured glasses by which it is insulated are the most common of any which occur in the shops, and may be had at any glazier's. If to such a combination a green glass be added, a total stoppage of all light takes place. The same kind of glass, too, enables us to insulate the yellow ray, corresponding to the maximum $Y$ in the type fig. 117, by combining it with a brown glass to stop out the more, and a green to destroy the less, refrangible rays, and by their means the existence of a considerable breadth of yellow light, evidently not depending on a mixture, or mutual encroachment of red and green, may be exhibited in the solar spectrum.

It has been found by Dr. Brewster, that the proportions of the different coloured rays absorbed by media depend on their temperature. The tints of bodies generally deepen by the application of heat, as is known to all who are familiar with the use of the blow-pipe; thus minium and red oxide of mercury deepen in their hues by heat till they become almost black, but recover their red colours on cooling. Dr. Brewster has, however, produced instances, not merely among artificial glasses, but among transparent minerals, where a transition takes place from red to green on the application of a high temperature; the original tint being, however, restored on cooling, and no chemical alteration having been produced in the medium.

The analysis of the spectrum by coloured media presents several circumstances worthy of remark. First, the irregular and singular distribution in the dark bands which cross the spectrum, when viewed through such
media as have several maxima of transmission, obviously leads us to refer Fraunhofer’s Fixed lines, and the analogous phenomena to be noticed in the light from other sources, to the same cause, whatever it may be, which determines the absorption of some ray in preference to others. It is no impossible supposition, that the deficient rays in the light of the sun and stars may be absorbed in passing through their own atmospheres, or, to approach still nearer to the organ of the light, we may conceive a ray stifled in the very act of emanation from a luminous molecule by an intense absorbent power residing in the molecule itself; or, in a word, the same indisposition in the molecules of an absorbent body to permit the propagation of any particular coloured ray through, or near them, may constitute an obstacle in time to the production of the ray from them. At all events, the phenomena are obviously related, though we may not yet be able to trace the particular maxima of their connection.

The next circumstance to be observed is, that when examined through absorbent media all idea of regular gradation of colour from one end to the other of the spectrum is destroyed. Rays of widely different refrangibility, as the two reds noticed in Art. 497, have absolutely the same colour, and cannot be distinguished. On the other hand, the transition from pure red to pure yellow, in the case there described, is quite sudden, and the contrast of colours most striking, while the dark interval which separates them, by properly adjusting the thickness of the glass, may be rendered very small without any tinge of orange becoming perceptible. What then, we may ask, is become of the orange; and how is it, that its place is partly supplied with red on one side, and yellow on the other? These phenomena certainly lead us very strongly to believe that the analysis of white light by the prism is not the only analysis of which it admits, and that the connection between the refrangibility and colour of a ray is not so absolute as Newton supposed. Colour is a sensation excited by the rays of light, and since two rays of different refrangibilities are found to excite absolutely the same sensation of colour, there is no prima facie absurdity in supposing the converse,—that two rays capable of exciting sensations of different colours may have identical indices of refraction. It is evident, that if this be the case, no mere change of direction by refractions through prisms, &c. could ever separate them; but should they be differently absorbable by a medium through which they pass, an analysis of the compound ray would take place by the destruction of one of its parts. This idea has been advocated by Dr. Brewster, in a Paper published in the Edinburgh Philosophical Transactions, vol. ix., and the same consequence appears to follow from experiments, published in the same volume of that collection. According to this doctrine, the spectrum would consist of at least three distinct spectra of different colours, red, yellow, and blue, overlapping each other, and each having a maximum of intensity at those points where the compound spectrum has the strongest and brightest tint of that colour.

It must be confessed, however, that this doctrine is not without its objections; one of the most formidable of which may be drawn from the curious affection of vision occasionally (and not very rarely) met with in certain individuals, who distinguish only two colours, which (when carefully questioned and examined by presenting to them, not the ordinary compound colours of painters, but optical tints of known composition) are generally found to be yellow and blue. We have examined with some attention a very eminent optician, whose eyes (or rather eye, having lost the sight of one by an accident) have this curious peculiarity, and have satisfied ourselves, contrary to the received opinion, that all the prismatic rays have the power of exciting and affecting them with the sensation of light, and producing distinct vision, so that the defect arises from no insensibility of the retina to rays of any particular refrangibility, nor to any colouring matter in the humours of the eye, preventing certain rays from reaching the retina, (as has been ingeniously supposed,) but from a defect in the sensorium, by which it is rendered incapable of appreciating exactly those differences between rays on which their colour depends. The following is the result of a series of trials, in which a succession of optical tints produced by polarized light, passing through an inclined plate of mica, in a manner hereafter to be described, was submitted to his judgment. In each case, two uniformly coloured circular spaces placed side by side, and having complementary tints (i. e. such that the sum of their light shall be white) were presented, and the result of his judgment is here given in his own words.
### Colours according to the judgment of an ordinary eye.

It appears by this, that the eyes of the individual in question are only capable of fully appreciating blue and yellow tints, and that these names uniformly correspond, in his nomenclature, to the more and less refrangible rays, generally; all which belong to the former, indifferently, exciting a sense of "blueness," and to the latter of "yellowness." Mention has been made of individuals seeing well in other respects, but devoid altogether of the sense of colour, distinguishing different tints only as brighter or darker one than another; but the case is, probably, one of extremely rare occurrence.

Mayer, in an Essay De Affinitate Colorum, (Opera inedita, 1775,) regards all colours as arising from three primary ones, red, yellow, and blue; regarding white as a neutral mixture of rays of all colours, and black as a mere negation of light. According to this idea, were we acquainted with any mode of mixing colours according to simple numerical ratios, a scale might be formed to which any proposed colour might be at once referred. He proposes to establish such a scale in which the degree of intensity of each simple colour shall be represented by the natural numbers 1, 2, 3, .. 12; 1 denoting the lowest degree of it capable of sensibly affecting a tint, and 12 the highest intensity of which the colour is capable, or the total amount of it existing in white light. Thus \( r^1 \) denotes a full red of the brightest and purest tint, \( y^1 \) the brightest yellow, and \( b^1 \) the brightest blue. To represent mixed tints, he combines the symbols of the separate ingredients. Thus \( r^2 y^3 \), or, more conveniently, \( 12r + 4y \), represents a red verging strongly to orange, such as that of a coal fire.

The scale proposed is convenient and complete, so far as regards what he calls perfect colours, which arise from white light by the subtraction of one or more proportions of its elementary rays; but a very slight modification of Mayer's scale.
ponent part of its green, (in this view of the composition of colours,) and its characteristic symbol may
thus be, perhaps, of some such form as 10 R + 9 Y + 1 B; that is to say, (9 R + 8 Y) + 1 (R + Y + B), or an
orange of the character 9 R + 8 Y diluted with one ray of white. It must be confessed, however, that the
composition of brown tints is the least satisfactory of all the applications of Mayer's doctrine. He himself has
passed it unnoticed.

Combination of red and blue, and their dilutions with white, form all the varieties of crimson, purple, violet,
rose colour, pink, &c. The richer purples are entirely free from yellow. The prismatic violet, when compared
with the indigo, produces a sensible impression of redness, and must therefore be regarded on this hypothesis
as consisting of a mixture of blue and red rays.

Blue and yellow, combined, produce green. The green thus arising is vivid and rich; and, when proper
proportions of the elementary colours are used, no way to be distinguished from the prismatic green. Nothing
can be more striking, and even surprising, than the effect of mixing together a blue and a yellow powder, or
of covering a paper with blue and yellow lines, drawn close together, and alternating with each other. The
elementary tints totally disappear, and cannot even be recalled by the imagination. One of the most marked
facts in favour of the idea of the existence of three primary colours, and of the possibility of an analysis of
white light distinct from that afforded by the prism, is to see the prismatic green thus completely imitated by
a mixture of adjacent rays totally distinct from it, both in refrangibility and colour.

The hypothesis of three primary colours, of which, in different proportions, all the colours of the spectrum
are composed, affords an easy explanation of a phenomenon observed by Newton, viz. that tints no way
distinguishable from each other may be compounded by very different mixtures of the seven colours into which
he divided it. Thus we may regard white light, indifferently, as composed of

\[
\begin{align*}
R &= a + b + c \text{ rays of pure red} \\
Y &= d + e + f + g \text{ rays of pure yellow} \\
B &= h + i + k + l \text{ rays of pure blue }
\end{align*}
\]

or of

\[
\begin{align*}
b \text{ rays of pure red} &= R' \\
c + d \text{ rays of orange (c red + d yellow)} &= O' \\
e \text{ rays of pure yellow} &= Y' \\
f + h \text{ rays of green (f yellow + h blue)} &= G' \\
g + i \text{ rays of prismatic blue (g yellow + i blue)} &= B' \\
k \text{ rays of indigo, or pure blue} &= I' \\
l + a \text{ rays of violet (l blue + a red)} &= V'
\end{align*}
\]
and any tint capable of being represented by \( x \cdot R + y \cdot Y + z \cdot B \), may be represented equally well by

\[ m \cdot R' + n \cdot O' + p \cdot Y' + q \cdot G' + r \cdot B' + s \cdot I' + t \cdot V' \]

provided we assume \( m, n, p, \ldots \), such as to satisfy the equations

\[ mb + nc + ta = x; \quad nd + pe + qf + rg = y; \quad gh + ri + sk + tl = z. \]

From what has been said we shall now proceed to show, that, without departing from Mayer's doctrine, any other three prismatic rays may still be equally assumed as fundamental colours, and all the rest compounded from them, provided we attend only to the predominant tint resulting, and disregard its dilution with white. For instance, Dr. Young has assumed red, green, and violet as his fundamental colours; and states, as an experimental fact in support of this doctrine, that the perfect sensations of yellow and blue may be produced, by these colours, the former by a mixture of red and green, and the latter by green and violet. (Lectures on Natural Philosophy, p. 439.) Now, if we mix together yellow and white in the proportion of \( m \) yellow + \( n \) white, the compound will produce a perfect sensation of yellow, unless \( m \) be small compared to \( n \); but, assuming white to be composed as above, this compound is equivalent to

\[ n \cdot R \cdot red + (m + n) \cdot Y \cdot yellow + n \cdot B \cdot blue. \]

On the other hand, if we mix together \( P \) such red rays (each of the intensity \( b \)) and \( Q \) such green rays (each consisting of yellow, of the intensity \( f \), and blue of the intensity \( h \)) as are supposed in the foregoing article to exist in the spectrum, we have a compound of

\[ P \cdot b \cdot red + Q \cdot f \cdot yellow + Q \cdot h \cdot blue, \]

and these will be identical with the former, if we take

\[ n \cdot R = P \cdot b; \quad (m + n) \cdot Y = Q \cdot f; \quad n \cdot B = Q \cdot h. \]

Eliminating \( Q \) from the two last of these, we get

\[ \frac{m}{n} = \frac{f}{h} \cdot \frac{R}{Y} - 1. \]

for the relation between \( M \) and \( N \). Now the only conditions to be satisfied are that \( M \) shall be positive, and not much less than \( N \); and it is evident that these conditions may be fulfilled an infinite number of ways by a proper assumption of the ratio of \( f \) to \( h \). In the same manner, if we suppose a mixture of \( M \) rays primary blue \( = B \) with \( N \) rays of white \((= R + Y + B)\) to be equivalent to \( P \) rays of prismatic green mixed with \( Q \) of violet, we get the equation

\[ \frac{m}{n} = \frac{l}{a} \cdot \frac{R}{B} + \frac{h}{f} \cdot \frac{Y}{B} - 1. \]

Suppose, for example, we regard white light as consisting of 20 rays of primary red, 30 of yellow, and 50 of blue, and the several prismatic rays to consist as follows:

- Red 8 rays primary red \( = k \).
- Orange 7 red + 7 primary yellow \( = c + d \).
- Yellow 8 yellow \( = c \).
- Green 10 yellow + 10 primary blue \( = f + h \).
- Blue 6 yellow + 12 primary blue \( = g + i \).
- Indigo 12 blue \( = k \).
- Violet 16 blue + 5 primary red \( = l + a \).

Then will the union of 15 rays of such red with 30 of such green, produce a compound ray containing

\[ 15 \times 8 = 120 \] of primary red, \[ 30 \times 10 = 300 \] of primary yellow, and \[ 30 \times 10 = 300 \] of primary blue; which are the same as exist in a yellow, consisting of 6 rays of white combined with 4 of primary yellow. In like manner, if 75 such green rays be combined with 100 such violet, the result will be 100 \( \times 5 = 500 \) rays of primary red, \( + 75 \times 10 = 750 \) of primary yellow, \( + 75 \times 10 + 100 \times 16 = 2350 \) of primary blue, which together compose a tint identical with that which would result from the union of 25 rays of white with 22 of primary blue; that is to say, a fine lively blue. The numbers assumed above, it must be understood, are merely taken for the sake of illustration, and are no way intended to represent the true ratios of the differently coloured rays in the spectrum.

The analogy of the fixed lines in the solar spectrum might lead us to look for similar phenomena in other sources of light. Accordingly, Fraunhofer has found, that each fixed star has its own particular system of dark Phenomena and bright spaces in its spectrum; but the most curious phenomena are those presented by coloured flames of coloured which produce spectra (when transmitted through a colourless prism) hardly less capricious than those afforded flames by solar light transmitted through coloured glasses. Dr. Brewster, Mr. Talbot, and others, have examined these
Light phenomena with attention; but the subject is not exhausted, and promises a wide field of curious research. The following facts may be easily verified:

521. Flames of combustible bodies burning feebly.
1. Most combustible bodies consisting of hydrogen and carbon, as tallow, oil, paper, alcohol, &c. when first lighted and in a state of feeble and imperfect combustion, give blue flames. These, when examined by the prism, by letting them shine through very narrow slits parallel to its edge, as described in Art. 487, all give interrupted spectra, consisting, for the most part, of narrow lines of very definite refrangibility, either separated by broad spaces entirely dark, or much more obscure than the rest. The more prominent rays are, a very narrow definite yellow, a yellowish green, a vivid emerald green, a faint blue, and a strong and copious violet.

522. Burning strongly.
2. In certain cases when the combustion is violent, as in the case of an oil lamp urged by a blow-pipe, (according to Fraunhofer,) or in the upper part of the flame of a spirit lamp, or when sulphur is thrown into a white-hot crucible, a very large quantity of a definite and purely homogeneous yellow light is produced; and in the latter case forms nearly the whole of the light. Dr. Brewster has also found the same yellow light to be produced when spirit of wine, diluted with water and heated, is set on fire; and has proposed this as a means of obtaining a supply of homogeneous yellow light for optical experiments.

523. Flames coloured by saline bodies.
3. Most saline bodies have the power of imparting a peculiar colour to flames in which they are present, either in a solid or vaporous state. This may be shown in a manner at once the most familiar and most efficacious, by the following simple process: Take a piece of packthread, or a cotton thread, which (to free it from saline particles should have been boiled in clean water,) and having wetted it, take up on it a little of the salt to be examined in fine powder, or in solution. Then dip the wetted end of it into the cup of a burning wax candle, and apply it to the exterior of the flame, not quite in contact with the luminous part, but so as to be immersed in the cone of invisible but intensely-heated air which envelopes it. Immediately an irregular sputtering combustion of the wax on the thread will take place, and the invisible cone of heat will be rendered luminous, with that particular coloured light which characterises the saline matter employed.

Thus it will be found that, in general,

- Salts of soda give a copious and purely homogeneous yellow.
- Salts of potash give a beautiful pale violet.
- Salts of lime give a brick red, in whose spectrum a yellow and a bright green line are seen.
- Salts of strontia give a magnificent crimson. If analyzed by the prism two definite yellows are seen, one of which verges strongly to orange.
- Salts of magnesia give no colour.
- Salts of lithia give a red, (on the authority of Dr. Turner's experiments with the blow-pipe.)
- Salts of baryta give a fine pale apple-green. This contrast between the flames of baryta and strontia is extremely remarkable.
- Salts of copper give a superb green, or blue green.
- Salt of iron (protoxide) gave white, where the sulphate was used.

Of all salts, the muriates succeed best, from their volatility. The same colours are exhibited also when any of the salts in question are put (in powder) into the wick of a spirit lamp. If common salt be used, Mr. Talbot has shown that the light of the flame is an absolutely homogeneous yellow; and, being at the same time very copious, this property affords an invaluable resource in optical experiments, from the great ease with which it is obtained, and its identity at all times. The colours thus communicated by the different bases to flame, afford in many cases a ready and neat way of detecting extremely minute quantities of them; but this rather belongs to Chemistry than to our present subject. The pure earths, when violently heated, as has recently been practised by Lieutenant Drummond, by directing on small spheres of them the flames of several spirit lamps urged by oxygen gas, yield from their surfaces lights of extraordinary splendour, which, when examined by prismatic analysis, are found to possess the peculiar definite rays in excess, which characterise the tints of flames coloured by them; so that there can be no doubt that these tints arise from the molecules of the colouring matter reduced to vapour, and held in a state of violent ignition.
OF THE THEORIES OF LIGHT.

§ I. Of the Newtonian or Corpuscular Theory of Light.

Postulata. 1. That light consists of particles of matter possessed of inertia and endowed with attractive and repulsive forces, and projected or emitted from all luminous bodies with nearly the same velocity, about 200,000 miles per second.

2. That these particles differ from each other in the intensity of the attractive and repulsive forces which reside in them, and in their relations to the other bodies of the material world, and also in their actual masses, or inertia.

3. That these particles, impinging on the retina, stimulate it and excite vision. The particles whose inertia is greatest producing the sensation of red, those of least inertia of violet, and those in which it is intermediate the intermediate colours.

4. That the molecules of material bodies, and those of light, exert a mutual action on each other, which consists in attraction and repulsion, according to some law or function of the distance between them; that this law is such as to admit, perhaps, of several alternations, or changes from repulsive to attractive force; but that when the distance is below a certain very small limit, it is always attractive up to actual contact; and that beyond this limit resides at least one sphere of repulsion. This repulsive force is that which causes the reflexion of light at the external surfaces of dense media; and the interior attraction that which produces the refraction and interior reflexion of light.

5. That these forces have different absolute values, or intensities, not only for all different material bodies, but for every different species of the luminous molecules, being of a nature analogous to chemical affinities, or electric attractions, and that hence arises the different refrangibility of the rays of light.

6. That the motion of a particle of light under the influence of these forces and its own velocity is regulated by the same mechanical laws which govern the motions of ordinary matter, and that therefore each particle describes a trajectory capable of strict calculation so soon as the forces which act on it are assigned.

7. That the distance between the molecules of material bodies is exceedingly small in comparison with the extent of their spheres of attraction and repulsion on the particles of light. And

8. That the forces which produce the reflexion and refraction of light are, nevertheless, absolutely insensible at all measurable or appreciable distances from the molecules which exert them.

9. That every luminous molecule, during the whole of its progress through space, is continually passing through certain periodically recurring states, called by Newton fits of easy reflexion and easy transmission, in virtue of which (from whatever cause arising, whether from a rotation of the molecules on their axes, and the consequent alternate presentation of attractive and repulsive poles, or from any other conceivable cause) they are more disposed, when in the former states or phases of their periods, to obey the influence of the repulsive or reflective forces of the molecules of a medium; and when in the latter, of the attractive. This curious and delicate part of the Newtonian doctrine will be developed more at large hereafter.
It is the 7th and 8th of these assumptions only which render the course pursued by a luminous molecule, under the influence of the reflective or refractive forces, capable of being reduced to mathematical calculation; for it follows immediately from the 8th, that, up to the very moment when such a molecule arrives in physical contact with the surface of any medium, it is acted on by no sensible force, and therefore not sensibly deviated from its rectilinear path; and, on the other hand, as soon as it has penetrated to any sensible depth within the surface, or among the molecules, by reason of the 7th of the above postulates, it must be equally attracted and repelled by them in all directions, and therefore will continue to move in a right line, as if under the influence of no force. It is only, therefore, within that insensible distance on either side the surface, which is measured by the diameter of the sphere of action of each molecule, that the whole flexure of the ray takes place. Its trajectory then may be regarded as a kind of hyperbolic curve, in which the right lines described by it, previous and subsequent to its arrival at the surface, are the infinite branches, and are confounded with the asymptotes, and the curvilinear portion is concentred as it were in a physical point. Now, in explaining the phenomena of reflexion and refraction, it is not the nature of this curve that we are called on to investigate. This will depend on the laws of corpuscular action, and must necessarily be of great complexity. All we have to inquire, is the direction the ray will ultimately take after incidence, and the final change, if any, in its velocity.

Let us, then, consider the motion of a molecule urged to or from the surface of a medium by the united attractions or repulsions of all its particles acting according to any conceivable mathematical law. And, first, it is evident, that supposing the surface mathematically smooth, and the number of attractive or repulsive particles of which it consists, infinite, their total resultant force on the luminous molecule will act in a direction perpendicular to the surface; and will be insensible at all sensible distances from the surface, provided the elementary forces of each molecule decrease with sufficiently great rapidity as the distances increase. This condition being supposed, let \( x \) and \( y \) be the coordinates of the molecule at any assigned instant; the plane of the \( x \) and \( y \) being supposed to coincide with that of its trajectory, out of which plane there is evidently no force to turn it, and which must of course be perpendicular to the surface of the medium in which \( x \) is supposed to lie: \( y \) then will be the perpendicular distance of the luminous molecule from this surface, and \( Y \) (some function of \( y \) decreasing with extreme rapidity) will represent the force urging it inwards, or towards the surface when the molecule is without, \( Y \) from when within the medium. Therefore, by the principles of Dynamics, supposing \( dt \) to denote the element of the time, we shall have for the equations of the motion

\[
\frac{d^2 x}{dt^2} = 0; \quad \frac{d^2 y}{dt^2} + Y = 0; \quad (a)
\]

and hence, multiplying the first by \( dx \), the second by \( dy \), adding and integrating, we get

\[
\frac{d^2 x^2 + d^2 y^2}{dt^2} + 2\int Y \, dy = \text{constant}. \quad (b)
\]

Now, \( v \) being the velocity of the molecule, we have \( v^2 = \frac{d^2 x^2 + d^2 y^2}{dt^2} \), and therefore this equation becomes

\[
v^2 = \text{constant} - 2\int Y \, dy. \quad (b)
\]

It is, however, only with the terminal velocity, or that attained by the light after undergoing the total action of the medium, that we are concerned, and therefore if we put \( V \) for its primitive, or initial, and \( V' \) for its terminal velocity, we shall have, by extending the integral from the value of \( y \) at the commencement of the ray's motion \((y_o)\) to its value at the end \((y)\),

\[
V^2 - V_o^2 = -2\int Y \, dy. \quad (b)
\]

Since \( y_o \) and \( y \) are supposed infinite, and since the function \( Y \) decreases by hypothesis with such rapidity as to become absolutely insensible for all sensible values of \( y \), it is clear that we may take \( y_o = +\infty \) for the first limit of the integral in all cases. With regard to the other, we have now to distinguish two principal cases:

The first is that of reflexion, where the ray, no matter whether before its arrival at the surface, or at reaching it, or even after passing some small distance into the medium, is turned back by the prevalence of the repulsive force, and pursues the whole of its course afterwards without the medium. Now in this case if we resolve the integral \( \int Y \, dy \) into its elements, these, in the approach of the molecule to the surface, may be represented as follows,

\[
&c. + Y'x - dy + Y''x - dy + Y'''x - dy + &c.
\]

But in the recess of the molecule, the values of \( y \) increase again by the same steps as they before diminished and become identical with the former ones; and \( Y', Y'', &c. \), the values of \( Y \) corresponding to the successive values of \( y \), remain therefore the same, both in size and magnitude; the corresponding elements of the integral generated during the recess of the molecule will be then

\[
&c. + Y'x + dy + Y''x + dy + Y'''x + dy + &c.
\]
So that, combining both, the latter exactly destroy the former, and give \( \int Y \, dy = 0 \) when extended from one end to the other of the trajectory. Thus we have, in the case of reflection,

\[ V^s - V = \theta, \quad \text{or} \quad V' = V. \]

The second case is that in which the whole course of the ray after incidence lies within the medium, or the case of refraction. Here the values of \( y \) before incidence are all positive, and after, all negative; and, moreover, the change of sign in \( dy \) which happened in the case of reflection, does not here take place. Hence \( \int Y \, dy \) must be extended from \( +\infty \) to \( -\infty \), and its value will not vanish, but (on account of the rapid decrease of the function \( Y \)) will have some finite value. Now this can only be dependent on the arbitrary quantities which enter into the composition of \( Y \); in other words, on the nature of the medium and the ray, and not at all on the constants which determine the direction of the ray with respect to the surface, (as its inclination or the position of the plane of incidence.) Hence we may suppose \( \int Y \, dy = -\frac{1}{2} k V^s \), where \( k \) is a constant independent of the direction of the ray, and determined only by its nature and that of the medium, and we shall have

\[ V^s = V^s (1 + k); \quad V' = V \cdot \sqrt{1 + k} = \mu V, \]

putting \( \sqrt{1 + k} = \mu. \)

Hence we see that both in refraction and reflection, on this hypothesis, the velocity of the ray after deviation is the same in whatever direction the ray be incident, viz. in a given ratio to the velocity before incidence, this ratio being one of equality in the case of reflection.

Let us next consider the direction of the ray after flexure. To this end let \( \theta \) be the angle made by its path at any moment with the perpendicular to the surface, then will \( \sin \theta = \frac{d s}{d t} \), putting \( d s \) for \( \sqrt{d x^2 + d y^2} \), the element of the arc. Now if we integrate the equation \( \frac{d^2 x}{d s^2} = 0 \) once we get \( \frac{d x}{d t} = \text{constant} = c \), and

\[ d x = c \, d t, \]

therefore \( \sin \theta = \frac{c}{v} \). But \( x = \frac{d s}{d t} \); therefore \( \sin \theta = \frac{c}{v} \). Let therefore \( \theta_0 \) and \( \theta_1 \) represent the initial and terminal values of \( \theta \), or the angles of incidence and reflection, or refraction of the rectilinear portions of the ray, and we get

\[ \sin \theta_0 = \frac{c}{V}, \quad \text{and} \quad \sin \theta_1 = \frac{c}{V'}. \]

and dividing one by the other

\[ \frac{\sin \theta_0}{\sin \theta_1} = \frac{V'}{V} = \mu. \]

That is to say, the sines of incidence and refraction, or reflection, are to each other in a constant ratio, viz. the inverse ratio of the velocities of the ray before and after incidence.

Thus we see the Newtonian hypothesis satisfies the fundamental conditions of refraction and reflection without entering into any consideration respecting the laws of the refracting and reflecting forces, or even the order of their superposition. There may be as many alternations of attraction and repulsion as we please, and the reflected or refracted ray may therefore, prior to its final recess from the surface, make any variety of undulations; all that is required is the extremely rapid decrease of the function \( Y \) expressing the total force before the distance attains a sensible magnitude.

Hence also, \( V \) and \( V' \) being the velocities before and after incidence, and \( \mu \) the index of refraction, we have

\[ V' : V :: \mu : 1, \]

which shows, that when a ray passes from a rarer medium to a denser, its velocity is increased, and vice versa.

Moreover, we have

\[ k = \frac{V'^s - V^s}{V^s} = \left( \frac{V'}{V} \right)^s - 1 = \mu^s - 1 = \frac{2 \int - Y \, dy}{V^s}. \]

Now if we suppose the form of the function \( Y \) to be the same for all media, and that they differ in the energy of action only by reason, first, of a greater density, owing to which more molecules are brought within the sphere of activity; and, secondly, by reason of a greater or less affinity, or intensity of action of each molecule, we may suppose \( Y \) to be represented by \( S \cdot \sigma \cdot \phi (y) \), where \( S \) is the specific gravity, or density, \( \sigma \) the intrinsic refractive energy of the medium, and \( \phi (y) \) a function absolutely independent of the peculiarities of the medium, and the same for all natural bodies. Hence \( \int - Y \, dy = S \cdot \sigma \cdot \int - \phi (y) \, dy = S \cdot \sigma \cdot \text{constant} \) because \( \int - \phi (y) \, dy \) taken from \( y = +\infty \) to \( y = -\infty \) will now be an absolute numerical constant. We have then, according to this doctrine,

\[ n = \frac{\mu^s - 1}{S} \times \frac{V^s}{2 \cdot \text{constant}}. \]

If \( \mu \) be the refractive index of a given standard ray out of a vacuum, \( V \) the velocity of that ray in vacuo is known, and is also an absolute constant; so that \( n \), the intrinsic refractive power of the medium is proportional to

\[ 3 \text{ M} \]
such is Newton's idea of the refractive power of a medium as differing from its specific gravity.

The constancy of the ratio of the sines of incidence and refraction has here been derived by direct integration of the fundamental equations. There is, however, another mode of deducing this important law, much more circuitous, it is true, in this simple case, but which offers peculiar advantages in the more complicated ones of double refraction; and which, therefore, we shall here explain, to familiarize the reader beforehand with its principle and mode of application. It consists in the employment of what is called, in Dynamics, the principle of least action, in virtue of which the sum of each element of the trajectory described by any moving molecule multiplied by the velocity of its description (or the integral \( \int v \, ds \)) is a minimum when taken between any two fixed points in the trajectory. The trajectory described by any luminous molecule may be regarded as consisting of two rectilinear portions, or hyperbolic branches, confounded with their asymptotes, and one curvilinear one concentrated in a space of insensible magnitude, a physical point. Within this point the whole operation of the flexure of the ray, however complicated, is performed; and here the velocity is variable. In the branches it is uniform. Suppose, then, \( A \) and \( B \) to be any two fixed points in these, taken as points of departure and arrival of a ray, and let \( C \) be the point in the surface of a reflecting or refracting medium where the flexure takes place, and suppose \( A \, C = S, \, B \, C = S' \) and let \( \sigma \) be the excessively minute curvilinear portion of the ray at \( C \), and \( w \) the variable velocity with which it is described, \( V \) and \( V' \) being those with which \( S \) and \( S' \) are described. Then may the integral \( \int v \, ds \) be resolved into the three portions \( \int V \, ds + \int V' \, ds' \). Of these the second is utterly insensible, by reason of the minuteness of \( \sigma \), and the other two, since \( V \) and \( V' \) are constant, become merely \( V. \, S + V'. \, S' \).

The position of \( C \), then, with respect to \( A \) and \( B \), will be determined by the condition \( V. \, S + V'. \, S' = \) a minimum, \( A \) and \( B \) being supposed fixed, and \( C \) any how variable on the surface. Now, in the case before us, \( V \) the velocity of the light before, and \( V' \) that after incidence, are both, as we showed in Article 529 and 530, independent of the direction of the incident and reflected or refracted rays, or of the position of \( C \); and, therefore, are to be considered as absolute constants in this problem of minima, which is thus reduced to a simple geometrical question. Given \( A \) and \( B \) to find \( C \), a point in a given plane, such that \( V' \) (\( = \) constant) \( \times (A + C) + V' \) (\( = \) constant) \( \times (B + C) \) shall be a minimum. Nothing is easier than the solution. Put \( a, b, c, a', b', c' \) for the respective coordinates of \( A \) and \( B \), and \( x, y, \sigma \) for that of \( C \), taking the given plane for that of the \( x, y \).

Then

\[
V. \, S + V'. \, S' = V \cdot \sqrt{(x - a)^2 + (y - b)^2 + \sigma^2} + V'. \sqrt{(x - a')^2 + (y - b')^2 + \sigma^2}
\]

is to be a minimum by the variation of \( x \) and \( y \), independent of each other. This gives, by differentiation,

\[
\frac{V}{S} \left\{ (a - x) \, dx + (b - y) \, dy \right\} + \frac{V'}{S'} \left\{ (a' - x) \, dx + (b' - y) \, dy \right\} = 0;
\]

and this, since \( x \) and \( y \) are independent, must vanish, whatever values are assigned to \( dx \) and \( dy \), therefore we must have separately

\[
\frac{V}{S} (a - x) + \frac{V'}{S'} (a' - x) = 0; \quad \frac{V}{S} (b - y) + \frac{V'}{S'} (b' - y) = 0.
\]

These give, respectively,

\[
S' = -\frac{V}{V'}. \frac{a - x}{a}; \quad S' = -\frac{V}{V'}. \frac{b - y}{b - y};
\]

by equating which we get

\[
(a' - x) (b - y) = (b' - y) (a - x);
\]

or multiplying out and reducing

\[
y = \frac{b - b'}{a - a'} + \frac{a b' - b a'}{a - a'};
\]

and, consequently,

\[
b' - y = \frac{b - b'}{a - a'} (a' - x).
\]

This expression expresses, that the two portions \( S \) and \( S' \) of the ray before and after incidence on the surface at \( C \) both lie in one plane, and that this plane is perpendicular to the surface, or to the plane of the coordinates \( x, y \).

Again, if we resume the equations (d) and putting them under the form

\[
S' (a - x) = -\frac{V'}{V} S (a' - x); \quad S' (b - y) = -\frac{V'}{V} (b' - y) \cdot S.
\]

Square and add them we get

\[
S'L = \frac{V'}{V} S (a - x) + \frac{V'}{V} S (a' - x) = 0.
\]
Light.

Now if we put $\theta$ for the angle made by the portion $S$ with a perpendicular to the surface, or the angle of incidence of the ray, and $\theta'$ for that made by the other $S'$ with the same perpendicular, or the angle of emergence, we shall have

$$\sin \theta = \frac{\sqrt{(a - x)^2 + (b - y)^2}}{S} \quad \text{and} \quad \sin \theta' = \frac{\sqrt{(a' - x)^2 + (b' - y)^2}}{S'}$$

So that the above equation is equivalent simply to

$$\sin \theta = \frac{V}{V} \cdot \sin \theta'$$

which is the same with the result before obtained.

The principle of least action, then, in the case before us, has enabled us to dispense with one integration of the differential equations expressing the motion of the luminous molecule; and its applicability to this purpose depends, as we have seen, on the relation between $V$ and $V'$; the velocities of the light, before and after incidence, being known. This relation has here been deduced $\textit{a priori}$; but had it been merely known, as a matter of fact, a conclusion established by experiment, it would not be on that account the less applicable to the same purpose, and the laws of refraction and reflexion would be derivable from it by the same process.

There would, however, be this main difference; that, in the latter case, we should have no occasion to employ the differential equations at all, and therefore none to enter into any consideration of the forces acting on the luminous molecule, or their mode of action. The principle of least action establishes, independent of, and anterior to, all particular suppositions as to the forces which operate the flexure of the ray, (farther than that they are functions of the distances from their origins or centres,) an analytical relation between the velocities before and after incidence, and the directions of its direct and deviated branches; a relation nearly as general as the laws of dynamics themselves, and expressive, in fact, of only the one condition above mentioned. And this relation, from its form, enables us, whenever the relation of the velocities is known, to determine that of the directions of the two portions of the ray, and $\textit{vice versâ}$, without having recourse to the differential equations at all. In the simple case before us this may seem a needless refinement, the equations being so simple. It is otherwise, however, in the theory of double refraction. There the forces in action are altogether unknown, not only in respect of their intensity, but of their directions; and so far, therefore, from being able in that theory to integrate the equations of the ray's motion, we cannot even express them analytically. The principle we are now considering is, in such a case, all the ground we have to stand upon; and has been ingeniously and elegantly applied by Laplace, in that theory, to reduce the complicated laws of double refraction under the dominion of analysis.

In fact, suppose that the velocities of the incident and deviated portions of the rays, instead of being the same in every direction, varied with the positions of these portions with respect to the surface of the medium, or to the Mode of its any fixed lines or axes in space. Then will $V$ and $V'$, instead of being invariable, be represented by functions of the three coordinates of the point $C$, either rectangular, as $x$, $y$, $z$; or polar, as $\phi$, $\theta$, and $\gamma$; and the portions $S$ and $S'$ of the rays intercepted between $A$ and $B$ respectively, and the surface at $C$, will, in like manner, be functions of the same coordinates. So that the condition

$$V \cdot S + V' \cdot S' = \text{a minimum}$$

will afford, by differentiation and putting the differential equal to zero, an equation of the form $L \cdot d x + M \cdot d y + N \cdot d z = 0$, or $L \cdot d \phi + M \cdot d \theta + N \cdot d \gamma = 0$, as the case may be. The equation of the surface also being differentiated affords another relation of the same kind; and these being the only conditions to which the differences $d x$, $d y$, $d z$ are subject, we may eliminate one, and put the coefficients of the remaining ones separately equal to zero. Thus we get two equations between the coordinates, which, combined with that of the surface, suffice to determine them, i.e. to fix the point $C$ at which the ray $AC$ must meet the surface, in order that, being there deviated by the action of the medium, it may, after flexure, proceed to $B$; and thus the problem of reflection or refraction may be resolved in all its generality, so soon as the nature of the functions $V$, $V'$ is known. But to return to the case of ordinary reflexion and refraction, from which this is a digression.

Let us consider, a little more in detail, what may be conceived to happen to a ray at the confines of the surface of a medium. We may suppose, then, that there exist a series of laminar spaces, or strata, within which the attractive and repulsive action of the molecules of the medium alternately predominate. Of these there may be any number, and either may be exterior to the rest. It is, in fact, the assemblage of these laminas which is to be regarded as the surface of the medium. Suppose now a ray $Aa$ (Fig. 119) to be moving towards the medium. Its course will be rectilinear up to $a$, where it first comes within the action of the medium. If the first stratum into which it enters be one of attraction, its course will be bent as $a\hat{b}b$ into a curve concave towards the surface, and its velocity in the direction perpendicular to the surface will be increased. Arrived at $b$ let the force change to repulsive; the trajectory will have at $b$ a point of contrary flexure, the portion $b\hat{c}c$ within this lamina will be convex to the surface, and the velocity towards the surface will be diminished in the whole progress of the ray through it, and so for any number of alternations. Let us now suppose, that in passing through any repulsive lamina, as $C$, the repulsion should be so strong, or the original velocity of approach to the surface so small, as that the whole of it shall be destroyed. In this case the ray for a moment will be moving as at $C$, parallel to the surface, but the repulsive force continuing its action will turn it back; and the forces
Light

542. Motion of a ray at common surface of two media.

Newtonian idea of a ray of light as composed of a succession of molecules.

543. In the Corpuscular doctrine, a ray of light is understood to mean a continued succession or stream of molecules, all moving with the same velocity along one right line, and following each other close enough to keep the retina in a constant state of stimulus, i.e. so fast, that before the impression produced by one can have time to subside another shall arrive. It appears, by experiment, that to produce a continued sensation of light, it is sufficient to repeat a momentary flash about 8 or 10 times in a second. If a red-hot coal on the point of a burning stick be whirled round, so as to describe a circle, and the velocity of rotation be greater than 8 or 10 circumferences per second, the eye can no longer distinguish the place of the luminous point at any instant, and the whole circle appears equally bright and entire. This shows, evidently, that the sensation excited by the light falling on any one point of the retina, must remain almost without diminution till the impression is repeated during the subsequent revolution of the luminous hand. But the uninterupted vision can be kept up by the repetition of the effervescence, repeated at intervals so distant as a tenth of a second, it is easy to conceive that the individual molecules of light in a ray will not require to follow close on each other to affect our organs with a continued sense of light. As their velocity is nearly 200,000 miles per second, if they follow each other at intervals of 1000 miles apart, 200 of them would still reach our retina per second, in every ray. This consideration frees us from all difficulties on the score of their jostling, or disturbing each other in space, and allows of infinite rays crossing at once through the same point of space without at all interfering with each other, especially when we consider the minuteness which must be attributed to them, that (moving with such swiftness) they should not injure our organs. If a molecule of light weighed but a single grain, its inertia would equal that of a cannon ball of upwards of 150 pounds weight, moving at the rate of 1000 feet per second. What then must be their tenacity, when the concentration of millions upon millions of them, by lenses or mirrors, has never been found to produce the slightest mechanical effect on the most delicately contrived mechanism, in experiments made expressly to detect it. (See Mr. Bennet's Experiments, Phil Trans. 1792, vol. lxxxii. p. 87.)

544. When a ray of light falls on a reflecting or refracting surface, since all its molecules move with equal velocity and are incident in the same line, it would seem that whatever took place with one should equally happen to all; and that, if the first underwent reflexion, all should do so; while, on the other hand, if one could penetrate the surface, and pursue its course entirely within the medium, all ought to do the same. This, however, is contrary to experience; as whenever a ray of light is incident on the exterior surface of any medium, a part only is reflected, and the rest enters the medium. No theory can be satisfactory which does not render a good account of so principal a fact. The Newtonian doctrine accounts for it by the fits of easy reflexion and transmission. To understand this explanation we must recur to the ninth postulate, (Art. 526,) and suppose two molecules to arrive at the surface under the same incidence, the one in a fit of easy reflexion, the other in one of easy transmission. The former will then be more affected by the repulsive forces, the latter by the attractive of the molecules of the medium; and hence it is evident, that the one may be reflected under circumstances of incidence, &c. in which the other will penetrate the surface and be refracted. Now it will depend entirely on the nature of the medium, and the initial velocity of a luminous molecule towards it, (which is as the cosine of the angle of incidence,) whether it will require the whole exertion of its repulsive forces, in their most energetic manner, to destroy that velocity and produce reflexion, or only a part of them. In the former case only such molecules as arrive in the most favourable disposition to be reflected, or in the most intense phase of a fit of easy reflexion, can be reflected. In the latter, such as arrive in less favourable dispositions, or in less intense phases of fits of reflexion, may be reflected; and if the repulsive forces of the medium be very intense, in comparison with the attractive ones, or if the obliquity of incidence be so great as to give the molecule a very small velocity perpendicular to the surface, even those molecules which arrive in the less energetic phases of fits of easy transmission may still be unable to penetrate the strata of repulsion.

545. Hence, then, we see that the proportion of the molecules of a ray falling on the surface of a medium in every possible state or phase of their fits, which undergo reflexion, will depend, first, on the nature of the medium on whose surface they fall, or if it be the common surface of two, then on both; secondly, on the angle of incidence. At great obliquities, the reflexion will be more copious; but even at the greatest, when the incident ray just grazes the surface, it by no means follows that every molecule, or even the greater part, must be reflected. Those which arrive in the most favourable phases of their fits of transmission, will obey the influence of small attractive forces, in preference to strong repulsive ones; but it will depend entirely on the nature of the media whether the former or the latter shall prevail, the fits in the Newtonian doctrine being conceived only to disperse the luminous molecules, other circumstances being favourable, to reflexion or transmission; to exalt the forces which
tend to produce the one and to depress those which act in favour of the other, but not to determine, absolutely, its reflection or transmission under all circumstances.

These conclusions are verified by experience. It is observed, that the reflection from the surfaces of transparent (or indeed any) media, becomes sensibly more copious as the angle of incidence increases; but at the external surface of a single medium is never total, or nearly total. In glass, for instance, even at extreme obliquities, a very large portion of the light still enters the glass and undergoes refraction. In opaque media, such as polished metals, the same holds good; the reflection increases in vividness as the incidence increases, but never becomes total, or nearly so. The only difference is, that here the portion which penetrates the surface is instantly absorbed and stifled.

The phenomena which take place when light is reflected at the common surface of two media, are much as from the above theory we might be led to expect,—with the addition, however, of some circumstances which lead us to limit the generality of our assumptions, and tend to establish a relation between the attractive and repulsive forces, to which the refraction and reflection of light are supposed to be owing. For it is found, that when two media are placed in perfect contact, (such as that of a fluid with a solid, or of two fluids with one another,) the intensity of reflection at their common surface is always less, the nearer the refractive indices of the media approach equality; and when they are exactly equal, reflection ceases altogether, and the ray pursues its course in the second medium, unchanged either in direction, velocity, or intensity. It is evident, from this fact, which is general, that the reflective or refractive forces, in all media of equal refractive densities, follow exactly the same laws, and are similarly related to one another; and that in media unequally refractive, the relation between the reflecting and refracting forces is not arbitrary, but that the one is dependent on the other, and increases and diminishes with it. This remarkable circumstance renders the supposition made in Art. 535, of the identity of form of the function $Y$, or $\phi(y)$ expressing the law of action of the molecules of all bodies on light indifferent, less improbable.

To show experimentally the phenomena in question, take a glass prism, or thin wedge of very small refracting angle (half a degree, for instance: almost any fragment of plate glass, indeed, will do, as it is seldom the two sides are parallel,) and placing it conveniently with the eye close to it, view the image of a candle reflected from the exterior of the face next the eye. This will be seen accompanied at a little distance by another image, reflected internally from the other face, and the two images will be nearly of equal brightness, if the incidence be not very great. Now, apply a little water, or a wet finger, or, still better, any black substance wetted, to the posterior face, at the spot where the internal reflection takes place, and the second image will immediately lose great part of its brightness. If olive oil be applied instead of water, the defalcation of light will be much greater; and if the substance applied be pitch, softened by heat, so as to make it adhere, the second image will be totally obliterated. On the other hand, if we apply substances of a higher refractive power than glass, the second image again appears. Thus, with oil of cassia it is considerably bright; with sulphur, it cannot be distinguished from that reflected at the first surface; and if we apply mercury, or amalgam, (as in a silvered looking-glass,) the reflection at the common surface of the glass and metal is much more vivid than that reflected from the glass alone.

The destruction of reflection at the common surface of two media of equal refractive powers explains many curious phenomena. If we immerse an irregular fragment of a colourless transparent body (as crown glass) in a colourless fluid of precisely equal refractive power, it disappears altogether. In fact, the surface being only visible by the rays reflected from it; destroy this reflection, and the object must cease to be seen, unless from any opacity in its substance reflecting rays from its interior, which is not here contemplated. Hence, if the powder of any such substance be moistened with a fluid of the same refractive density, all the internal and external reflections at the surfaces of the small fragments of which it consists, which, blended and confused, present the general appearance of a white opaque mass, will be destroyed, and the powder will be rendered perfectly transparent. A familiar instance of this nature is the transparency given to paper by moistening it with water, or, still better, with oil; paper is composed of an infinity of minute transparent, or nearly transparent fibres of a ligneous substance, having a refractive power probably not very different from some of the more refractive oils. Its whiteness is caused by the confused reflexion of the incident rays at all possible angles, both internally and externally, those which have escaped reflexion at one fibre, undergoing it among those beneath. If moistened with any liquid, the intensity of these reflexions is weakened, and the more the more nearly its refractive power approaches to that of the paper itself; so that a considerable number of rays find their way through it, and emerge at the posterior surface. The transparency acquired by the hydrophane, by immersion in water, is, no doubt, owing to this cause; the water filling up the minute pores, and enfeebling the internal reflexion; and Dr. Brewster, in a very curious and interesting Paper on the tabasheer, (a siliceous concretion found in sugar-canes, and the lowest in the scale of refracting powers among solids,) has explained on this principle a number of extraordinary phenomena exhibited on moistening that substance with various liquids, (see Philosophical Transactions, 1819.)

The reasoning of Art. 559 applies, it is evident, equally to the case when a ray is reflected from the interior surface of a dense medium placed in air, and when from the exterior. The only difference is, that in the latter case the reflexion is performed by the action of repulsive, and in the former by that of attractive forces. The course of a ray internally reflected may be conceived, as in fig. 121 and 122; and the reflexion may take place in any of the attractive regions, or laminae, whether within or without the true surface, i.e. the last layer of molecules which constitute the medium. There is one case of internal reflexion, however, too remarkable to be passed without more particular notice. It is, that when the interior angle of incidence exceeds the limiting angle whose sine is $\frac{1}{\sqrt{1}}$, (see Art. 183 et seq.;) and when, as we there stated, as a result of experiment, the
internal reflexion is total. To see how this happens, let us consider a ray incident exactly at this angle, and in the most intense phase of its fit of transmission. Then will it be refracted; and, since the angle of reflexion must be just 90°, (by reason of the generality of the demonstration of the law of refraction in Art. 529,) it will emerge, grazing the surface, exactly at the extreme boundary of the outermost region C B, (fig. 123,) where all sensible action ceases. Its initial velocity under these circumstances in the direction perpendicularly to the surface, is barely sufficient to carry it up to this extreme limit, where it is quite annihilated. If, then, we conceive another ray, also incident in the most intense phase of its fit of transmission, but at an angle more oblique by an infinitely small quantity, then, since its initial velocity at right angles to the surface is less, it will be destroyed before it has quite reached this limit, and the ray will therefore begin to move parallel to the surface, just within the last limit to the sphere of its action.

Now the last action which the surface exerts, or that force which extends to the greatest distance from it, cannot be otherwise than attractive; for, first, were it repulsive, it is evident that no ray incident externally at an extreme incidence, (i.e. approaching indefinitely to 90°,) could by possibility escape reflexion; and, secondly, no ray on that supposition could emerge from within the medium, without having at its emergence an obliquity to the surface greater than some finite angle, the last action of the medium being in this case to bend it outwards, both of which consequences are contrary to fact. Or we may consider the point thus, Since a ray incident within, at the limiting angle, emerges, if it emerge at all, parallel to the surface; and since every point in the curve described by it previous to the instant of emergence is nearer to the medium than the line of its ultimate direction, it is geometrically impossible that the curvature immediately adjacent to the point of emergence should be otherwise than concave towards the medium; and must, therefore, of necessity be produced by a force directed to it, i.e., an attractive one.

Hence, the luminous molecule we have been considering, will be within the attractive region at the moment when its perpendicular motion is destroyed; it will, therefore, be turned inwards, as at the dotted line fig. 123, and be reflected. A fortiori, therefore, will every molecule incident in a less intense phase of a fit of transmission, or in one of reflexion, as well as every one incident at a more oblique incidence, i.e., with a less initial perpendicular velocity, be reflected. Those in which the circumstances are most favourable to reflexion will reach the exterior attractive region, as in fig. 123. Others in which they are less so will be reflected in some intermediate region, as in fig. 124, while those which are incident at extreme internal obliquities, or in the most intense phases of fits of reflexion, will have their courses as represented in fig. 121.

The conclusion at which we have arrived in the last Art. that the attractive force of a medium on the molecules of light extends to a greater distance than the repulsive, is, as we have seen, a necessary consequence of dynamical principles; and so far from being in opposition to Newton's doctrine of reflexion, as has been said, is in perfect accordance with it. Dr. Brewster has been led to the same conclusion by peculiar considerations grounded on his experiments on the law of polarization, (Phil. Trans., 1815, p. 133,) and has applied it to water.

A C of the prism;) and, first, considering only the extreme red rays, if we drop a ray on that supposition could emerge from within the medium, without having at its emergence an obliquity to the surface greater than some finite angle, the last action of the medium being in this case to bend it outwards, both of which consequences are contrary to fact. Or we may consider the point thus, Since a ray incident within, at the limiting angle, emerges, if it emerge at all, parallel to the surface; and since every point in the curve described by it previous to the instant of emergence is nearer to the medium than the line of its ultimate direction, it is geometrically impossible that the curvature immediately adjacent to the point of emergence should be otherwise than concave towards the medium; and must, therefore, of necessity be produced by a force directed to it, i.e., an attractive one.

Hence, the luminous molecule we have been considering, will be within the attractive region at the moment when its perpendicular motion is destroyed; it will, therefore, be turned inwards, as at the dotted line fig. 123, and be reflected. A fortiori, therefore, will every molecule incident in a less intense phase of a fit of transmission, or in one of reflexion, as well as every one incident at a more oblique incidence, i.e., with a less initial perpendicular velocity, be reflected. Those in which the circumstances are most favourable to reflexion will reach the exterior attractive region, as in fig. 123. Others in which they are less so will be reflected in some intermediate region, as in fig. 124, while those which are incident at extreme internal obliquities, or in the most intense phases of fits of reflexion, will have their courses as represented in fig. 121.

The conclusion at which we have arrived in the last Art. that the attractive force of a medium on the molecules of light extends to a greater distance than the repulsive, is, as we have seen, a necessary consequence of dynamical principles; and so far from being in opposition to Newton's doctrine of reflexion, as has been said, is in perfect accordance with it. Dr. Brewster has been led to the same conclusion by peculiar considerations grounded on his experiments on the law of polarization, (Phil. Trans., 1815, p. 133,) and has applied it to water.

A C of the prism;) and, first, considering only the extreme red rays, if we drop a ray on that supposition could emerge from within the medium, without having at its emergence an obliquity to the surface greater than some finite angle, the last action of the medium being in this case to bend it outwards, both of which consequences are contrary to fact. Or we may consider the point thus, Since a ray incident within, at the limiting angle, emerges, if it emerge at all, parallel to the surface; and since every point in the curve described by it previous to the instant of emergence is nearer to the medium than the line of its ultimate direction, it is geometrically impossible that the curvature immediately adjacent to the point of emergence should be otherwise than concave towards the medium; and must, therefore, of necessity be produced by a force directed to it, i.e., an attractive one.

Hence, the luminous molecule we have been considering, will be within the attractive region at the moment when its perpendicular motion is destroyed; it will, therefore, be turned inwards, as at the dotted line fig. 123, and be reflected. A fortiori, therefore, will every molecule incident in a less intense phase of a fit of transmission, or in one of reflexion, as well as every one incident at a more oblique incidence, i.e., with a less initial perpendicular velocity, be reflected. Those in which the circumstances are most favourable to reflexion will reach the exterior attractive region, as in fig. 123. Others in which they are less so will be reflected in some intermediate region, as in fig. 124, while those which are incident at extreme internal obliquities, or in the most intense phases of fits of reflexion, will have their courses as represented in fig. 121.

The conclusion at which we have arrived in the last Art. that the attractive force of a medium on the molecules of light extends to a greater distance than the repulsive, is, as we have seen, a necessary consequence of dynamical principles; and so far from being in opposition to Newton's doctrine of reflexion, as has been said, is in perfect accordance with it. Dr. Brewster has been led to the same conclusion by peculiar considerations grounded on his experiments on the law of polarization, (Phil. Trans., 1815, p. 133,) and has applied it to explain a curious fact noticed by Bouguer, viz., that although water be much less reflective than glass at small incidences, yet at great ones (as 87°4) it is much more so. Now, supposing the light to have undergone the whole effect of the refracting forces, in both cases before it suffers reflexion, its incidence, when it reaches the region of the repulsive forces, will have been diminished in the case of glass, to 57° 44', but in that of water only to 61° 5', and therefore being incident more obliquely on the water it ought to be more copiously reflected. Whatever we may think of the validity of this explanation, it is certainly ingenious, and the fact extremely remarkable, and deserving of all attention.

To see the phenomena of total reflexion to the best advantage, lay down a right-angled glass prism on a black substance close to a window, with its base horizontal, as in fig. 124, and apply the eye close to the side, looking downwards. The base will be divided into two portions by a beautiful coloured arch like a rainbow conceave to the eye, the portion above the arch being extremely brilliant and vivid, and giving a reflexion of all external objects so way to be distinguished from reality. On the other hand, the space within the concavity of the bow is comparatively sombre, the reflexion of the clouds, &c. on that part of the base being much less vivid. If, instead of placing it on a black body, we hold it in the hand, and place a candle below it, this will be visible; but (wherever placed) will always appear in some part of the base within the concavity of the bow. Fig. 124 represents the course of the rays in this experiment, E being the eye, N G, O F, P D rays incident through the farther side at various angles of obliquity on the base, and reflected to the eye at E, of which O F is incident precisely at the limiting angle. It is obvious, that all the rays towards N incident on that part of the base beyond F being too oblique for transmission will be totally reflected, while those incident between F and A, being less oblique than is required for total reflexion, will be only partially so, a portion escaping through the base in the direction D Q. Again, if we place a luminary at any point as L below the base, it is manifest that to reach the eye, a ray from it must fall between A and F, as L D, and that no ray falling on any part of the base between B and F can be refracted to E.

The coloured arch separating the region of total from that of partial reflexion, is thus explained. For, simplicity, let us suppose the eye within the medium, (to avoid considering the reflexion at the inclined surface A C of the prism,) and, first, considering only the extreme red rays, if we drop a perpendicular from the eye on the base of the prism, and make this the axis of a cone, the side of which is inclined to the axis at the angle whose sine is \( \frac{1}{r} \), (or the limiting angle for extreme red rays;) and if we conceive such rays to emanate in all directions from the eye, then all which fall without the circular base of this cone will be totally, but those within only partially reflected. Thus, were there no other than such red rays of this precise refrangibility, the
Light.

...region of partial reflection would be a circle whose radius = height of the eye above the base × tangent of the angle whose sine is \( \frac{1}{\rho} = \frac{H}{\sqrt{\mu^2 - 1}} \). In like manner, the radius of the circular space, within which only a partial reflection of violet rays takes place, is \( \frac{H}{\sqrt{\rho^2 - 1}} \), or \( \frac{H}{\sqrt{(\mu + \delta \rho)^2 - 1}} \), being less than the value of the same radius for the red rays. Hence, in the space between the two circles, the violet rays will be totally reflected, and the red only partially reflected; and, therefore, the whole of this space will have an excess of violet light. A similar reasoning holds good for the intermediate rays; and the shading away from the bright space without, to the comparatively dark one within, will be performed by the absorption first of the red, next of the orange rays, and so on through the spectrum, leaving a residual light, which continually deviates more and more from white, and verges to blue. If now we suppose each ray to be incident in the contrary direction so as to be reflected to the eye instead of emanating from it, every thing will equally hold good, and the eye will see a bright space without; separated from an obscure space within the base of the cone, the transition from one to the other being not sudden, but marked by a blue border, the colour of which is more lively towards the interior.

Now such is the fact, with one difference, however, that the coloured arch appears slightly tinged with pink on its convex side. This, as it is incompatible with theory, can be owing, it should seem, to no cause but contrast; a most powerful source of illusion in all the phenomena of colours, and of which this is, perhaps, one of the most striking and curious instances. Newton (Optics, part ii. exp. 16) takes no notice of this part of the phenomenon, (which was first observed and described by Sir W. Herschel,) though he gives the same explanation of the rest with that here set down. The effect of refraction at the side B A of the prism will somewhat modify the figure of the bow, giving it a tendency to a conchoidal form at great obliquities of the emergent rays.

If the side B C of the prism be covered with black paper, and a bright scattered light be thrown on the base from below, (as from an emered glass applied with its rough side close to the base,) the converse of the above described phenomena will be seen. A totally black space will be seen beyond F, and a bright one within it. The separation being marked by a bow of a vivid red colour, graduating through orange and pale yellow into white, the red being outwards. It is evident that this phenomenon is, in all its parts, complementary to that of the blue bow seen by reflexion, and therefore requires no more particular explanation. It should be noticed, however, that in this bow no appearance of blue or violet within its concavity is ever seen; so that the effect which we have above attributed to contrast in the reflected bow has nothing corresponding to it in the transmitted one.

The intensity and regularity of reflexion at the external surface of a medium, is found to depend not merely on the nature of the medium, but very essentially on the degree of smoothness and polish of its surface. But it may reasonably be asked, how any regular reflexion can take place on a surface polished by art, when we recollect that the process of polishing is, in fact, nothing more than grinding down large asperities into smaller ones by the use of hard gritty powders, which, whatever degree of mechanical comminution we may give them, are yet vast masses, in comparison with the ultimate molecules of matter, and their action can only be considered as an irregular tearing up by the roots of every projection which may occur in the surface. So that, in fact, a surface artificially polished must bear somewhat of the same kind of relation to the surface of a liquid, or a crystal, that a ploughed field does to the most delicately polished mirror, the work of human hands. Now to this question the Newtonian doctrine furnishes an answer quite satisfactory. Were the reflexion of light performed by actual impact of its molecules upon those of the reflecting medium, no regular ordinary reflexion could ever take place at all, as it would depend entirely on the shape of the molecules, or asperities of the surface, and the inclinations of their surfaces to the general surface of the medium at the point of incidence, what should be the direction ultimately taken by each particular ray. Now these must vary in every possible manner in uncrystallized bodies, so that in reflexion from the surfaces of these the light would be uniformly scattered in every direction. On the other hand, in crystallized media, each molecule presenting only a limited number of strictly plane surfaces, and the corresponding faces of all being mathematically parallel, reflexion would indeed be regular; but its direction would be regulated only by that of the incident ray and the position of certain fixed lines within the crystal; and would be quite independent of either the smoothness or the inclination of the polished surfaces of it, whether natural or artificial; add to which, that instead of the reflexion of a pencil of rays being single, it would in most cases be multiple. All these consequences are so contrary to fact, that it is evident we must suppose the distance to which the forces producing reflexion extend much greater not only than the size of, or interval between individual molecules, but even greater than the minute inequalities or furrows in the artificially polished surfaces of media. Granting this, the difficulty vanishes; for the average action of many molecules, or many corrugations, will present an uniformity, while individually they may offer the greatest diversity. To illustrate this, we need only cast our eyes on fig. 129, where A B represents the rough surface of a medium, and A C the radius of one of the spheres of attraction, or repulsive activity of a single molecule A. Conceiving now the summits of all the elevations a, b, c, d to lie in a plane, let spheres be described with their centres equal to A C. Then their intersections will generate a kind of mamillated surface a b c d, which, however, if the radii of the spheres be at all considerable with respect to the distances of their centres, we approach exceedingly near to a mathematical plane, infinitely more so than the surface A B need be supposed. Hence, a ray of light impinging on the medium will come within the sphere of its action not at an irregular surface, but nearly at a plane one; and the resultant action of all the molecules in action, in supporting them distributed with uniformity over A B, will be perpendicular to this surface. The same will hold good of the layer of molecules (however interrupted) immediately under the summits b, c, d, &c., and of all the other

Light not reflected by direct impact on bodies.

But by forces at a distance.

L I G. H. T. 447

Part III.
layers into which the whole surface can be divided. So that the essential conditions on which the Newtonian doctrine of reflexion and refraction reposes, (viz. equality of force at equal distances from the general level of the surface, and the perpendicularity of its direction to that level,) still obtain.

It is evident that the inequalities in the mamillary surfaces above described will become more considerable as their radii are diminished, or as the interval of their centres is greater, and in proportion will the regularity of refraction and reflexion be interrupted. Hence it too follows, that the more oblique the incidence of the ray, the greater may be the roughness of the surface which will give a regular reflexion; and this is perfectly consonant to fact, as may be easily tried with a piece of emered glass, which, although so rough as to give no regular image at a perpendicular incidence, will yet give a pretty distinct one at great obliquities. The reasons are, first, that a very oblique ray will not require to penetrate so far within the sphere of repulsion, to have its motion perpendicular to the surface destroyed; and, secondly, that it cannot pass between two contiguous elevations or depressions of the imaginary surface \( \beta \gamma \), but by reason of its obliquity must traverse several of them, and thus undergo a more regular average exertion of the forces of the medium.

Thus the reflexion of light is explained on the Newtonian doctrine. But it may still be asked, how reflexion at a surface artificially polished can ever be regular. In reflexion, the ray never reaches the asperities of the surface; it undergoes their average action, equalized by distance, and mutually compensated. In refraction, it is otherwise. Here the rays must actually traverse the surface, and must therefore actually pass through all its inequalities at every possible angle of obliquity. The answer to this is equally plain. Neither refraction nor reflexion are performed close to the surface, either wholly, or in great part. The greater part by far of the flexure of the ray is performed (either internally or externally) at a distance, out of the reach of these irregularities, and by the action of a much more considerable thickness of the medium than is occupied by them. Their action must be compared to the effect of mountains on the earth's surface in disturbing the general force of gravity. A stone let fall close to one of them, from a moderate height, follows not the true vertical but the direction of the deviated plumbline, which is sensibly different. Whereas, if let fall from the moon to the earth's centre, it would pass among them, were they greater a thousand fold than they are, without experiencing any sensible perturbation or change of direction in their neighbourhood.

In fact, however, no regular reflexion can be obtained from surfaces sensibly rough, at all comparable to the regularity of their reflexion. This may arise from the impossibility of a refracted ray penetrating the surface at a sufficient degree of obliquity. It is, however, a remarkable fact, that the regular internal reflexion from a roughened surface, even at extreme obliquities, is scarcely sensible, even in cases where the external reflexion at the same obliquities is perfectly regular and copious. This would seem to indicate, that the forces which operate the external reflexion of a ray exert their energy wholly without the medium.

Whatever be the forces by which bodies reflect and refract light, one thing is certain, that they must be incomparably more energetic than the force of gravity. The attraction of the earth on a particle near its surface produces a deflexion of only about 16 feet in a second; and, therefore, in a molecule moving with the velocity of light, would cause a curvature, or change of direction, absolutely insensible in that time. In fact, we must consider, first, that the time during which the whole action of the medium takes place, is only that within which light traverses the diameter of the sphere of sensible action of its molecules at the surface. To allow so much as a thousandth of an inch for this space is beyond all probability, and this interval is traversed by light in the

\[ \frac{1}{12,679,000,000} \] part of a second. Now, if we suppose the deviation produced by refraction to be 30\(^\circ\) (a case which frequently happens,) and to be produced by a uniform force acting during a whole second; since this is equivalent to a linear deflexion of 200,000 miles \( \times \sin 30\(^\circ\)\), or of 100,000 miles \( = 33,000,000 \times 16 \) feet, such a force must exceed gravity on the earth's surface 33,000,000 times. But, in fact, the whole effect being produced not in one second, but in the small fraction of it above mentioned, the intensity of the force operating it (see MECHANICS) must be greater in the ratio of the square of one second to the square of that fraction; so that the least improbable supposition we can make gives a mean force equal to 4,969,126,272 \( \times 10^4 \) times that of terrestrial gravity. But in addition to this estimate already so enormous, we have to consider that gravity on the earth's surface is the resultant attraction of its whole mass, whereas the force deflecting light is that of only those molecules immediately adjoining to it, and within the sphere of the deflecting forces. Now a sphere of \( \tau \nu \nu \nu \) of an inch diameter, and of the mean density of the earth, would exert at its surface a gravitating force only \( \tau \nu \nu \nu \times \frac{1}{\text{diameter of the earth}} \) of ordinary gravity, so that the actual intensity of the force exerted by the molecules concerned cannot be less than 1000 \( \times \text{earth's diameter} \) \( (= 46,352,000,000) \) times the above enormous number, or upwards of \( 2 \times 10^4 \) when compared with the ordinary intensity of the gravitating power of matter. Such are the energies concerned in the phenomena of light on the Newtonian doctrine. In the undulatory hypothesis, numbers not less immense will occur; nor is there any mode of conceiving the subject which does not call upon us to admit the exertion of mechanical forces which may well be termed infinite.

Dr. Wollaston has proposed the observation of the angle at which total reflexion first takes place at the common surface of two media, the index of reflexion of one of which is known, as a means of determining that of the other; and, in the Philosophical Transactions for 1809, has described an ingenious apparatus which gives a measure of the index required almost by inspection. If we lay any object under the base of a prism
Light

of flint glass with air alone interposed, the internal angle of incidence at which the visual ray begins to be totally reflected, and at which of course the object ceases to be seen by refraction is about 39° 10'; but when the object has been dipped in water, and brought into contact with the glass, it continues visible (while the eye is depressed) by means of the greater refractive power of the water, as far as 57° 5'. When any kind of oil, or any resinous cement, is interposed, this angle is still greater, according to the refractive power of the medium employed; and by cements that refract more strongly than the glass, the object may be seen through the prism at whatever angle of incidence it is viewed. All that is requisite, then, to determine the refractive index of any body less refractive than glass, is to bring the substance to be examined in optical contact with the base of a prism, and to depress the eye (or increase the angle of incidence) till it ceases to be seen as a dark spot on the silvery reflexion of the sky on the rest of the base. With fluids and soft solids, or fusible ones, the requisite contact is easily obtained; but with solids, they must be brought to smooth surfaces, and applied to the base by the intervention of some fluid or cement of higher refractive power than the glass, which (since the surfaces of the interposed stratum are parallel) will produce no change in the total deviation of a ray passing through it, and therefore no error in the result. By this method, opaque as well as transparent substances may be examined, or bodies of unhomogeneous density, as the crystalline lens of the eye. It may seem paradoxical to speak of the refractive power of an opaque body; but it will be remembered, that opacity is merely a consequence of intense absorbent power, and that before a ray can be absorbed, it must enter the medium, and of course obey the laws of refraction at its surface. By this method, Dr. Wollaston has determined the refractions of a great variety of bodies; but Dr. Brewster remarks, that the method must be liable to some source of inaccuracy, which renders it unsafe to trust entirely to it in practice. Dr. Young has remarked, that the index of refraction given by it, belongs in strictness to the extreme red rays.

§ II. General Statement of the Undulatory Theory of Light.

The undulatory theory, among whose chief supporters we have to number Huygens, Descartes, Hooke, and Euler, and in later times, the illustrious names of Young and Fresnel, who have applied it with singular success and ingenuity to the explanation of those classes of phenomena which present the greatest difficulties to the Corpuscular doctrine, requires the admission of the following hypotheses or postulata:

1. That an excessively rare, subtle, and elastic medium, or ether, as it is called, fills all space, and pervades all material bodies, occupying the intervals between their molecules; and, either by passing freely among them, or, by its extreme rarity, offering no resistance to the motions of the earth, the planets, or comets in their orbits, is a system of undulations appreciable by the most delicate astronomical observations; and having inertia, but not gravity.

2. That the molecules of the ether are susceptible of being set in motion by the agitation of the particles of ponderable matter, and that when any one is thus set in motion it communicates a similar motion to those adjacent to it; and thus the motion is propagated further and further in all directions, according to the same mechanical laws which regulate the propagation of undulations in other elastic media, as air, water, or solids, according to their respective constitutions.

3. That in the interior of refracting media the ether exists in a state of less elasticity, compared with its density, than in vacuo, (i.e. in space empty of all other matter;) and that the more refractive the medium, the less, relatively speaking, is the elasticity of the ether in its interior.

4. That vibrations communicated to the ether in free space are propagated through refractive media by means of the ether in their interior, but with a velocity corresponding to its inferior degree of elasticity.

5. That when regular vibratory motions of a proper kind are propagated through the ether, and, passing through our eyes, reach and agitate the nerves of our retina, they produce in us the sensation of light, in a manner bearing a more or less close analogy to that in which the vibrations of the air affect our auditory nerves with that of sound.

6. That as, in the doctrine of the aerial pulses, or the number of excursions to and fro from its point of rest made by each molecule of the air, determines the pitch, or note, so, in the theory of light, the frequency of the pulses, or number of impulses made on our nerves in a given time by the ethereal molecules next in contact with them, determines the colour of the light; and that as the absolute extent of the motion to and fro of the particles of air determine the loudness of the sound, so the amplitude, or extent of the excursions of the ethereal molecules from their points of rest, determine the brightness or intensity of the light.

The application of these postulates to the explanation of the phenomena of light, presumes an acquaintance with the theory of the propagation of motion through elastic media. This we shall assume, referring to our article on sound for the demonstration of all the properties and laws of motions so propagated, as we shall have occasion to employ. One of the principal of these is, that supposing the elastic medium uniform and homogeneous, all motions of whatever kind are propagated through it in all directions with one and the same uniform velocity, a velocity depending solely on the elasticity of the medium as compared with its inertia, and bearing no relation to the greatness or smallness, regularity or irregularity of the original disturbance. Thus, while the intensity of light, like that of sound, diminishes as the distance from its origin increases, its velocity remains invariable, and thus, too, as sounds of every pitch, so light of every colour, travels with one and the same velocity, either in vacuo, or in a homogeneous medium.

Now here arises, in timine, a great difficulty; and it must not be dissembled, that it is impossible to look on
it in any other light than as a most formidable objection to the undulatory doctrine. It will be shown presently that the deviation of light by refraction is a consequence of the difference of its velocities within and without the refracting medium, and that when these velocities are given the amount of deviation is also given. Hence it would appear to follow unavoidably, that rays of all colours must be in all cases equally refracted; and that, therefore, there could exist no such phenomenon as dispersion. Dr. Young has attempted to gloss over this difficulty, by calling in to his assistance the vibrations of the ponderable matter of the refracting medium itself, as modifying the velocity of the ethereal undulations within it, and that differently according to their frequency, and thus producing a difference in the velocity of propagation of the different colours; but to us it appears with more ingenuity than success. We hold it better to state it at once in its broadest terms, and call on the reader to suspend his condemnation of the doctrine for what it apparently will not explain, till he has become acquainted with the immense variety and complication of the phenomena which it will. The fact is, that neither the competency nor the exigency of the medium which has yet been discovered, will furnish that complete and satisfactory explanation of all the phenomena of light which is desirable. Certain admissions must be made at every step, as to modes of mechanical action, where we are in total ignorance of the acting forces; and we are called on, where reasoning fails us, occasionally for an exercise of faith. Still, if we regard hypotheses and theories as no other way valuable than as means of classifying and grouping together phenomena, and of referring facts to laws which, though possibly empirical, are yet, so far as they are so, correct representations of nature, and as such must be deductible from real primary laws, whenever they shall be discovered, we cannot but admit their importance. The undulatory system especially is necessarily liable to considerable obscurities; as the doctrine of the propagation of motion through elastic media is one of the most abstruse and difficult branches of mathematical inquiry, and we are therefore perpetually driven to indirect and analogical reasoning, from the utter hopelessness of overcoming the mere mathematical difficulties inherent in the subject when attacked directly.

It is thus that we are encountered at the very outset of its application with another objection, which, in the eye of Newton, appeared decisive against its admission, but which has since been, in a considerable degree, overcome. How is it that shadows exist. Sounds make their way freely round a corner, why does not light do so? A vibration propagated from a centre in an elastic medium, and intercepted by an immovable obstacle having a small orifice, ought to spread itself, it is said, from this orifice beyond the screen as from a new centre, and fill the space beyond with undulations propagated from it in every direction. Thus, as in Acoustics, the orifice is heard as a new source of sound; so, in Optics, it ought to be seen in all directions as a new luminary. To this the answer is, first, that it is not demonstrable that a vibratory motion communicated to one particle of an elastic medium is propagated with equal intensity to every surrounding molecule in whatever direction situated with respect to the line of its motion, though it is with equal rapidity; and therefore that we have no reason to presume, a priori, but rather the contrary, that the motions of the vibrating particles at the orifice should be propagated laterally with equal intensity in all directions; secondly, that it is not true, in fact, that sounds are propagated round the corner of an obstacle with the same intensity as in their original direction, as any one may convince himself by the following simple experiment. Take a common tuning fork, and, holding it (when set in vibration) about three or four inches from the ear, with its flat side towards it, when its sound is distinctly heard, let a strip of card, somewhat longer than the flat of the tuning fork, be imposed on half an inch from the fork. The sound will be almost entirely intercepted by it; and if the card be alternately removed and replaced in pretty quick succession, alternations of sound and silence will be perceived; proving that the undulations of the air are by no means propagated with equal intensity by the circuitous route round the edge of the card, as by the direct one. Indeed any one has only, to be convinced of the fact, to attend to the sound of a carriage in the act of turning a corner from the street in which he happens to be to an adjoining one; to which we may add, that, even when there is no obstacle in the way, sounds are by no means equally audible in all directions from the sounding body, as any one may convince himself by holding a vibrating tuning fork, or pitchpipe, near his ear, and turning it quickly on its axis. This last phenomenon was first noticed, we believe, by Dr. Young, (Phil. Trans., 1802, p. 25,) and since more fully described (in Schweigger's Jahrbuch, 1826) by M. Weber. Now if there be any inequality at all in the intensity of the direct and lateral propagation of undulations in a medium, it must arise from the constitution of the medium, and the proportion of the amplitudes of the excursions of the vibrating particles to their distance from each other; and may therefore easily be conceived to differ in any imaginable degree in different media, and there is, at least, no absurdity in supposing the ether so constituted as to admit of comparatively very feeble lateral propagation. Now, thirdly, in point of fact, light does spread itself in a certain small degree into the shadows of bodies, out of its strict rectilinear course, giving rise to the phenomena of inflexion or diffraction, of which more presently, and which are completely accountable for on the undulatory doctrine, and form, in fact, its strongest points. For further information on this confessedly abstruse subject, the reader must consult our article on Sound, and the works cited at the end of this Essay. It is enough here to show, that the objection which has been urged by Newton and his followers with such force against the doctrine of undulations, is really not conclusive against it, but founded rather on inadequate conceptions of the nature of elastic fluids, and the laws of their undulations.

Although any kind of impulse, or motions regulated by any law, may be transferred from molecule to molecule in an elastic medium, yet in the theory of light it is supposed that only such primary impulses as recur according to regular periodical laws, at equal intervals of time, and repeated many times in succession, can affect our organs with the sensation of light. To put in motion the molecules of the nerves of our retina with sufficient efficacy, it is necessary that the almost infinitely minute impulse from the motions of the adjacent ether should be often and regularly repeated, so as to multiply, and, as it were, concentrate their effect. Thus, as a great pendulum may be set in swing by a very minute force often applied at intervals exactly equal to its time.
of oscillation, or as one elastic solid body can be set in vibration by the vibration of another at a distance, propagated through the air, if in exact unison, even so may we conceive the gross fibres of the nerves of the retina to be thrown into motion by the continual repetition of the ethereal pulses; and such only will be thus agitated, as from their size, shape, or elasticity are susceptible of vibrating in times exactly equal to those at which the impulses are repeated. Thus it is easy to conceive how the limits of visible colour may be established; for if there be no nervous fibres in unison with vibrations more or less frequent than certain limits, such vibrations, though they reach the retina, will produce no sensation. Thus, too, a single impulse, or an irregularly repeated one, produces no light; and thus also may the vibrations excited in the retina continue a sensible time after the exciting cause has ceased, prolonging the sensation of light (especially of a vivid one) for an instant in the eye in the manner described, (Art. 543.) We may thus conceive the possibility of other animals, such as insects, incapable of being affected with any of our colours, and receiving their whole stock of luminous impressions from a class of vibrations altogether beyond our limits, as Dr. Wollaston has ingeniously imagined (we may almost say proved) to be the case with their perceptions of sound.

The law of motion of every particle of the ether is regulated by that of the molecule of the luminary from which it takes its origin; and will be regular or irregular, periodical or not, according as that of the original molecule is so or otherwise. But it is only with motions which may be regarded as infinitely small that we are concerned in this theory. The displacement of each particle, either of the ether or of the luminary, is supposed to be so minute as not to detach it from, or change its order of situation among the neighbouring ones. Now when we consider only such infinitesimal displacements from the position of equilibrium, it is evident, that the tension arising from them, or the force by which the displaced molecule is urged, must be proportional in quantity to its distance from its point of rest, and must tend directly to that point, provided we suppose the medium equally elastic in all directions. Hence, by the laws of Dynamics, its trajectory must be an ellipse described in one plane about the point of equilibrium as its centre; or, if one of the axes of the ellipse vanish, a straight line having that point in its middle, in which it oscillates to and fro, performing all its excursions in the latter case, or its revolutions in the former, whether great or small, in equal times, and following the law of a vibrating pendulum. We will, for the present, consider the case of rectilinear vibrations as the most simple, and show hereafter how the more general one may be reduced to it.

**Proposition.** To define the motion of a vibrating molecule of a luminary, supposing its excursions to and fro to be performed in straight lines.

Putting \( x \) for its distance from its point of rest, \( t \) for the time elapsed since a given epoch, and \( v \) for its velocity, and \( E \) for the absolute elastic force, the force urging the molecule to its point of equilibrium will be \( E \cdot x \), and will tend to diminish \( x \); hence (supposing gravity to be represented by 32 \( \frac{1}{2} \) feet) we must have

\[
\frac{dv}{dt} = -\frac{dx}{dt} = E \cdot x,
\]

and therefore \( \frac{dx}{dt} \cdot \frac{dx}{dt} = -2 \cdot E \cdot x \cdot dx \), or, integrating, \( \frac{dx^2}{dt^2} \) or \( v^2 = E \cdot (a^2 - x^2) \) where \( a \) is the greatest distance of excursion, or the semiamplitude of the vibration. Hence,

\[
v = \sqrt{\frac{E}{a^2 - x^2}} \cdot \frac{dx}{dt},
\]

and therefore \( \frac{dx}{dt} = -\frac{v \cdot dx}{\sqrt{E \cdot (a^2 - x^2)}} \); or, integrating, \( t + C = \frac{1}{\sqrt{E \cdot (a^2 - x^2)}} \), that is

\[
s = a \cdot \cos \left( \sqrt{\frac{E}{a} \cdot (t + C)} \right); \quad v = a \cdot \sqrt{\frac{E}{a}} \cdot \sin \left( \sqrt{\frac{E}{a} \cdot (t + C)} \right).
\]

Such are the velocity and distance from the middle point of its vibration of the molecule at any instant. If we call \( T \) the whole period in which the molecule has performed one complete evolution, consisting of a complete excursion to and fro on both sides of its point of equilibrium, we shall have at the commencement of the motion when \( v = 0 \), or \( x = a, a \cdot \cos \left( \sqrt{\frac{E}{a} \cdot (t + C)} \right) = a, \) or \( (t + C) \sqrt{\frac{E}{a}} = 0 \); and when one quarter of a period has been performed, or the molecule has arrived at its greatest distance \( a \) on the opposite side of the centre \( -a = a \cdot \cos \left( \sqrt{\frac{E}{a} \cdot (t + 1T + C)} \right), \) or \( \sqrt{\frac{E}{a}} \cdot (t + 1C + \frac{1}{2}T) = r, \) putting \( r \) for the semicircumference of a circle whose diameter is \( 1 \). Hence we get by subtraction

\[
\frac{1}{2} \cdot T \cdot \sqrt{\frac{E}{a}} = \pi; \quad T = \frac{2\pi}{\sqrt{\frac{E}{a}}}.
\]

Hence we may eliminate \( E \), and introduce \( T \) instead of it, which will give the equations \( \sqrt{\frac{E}{a}} = \frac{2\pi}{T}, \)

\[
s = a \cdot \cos 2\pi \cdot \frac{t + C}{T}; \quad v = a \cdot \sqrt{\frac{E}{a}} \cdot \sin 2\pi \cdot \frac{t + C}{T};
\]

which equations express the laws required, and which if the time \( t \) be supposed to commence at the moment when \( v = 0 \), or when the molecule is at the extremity of one of its excursions, become simply

\[
s = a \cdot \cos 2\pi \cdot \frac{t}{T}; \quad v = a \cdot \sqrt{\frac{E}{a}} \cdot \sin 2\pi \cdot \frac{t}{T}.
\]

\( s n 2 \)
Corol. Hence the excursions of the molecule to and fro will consist of four principal phases, in each of which its motion is similar, but in contrary directions, or on contrary sides of the centre. In the first phase the molecule is to the right of the centre of motion, and is approaching the centre, or moving from right to left.

In the second, it is to the left of the middle point, and moving from it, or still from right to left. These two phases we shall term the positive phases. In the third phase the molecule lies on the left side, and its motion is towards the centre, and from left to right. In the fourth, it is to the right again, receding from the centre, and moving still from left to right. These we shall term the negative phases of its vibration.

Proposition. To define the rectilinear vibrations of any molecule of the ether, propagated from a luminous particle vibrating as in the last proposition.

In the propagation of motions through elastic, uniform media, the same or a similar motion to that of any one molecule is communicated to every other in succession; but this communication occupies time, and the motion of a molecule at a distance from the origin of the vibrations does not commence till after the lapse of an interval of time proportional to that distance, being the time in which the propagated impulse, whether of sound or light, &c. runs over that distance with a certain uniform velocity due to the intrinsic elasticity of the medium, and which in the case of light is about 200,000 miles per second; in that of sound about 1200 feet. And when the vibration of the original source of motion has ceased, that of the ethereal molecule does not cease on the instant, but continues for a time equal to that which elapsed before its commencement. Hence, if we call $V$ the velocity of light, and $D$ the distance of the molecule from the luminous point, $\frac{D}{V}$ will be the interval between the commencement of the motion of the latter and of the former; hence $t$ being the time elapsed at any instant since the commencement of the first positive phase of the vibration of the luminous point, $t - \frac{D}{V}$ will be the corresponding time in the case of the ethereal molecule. Thus we have, for the equations of the motions of the former,

$$x = a \cdot \cos 2 \pi \cdot \frac{t}{T}; \quad v = b \cdot \sin 2 \pi \cdot \frac{t}{T}; \quad \text{where } b = a \sqrt{E}$$

and in that of the latter

$$x = a \cdot \cos 2 \pi \left(\frac{t - \frac{D}{V}}{T}\right); \quad v = \beta \cdot \sin 2 \pi \left(\frac{t - \frac{D}{V}}{T}\right); \quad \text{where } \beta = a \sqrt{E}$$

$\alpha$ being the semi-amplitude of the vibration, or the extent of the excursion of the ethereal molecule from its point of rest.

Corol. Hence it is evident that the actual velocity of the molecules of ether may be less in any proportion than that of light; for the maximum value of $v$ depends for its numerical magnitude solely on $\alpha$, or on the amplitude of excursion, and on $E$, and not at all on $V$ the velocity of propagation of the wave.

Corol. 2. If we suppose the luminous molecule to have made, from the commencement of its motion, any number of vibrations and parts of a vibration in the time $t$; then if we consider an ethereal molecule at a distance $V \cdot t$ from it in any direction, (i.e. situated in a spherical surface whose radius is $V \cdot t$) this molecule will be just beginning to be put in motion. If we suppose another spherical surface concentric with the former, but having its radius less than the former by $V \cdot T$, which in future we shall call $\lambda$, every particle situated in this surface will have just completed one vibration, and be commencing its second, and so on. The interval between these surfaces will comprehend, arranged in spherical, concentric shells, molecules in every phase of their vibrations,—those in each shell being in the same phase. This assemblage of molecules is termed a wave, and as the impulse continues to be propagated forwards it is evident that the wave will continue to increase in radius, and will comprehend in succession all the molecules of the medium to infinity.

Definition. The interval between the internal and external surface of a luminous wave is called an undulation, or a pulse, and its length is evidently $V \cdot T = \lambda$, or the space run over by light in the time $T$ of one complete period, or vibration of the ethereal molecule. It is therefore proportional to that time.

Hence the lengths of the undulations of differently coloured rays differ inter se. For, by Postulate 6, the number of vibrations made in any given time by the ethereal particles determines the colour. Now the more numerous the vibrations are, dato tempore, the shorter their duration; hence $T$, which represents this duration, is less; and therefore $\lambda$, or the length of the undulation less for the violet than for the red rays. From experiments to be presently described, it has been found, that the lengths of the undulations in air, or the values of $\lambda$ for the different rays, as also the number of times they are repeated in one second, are as in the following table:
The direction of a ray in the undulatory system is a line perpendicular to the surface of the wave at any point. When, therefore, the vibration is propagated through an uniform ether, the wave being bounded by spherical surfaces, the direction of the ray is constant, and from the centre. Thus in this system a ray of light moves in a right line in an uniform medium.

The intensity of a ray is, of course, in some certain determinate ratio of the impulse made on the retina dato tempore by the ethereal molecules, and therefore in some certain ratio of their amplitudes of excursion, or their absolute velocities. The principle of the conservation of living forces requires that the amplitude of excursion of a molecule, situated at any distance from the vibrating centre, should be as the distance inversely, (see Acoustics.) If then we suppose the sensation created in the retina to be as the simple vis inertiae of the molecules producing it, light ought to decrease inversely as the distance; if as the vis viva, (which is as the square of the velocity,) inversely as the square of the distance. As we know nothing of the mode in which the immediate sensation of light or sound is produced in the sensorium, we have no reason to prefer one of these ratios to the other a priori. But when we consider, that in the division of a beam of light by partial reflection, or by double refraction, or otherwise, there is neither gain nor loss of light, (supposing the perfect transparency and polish of the medium which operates the division) so that the sum of the intensities remains constant, however the absolute velocities of the vibrating molecules may change, either in quantity, or (as in the case of reflection, where they must be conceived to rebound from each other, mediatly or immediately) in sign, the agreement of this law in all cases with that of the conservation of the vis viva, and its opposition in the other mentioned case to that of the uniform motion of the centre of gravity, (which would make not the sum, but the difference of the intensities constant, were the simple ratio of their velocities supposed for their measure,) (see Dynamics,) leaves us no choice in preferring the square of the absolute velocity, or of the amplitude of excursion of a vibrating molecule, for the measurement of the intensity of the ray it propagates; and thus the observed law of the diminution of light is reconciled to the undulatory doctrine.

When the medium through which the vibrations are transmitted is not uniformly elastic, the waves will make unequal progress in different directions, according to the law of elasticity. In this case the figure of the wave will not be spherical. If we suppose the elasticity to vary by insensible gradations, as when light passes through the atmosphere, whose refracting power is variable, the figure of the wave will be flattened towards that part where the elasticity is less. Thus, in fig. 126, if A B be the earth's surface, C D, E F, G H, &c. the atmospheric strata, and S a luminous point, the waves will be less curved as they approach the perpendicular S B; and the line S, 1, 2, 3, 4, 5, &c. drawn so as to intersect them all at right angles, will be a curve convex downwards, so that a ray will appear to be continually bent downwards towards the earth, as we see really happens. Let us now proceed to consider the explanation of the phenomena of reflexion and refraction on the undulatory system.
Light.

1. When any number of very minute impulses is communicated at once to the particles of any medium, or of any mechanical system under the influence of any forces, the motion of each particle at any instant will be the sum of all the motions which it would have at that instant, had each of the impulses been communicated to the system alone, (the word sum being understood in its algebraical sense.)

2. Every vibrating molecule in an elastic medium, whether vibrating by an original impulse, or in consequence of an impulse propagated to it from others, may be regarded as a centre of vibration from which a system of secondary waves emanates in all directions, according to the laws of the propagation of waves in the medium.

Proposition. In the reflexion of light on the undulatory doctrine, the angle of incidence is equal to that of reflexion.

Law of Reflection at a Plane.

Law of Superposition of Small Motions.

Principle of Secondary Waves.

Law of Propagation of Impulse.

Principle of an Impulse propagated to it from others, may be regarded as a centre of vibration from which a system of secondary waves emanates in all directions, according to the laws of the propagation of waves in the medium.

Waves.

Proposition. To demonstrate the law of refraction in the undulatory system.

Law of Refraction.

Fig. 129.

Fig. 128.
LIGHT.

Definition. A focus is a point at which the same wave arrives at the same instant from more than one point in a surface.

It is evident, that when this is the case, the ethereal molecules in the focus will be agitated by the united force of all the undulations which reach them in the same phase at the same instant, and will be proportionally more violent as the focus is common to a greater number of points, and the light in the focus will be proportionally more intense.

Proposition. Required to determine the nature of the surface which shall refract all rays from one point rigorously to one focus. Let $F$ (fig. 189) be the focus, then every part of a wave propagated from $S$ and refracted at the surface $AB$, reach $F$ at the same instant; therefore time of describing $SX$ with velocity $V$ + time of describing $XF$ with velocity $v$ is constant for every point in the surface. Or,

$$\frac{SX}{V} + \frac{FX}{v} = \text{constant, or } SX + \mu \cdot FX = \text{constant, } \mu \text{ being the relative index of refraction.}$$

This equation then defines the nature of the curve sought, and it is easy to perceive its identity with that expressed by the equation \(\text{(n)}\) Art. 232, obtained from a direct consideration of the law of refraction, but by a much more intricate method.

The intensity of the reflected or refracted ray cannot be computed generally in the present very imperfect state of our knowledge of the theory of waves. M. Poisson, however, in the case of perpendicular incidence, and on intensity of the particular hypothesis of the luminous vibrations being performed in the direction of the ray itself, has succeeded in investigating the comparative intensities of the incident, reflected, and transmitted rays. His results are as follows: Taking $\mu$, $\mu'$ for the absolute refractive indices of the media, he finds (on the supposition that the intensity of light is equal to the square of the absolute velocity of the vibrating molecules) :

Intensity of reflected ray : that of incident :\(\mu - \mu'\) : ($\mu' + \mu$). Intensity of the transmitted ray : that of the incident :\(\mu'\) :\(\mu' + \mu\). Intensity of the refracted ray from a medium whose refractive index is $\mu$ into a parallel plate of one whose refractive index is $\mu'$, in contact with its second surface with a third whose refractive index is $\mu''$, reflected at their common surface, and again emergent at the first surface : intensity of the ray originally incident on the first surface :\(\mu'\mu''\) ($\mu' + \mu$) ($\mu' + \mu''$). And, lastly, the intensity of the ray transmitted through the parallel plate of the second medium into the third : that of the original incident ray :\(\mu'\mu''\) ($\mu' + \mu$) ($\mu' + \mu''$) which (in the case where the third medium is the same as the first) becomes\(16\mu'\mu''\) ($\mu' + \mu$). These results of M. Poisson, so far as they have hitherto satisfactorily compared with experiment, manifest at least a general accordance, and the undulatory doctrine thus furnishes a plausible explanation of the connection of the reflecting power of a medium with its refractive index, and of the diminished reflection at the common surfaces of media in contact.—They have been in great measure (it should be observed) anticipated by Dr. Young, in his Paper on Chromatics, (Encyclop. Brit.) by reasoning which M. Poisson terms indirect, but which, we confess, appears to us by no means to merit the epithet.
§ III. Of the Interference of the Rays of Light.

The principle on which this part of the theory of Light depends, is a consequence of that of the "Superposition of small motions" laid down in Art. 583. If two waves arrive at once at the same molecule of the ether, that molecule will receive at once both the motions it would have had in virtue of each separately, and its resultant motion will, therefore, be the diagonal of a parallelogram whose sides are the separate ones. If, therefore, the two component motions agree in direction or very nearly so, the resultant will be very nearly equal to their sum, and in the same direction. If they very nearly oppose each other, then to their difference. Suppose, now, two vibratory motions consisting of a series of successive undulations in an elastic medium, all similar and equal to each other, and indefinitely repeated, to arrive at the same point from the same original centre of vibration, but by different routes (owing to the interposition of obstacles or other causes) exactly, or very nearly in the same final direction; and suppose, also, that owing either to a difference in the lengths of the routes, or to a difference in the velocities with which they are traversed, the time occupied by a wave in arriving by the first route (A) is less than that of its arriving by the other (B). It is clear, then, that any ethereal molecule placed in any point common to the two routes A, B, will begin to vibrate in virtue of the undulations propagated along A, before the moment when the first wave propagated along B reached it. Up, then, to this moment its motions will be the same as if the waves along B had no existence. But after this moment, its motions will be very nearly the sum or difference of the motions it would have separately in virtue of the two undulations each subsisting alone, and the more nearly, the more nearly the two routes of arrival agree in their final direction.

Now it may happen, that the difference of the lengths of the routes on the difference of velocities is such, that the waves propagated along B shall reach the intersection exactly one half an undulation behind the others, &c. later by exactly half the time of a wave running over a space equal to a complete undulation. In that case, the molecule which in virtue of the vibrations propagated along A would (at any future instant) be in one phase of its excursions from its point of rest, would, in virtue of those propagated along B, if subsisting alone, be at the same instant in exactly the opposite phase, i.e. moving with equal velocity in the contrary direction. (See Art. 570.) Hence, when both systems of vibration coexist the motions will constantly destroy each other, and the molecule will remain at rest. The same will hold good if the difference of routes or velocities be such, that the vibrations propagated along B shall reach the intersection of the routes exactly \( \frac{1}{2}, \frac{1}{4}, \frac{1}{8}, \&c. \) of a complete period of undulation after those propagated along A; for the similar phases of vibration recurring periodically, and being (by hypothesis) continually repeated for an indefinite time, it is no matter whether the first vibration propagated along B be superimposed on, or interfere with (as it is called) the first, or any subsequent one propagated along A, provided the difference of their phases be the same.

On the other hand it may happen, that the waves propagated along B do not reach the intersection till exactly one, two, or more whole periods after the corresponding waves propagated along A. In this case, the molecule at the intersection will, at any instant subsequent to the time of arrival of the first wave along B, be agitated at once by both vibrations in the same phase, and therefore the velocity and amplitude of its excursions will, instead of being destroyed, be doubled.

If photometrical experiments enable us to determine the proportion of the reflected to the incident light, we may thence conclude the index of refraction of the reflecting medium, and that in cases where no other mode will apply. Thus, M. Arago having ascertained that about half the incident light is reflected at a perpendicular incidence from mercury, we have in this case \( \left( \frac{\mu' - \mu}{\mu' + \mu} \right)^n = \frac{1}{2} \); \( \frac{\mu'}{\mu} = 5.829 \) for the refractive index of mercury out of air; and this is perfectly consonant to the general tenor of optico-chemical facts, which assign to the heavy and especially to the white metals (as indicated in their transparent combinations) enormous refractive and dispersive powers. This curious and interesting application has not been overlooked by Dr. Young in the Paper alluded to.

To complete the theory of reflexion and refraction on the undulatory hypothesis, it will be necessary to show what becomes of those oblique portions of the secondary waves, diverging in all directions from every point of the reflecting or refracting surfaces (as \( X_7, fig. 127 \)) which do not conspire to form the principal wave. But to understand this, we must enter on the doctrine of the interference of the rays of light,—a doctrine we owe almost entirely to the ingenuity of Dr. Young, though some of its features may be pretty distinctly traced in the writings of Hooke, (the most ingenious man, perhaps, of his age,) and though Newton himself occasionally indulged in speculations bearing a certain relation to it. But the unpursued speculations of Newton, and the appercus of Hooke, however distinct, must not be put in competition, and, indeed, ought scarcely to be mentioned with the elegant, simple, and comprehensive theory of Young,—a theory which, if not founded in nature, is certainly one of the happiest fictions that the genius of man has yet invented to group together natural phenomena, as well as the most fortunate in the support it has unexpectedly received from whole classes of new phenomena, which at their first discovery seemed in irreconcilable opposition to it. It is, in fact, in all its applications and details one succession of felicities, insomuch that we may almost be induced to say, if it be not true, it deserves to be so. The limits of this Essay, we fear, will hardly allow us to do it justice.
Lastly, it may happen, that the difference of the times of arrival of the corresponding waves is neither an exact even, or odd multiple of half a complete period of undulation. In that case, the molecule will vibrate with a joint motion, less than double what it would have in virtue of either separately.

An apt illustration of the case of interference here described, may be had by considering the analogous case in the interference of waves on the surface of water. Conceive, for instance, two equally broad canals A and B to enter two canals at right angles into the side of a reservoir, at both whose apertures, from an origin at a great distance, a wave arrives at the same instant, and runs along the two canals with equal, uniform velocities. Let their sides be perfectly smooth, and their breadths everywhere equal, but let them be led, by a gentle curve, to meet in a point at some distance, and, the curvature of B being supposed somewhat greater than that of A, let the distance from their intersection to the reservoir, measured along B, be greater than along A. It is obvious, that (if we consider only a single wave) the portion of it propagated along A will reach the intersection first, and after it that propagated along B, so that the water at that point will be agitated by two waves in succession. But, let the original cause of undulation be continually repeated so as to produce an indefinite series of equal and similar waves. Then, if the difference of lengths of the two canals be just equal to half the interval between the summits of two consecutive waves, it is evident that when the summit of any wave propagated along A has reached the intersection, the depression between two consecutive summits (viz. that corresponding to the wave propagated along A, and that of the wave immediately preceding it) will arrive at the intersection by the course B. Thus, in virtue of the wave along A the water will be raised as much above its natural level, as it will be depressed below it by that along B. Its level will, therefore, be unchanged.—Now as the wave propagated along A passes the intersection, it subsides, from its maximum, by precisely the same gradations as that along B, passing it with equal velocity, rises, from its minimum, so that the level will be preserved at the point of intersection, undisturbed so long as the original cause of undulation continues to act regularly. So soon as it ceases, however, the last half wave which runs along B will have no corresponding portion of a wave along A to interfere with, and will, therefore, create a single fluctuation at the point of concourse.

In the theory of the interferences of light we may disregard these commencing and terminal, uncompensated undulations, and parts of undulations, as being so few in number as to excite no impression on the retina, and consider the interfering rays as of indefinite duration, or as destitute of either beginning or end.

According to the foregoing reasoning then it appears, that if two rays having a common origin, t. e. forming parts of one and the same system of luminous waves proceeding from a common centre, be conducted by different routes to one point which we will suppose to be situated on a white screen, or on the retina of the eye, they will there produce a bright point, or the sensation of light, if their difference of routes be an even multiple of half an undulation, and a dark one; or the sense of darkness, if an odd multiple of it; and if intermediate, then a feebler or a stronger sense of light, as the difference of routes approaches to one or the other of these limits. That two lights should in any case annihilate each other, and produce darkness, appears a strange paradox, yet experiment confirms it; and the fact was observed, and broadly stated by Grimaldi long before any plausible reason could be given of it.

Having thus obtained a general idea of the nature of interferences, let us now endeavour to subject their effects to a more strict calculation. To this end it will be necessary to fix with precision the sense of some words hitherto used rather loosely.

Definition. The phase of an undulation affecting any given molecule of ether at any instant of time, is numerically expressed by an arc of a circle to radius unity, increasing proportionally to the time—commencing at 0 when the molecule is at rest at its greatest positive distance of excursion, and becoming equal to one circumference when the molecule, after completing the whole of a vibration, returns again to the same state of rest at the same point. Thus, in the equation \[ v = a \cdot \sqrt{E} \sin \left( \frac{2\pi}{T} \cdot t + \frac{C}{T} \right), \] \[ 2\pi \cdot \frac{t + C}{T} \] is the phase of the undulation at the instant \( t \).

Definition. The amplitude of vibration of a ray or system of waves is the coefficient \( a \), or the maximum excursion from rest, of each molecule of the ether in its course.

Corol. The intensity of a ray of light is as the square of the amplitude of the vibrations of the waves of which it consists.

Definition. Similar rays, or systems of luminous waves, are such as have the vibratory motions of the etheral molecules which compose them regulated by the same laws, and their vibrations performed in equal times, and the curves or straight lines they describe in virtue of them, similar and similarly situated in space, so that the motions of any two corresponding molecules in each, shall at every instant of time be parallel to each other.

Corol. Similar rays have the same colour.

Definition. The origin of a ray, or a system of waves, is the vibrating material centre from which the waves begin to be propagated, or more generally, a fixed point in its length, at which an etheral molecule, at an assumed epoch, was in the phase 0 of its undulation.

Corol. Two systems of interfering waves having their origins distant by an exact number of undulations, may be regarded as having a common origin.

Proposition. To find the origin of a ray, having given the expression for the velocity of one of its vibrating molecules.

Let \[ a = a \cdot \sqrt{E}, \] and let \[ v = a \cdot \sin \left( \frac{2\pi}{T} \cdot \frac{t + C}{T} \right) \] be the expression given for the velocity of the wave at the instant \( t \).
of any assumed molecule \( (M) \) at the instant \( t \). Let \( V \) represent the velocity of light, and \( \lambda \) the length of an undulation, and \( \delta \) the distance run over by light in the time \( t \). Then will \( \delta = V t \) and \( \lambda = V T \), and consequently

\[
\frac{t}{T} = \frac{\delta}{\lambda}.
\]

Suppose \( v \) to represent the velocity of a vibrating molecule at the origin of the ray at the instant \( t \), then will \( v = a \cdot \sin \left( 2 \pi \cdot \frac{t}{T} \right) = a \cdot \sin \left( \frac{2 \pi \cdot \delta}{\lambda} \right) \). But the molecule \( M \) moves only by an impulse communicated to it from the origin, and therefore all its motions are later than those at the origin by a constant interval equal to the time required for light to run over the distance of \( M \) from the origin. Call \( D \) that distance, then \( \frac{D}{V} \) is the interval in question, and \( t - \frac{D}{V} \) is the time elapsed at the instant \( t \), since the molecule commenced its periodic motions; therefore its velocity \( v \) must = \( a \cdot \sin \left( \frac{2 \pi \cdot t - D}{V} \right) \), and consequently \( C = \frac{D}{V} \), or \( D = -V C \).

Hence we see that the distance of the molecule \( M \) from the origin of the ray, is equal to the space described by Light, in a time represented by the arbitrary constant \( C \), and is therefore given when \( C \) is so, and vice versa.

610. Corol. Since \( VT = \lambda \), the expression for the velocity becomes

\[
v = a \cdot \sin \left( 2 \pi \cdot \frac{t - \frac{D}{V}}{\lambda} \right) = a \cdot \sin \left( \frac{2 \pi \left( \delta - \frac{D}{\lambda} \right)}{\lambda} \right) \text{ and similarly } x = a \cdot \cos 2 \pi \left( \frac{t - \frac{D}{V}}{\lambda} \right).
\]

Proposition. To determine the colour, origin, and intensity of a ray resulting from the interference of two similar rays, differing in origin and intensity.

Let \( a^* \) and \( a'^* \) be the intensities of the rays, or \( a, a' \) their amplitudes of vibration, and take \( a = a \cdot \sqrt{E} \), \( a' = a' \cdot \sqrt{E} \), then, if we put \( \theta \) for the phase of vibration of a molecule \( M \) at the instant \( t \) which it would be in, in virtue of the first system of waves \((A)\), and \( \theta + k \) for its phase, in virtue of the other \((B)\), \( k \). \( T \) will represent the time taken by light to run over a space equal to the interval of their origin, and the velocities and distances from rest which \( M \) would have, separately at the instant \( t \), in virtue of the two rays, will be

\[
v = a \cdot \sin \theta \; ; \; v' = a' \cdot \sin (\theta + k), \text{ and } x = a \cdot \cos \theta \; ; \; x' = a' \cdot \cos (\theta + k).
\]

Therefore, in virtue of the resulting ray, it will have the velocity

\[
v + v' = a \cdot \sin \theta + a' \cdot \sin (\theta + k), \text{ and } x + x' = a \cdot \cos \theta + a' \cdot \cos (\theta + k).
\]

Let the former be put equal to \( A \cdot \sin (\theta + B) \), the possibility of which assumption will be shown by our being able to determine \( A \) and \( B \), so as to satisfy this condition. Then we have

\[
(\alpha + \alpha' \cdot \cos \kappa) \sin \theta + \alpha' \cdot \sin k \cdot \cos \theta = A \cdot \cos B \cdot \sin \theta + A \cdot \sin B \cdot \cos \theta,
\]

and equating like terms,

\[
A \cdot \cos B = a + a' \cdot \cos k \; ; \; A \cdot \sin B = a' \cdot \sin k,
\]

whence we get, dividing one by the other,

\[
tan B = \frac{a' \cdot \sin k}{a + a' \cdot \cos k} \; ; \; A = \frac{a' \cdot \sin k}{\sin B} = \sqrt{a^2 - 2 \cdot a' \cdot \cos k + a'^2}.
\]

and these values being determined, \( A \) and \( B \) are known, and, therefore, \( v + v' = A \cdot \sin (\theta + B) \). Similarly, if we put \( x + x' = A' \cdot \cos (\theta + B) \) we obtain values of \( A' \) and \( B' \) precisely similar, writing only \( a \; a' \) for \( a, a' \) respectively.

612. Corol. 1. Hence we conclude, 1st. that the resultant ray is similar to the component ones, and has the same period, i.e. the same colour.

613. Fresnel's theorem. Corol. 2. M. Fresnel has given the following elegant rule for determining the amplitude and origin of the resultant ray, which follows immediately from the value of \( A \) and the equation \( \sin B = \frac{a'}{A} \cdot \sin \kappa \) above found.

Construct a parallelogram, having its adjacent sides proportional to the amplitudes \( a, a' \) of the component rays, and the angle between them measured by a circular arc to radius unity, equal to the differences of their phases, then will the diagonal of this parallelogram represent the same scale the amplitude of the resulting ray, and the angle included between it, and either side will represent the difference of phases between it and the ray corresponding; or, which comes to the same thing, the difference of their origins (when reduced to space.)
Corol. 3. Thus in the ease of complete discordance, the diagonal of the parallelogram vanishes, and the angle becomes 180°, or half a circumference, corresponding to a difference of origins of half an undulation. In that of complete accordance, the angle is 0, or 360°, and the origins of the rays coincide, or (which comes to the same thing) differ by an exact undulation, and the diagonal is double of the side, so that the intensity of the compound ray is four times that of either ray singly.

Corol. 4. If the origins of two equally intense rays differ by one quarter of an undulation, the resultant ray will have its amplitude to that of either component one, as \(\sqrt{2} : 1\), and, therefore, its intensity double, and its origin will differ one-eighth of an undulation from that of either. Thus in this particular case, the brightness of the compound ray is the sum of the brightnesses of the components, and its position exactly intermediate between them.

Corol. 5. Any ray may be resolved into two, differing in origin and amplitude, by the same rules as govern the resolution of forces in Mechanics.

Corol. 6. The sum of the intensities of the component rays exceeds that of the resultant, when their origins differ by less than a quarter of an undulation, falls short of it when the difference is between \(\frac{1}{4}\) and \(\frac{1}{2}\), again exceeds it when between \(\frac{1}{2}\) and \(\frac{3}{4}\), and so on. For the value of \(A\), above found, gives

\[\alpha^2 + \beta^2 - A^2 = 2a \alpha' \cos k;\]

now \(\alpha^2\), \(\beta^2\), and \(A^2\), represent the intensities of the respective rays whose momenta are \(a, a'\), and \(A\).

Corol. 7. In the same manner may any number of similar rays be compounded, and the resultant ray will be similar to the elementary rays, and vice versa.

Let us now consider the interference of waves having the same period (or colour) but in all other respects dissimilar.

The law of vibration of the molecules of the luminous bodies which agitate the ether, restricting their motions to ellipses performed in planes, the same will hold good of the motions of each molecule of the ether. Now every elliptic vibration, or rather revolution, performed under the influence of a force directed to its centre and proportional to the distance, is decomposed into three rectilinear vibrations, lying in any three planes at right angles to each other, each of which separately would be performed by the action of the same force in the same time, and according to the same laws of velocity, time, and space. Hence, every elliptic vibration may be expressed by regarding the place of the vibrating molecule at any instant \(t\) as determined by three coordinates \(x, y, z\), such that, \(\theta\) being an arc proportional to the time, we shall have

\[
\begin{align*}
 z &= a \cos(\theta + p); \\
 y &= b \cos(\theta + q); \\
 x &= c \cos(\theta + r);
\end{align*}
\]

(1.)

\[
\begin{align*}
 \frac{dx}{dt} &= u = a \sin(\theta + p); \\
 \frac{dy}{dt} &= v = b \sin(\theta + q); \\
 \frac{dz}{dt} &= w = c \sin(\theta + r);
\end{align*}
\]

(2.)

In fact, if we multiply the first of these equations by an indeterminate \(l\), the second by \(m\), and the third by \(n\) and add, we get

\[
\begin{align*}
 lx + my + nz &= \cos \theta \{ la \cos p + mb \cos q + nc \cos r \} \\
 &= \sin \theta \{ la \sin p + mb \sin q + nc \sin r \}
\end{align*}
\]

(3.)

and, therefore, if we determine \(l, m, n\), so that

\[
la \cos p + mb \cos q + nc \cos r = 0; \\
la \sin p + mb \sin q + nc \sin r = 0
\]

which (being equations of the first degree only) is always possible, we shall have, independently of \(\theta\),

\[
x + my + nz = 0; \quad (4.)
\]

and this, being the equation of a plane, shows that the whole curve represented by the above equations lies in one plane. Again, if we eliminate \(\theta\) between the equations, involving \(x\) and \(y\) only, we have

\[\cos \frac{1}{a} x - \cos \frac{1}{b} y = p - q,\]

or, taking the cosines on both sides,

\[\frac{x}{a} \frac{y}{b} - \sqrt{1 - \frac{x^2}{a^2}} \sqrt{1 - \frac{y^2}{b^2}} = \cos (p - q)\]

and reducing, we get the equation

\[\left(\frac{x}{a}\right)^2 + \left(\frac{y}{b}\right)^2 - 2 \frac{x}{a} \frac{y}{b} \cos (p - q) = \sin (p - q)^2; \quad (5.)\]

which is the equation of an ellipse having the origin of the \(x\) and \(y\) in its centre, and the same is true \textit{mutatis mutandis} of the equations between \(x\) and \(z\), and between \(y\) and \(z\). Thus the curve represented by the three equations between \(x, y, z, \theta\), has an ellipse about the centre for its projection on each of the planes at right angles to each other, and is, of course, itself an ellipse.
Suppose now two systems of waves, or two rays coincident in direction, to interfere with each other. If we accent the letters of the above expressions to represent corresponding quantities for the second system, we shall have

\[
\begin{align*}
X &= x + x' = a \cdot \cos (\theta + p) + a' \cdot \cos (\theta + p') \\
Y &= y + y' = b \cdot \cos (\theta + q) + b' \cdot \cos (\theta + q') \\
Z &= z + z' = c \cdot \cos (\theta + r) + c' \cdot \cos (\theta + r') 
\end{align*}
\]

and similarly for the velocities \( u + u', v + v', w + w' \). In the same manner, then, as we proceeded in the case of two similar rays, let us suppose

\[
a \cdot \cos (\theta + p) + a' \cdot \cos (\theta + p') = A \cdot \cos (\theta + P)
\]

and developing

\[
(a \cdot \cos p + a' \cdot \cos p') \cos \theta - (a \cdot \sin p + a' \cdot \sin p') \sin \theta = A \cdot \cos P \cdot \cos \theta - A \cdot \sin P \cdot \sin \theta,
\]

whence we get

\[
\tan P = \frac{a \cdot \sin p + a' \cdot \sin p'}{a \cdot \cos p + a' \cdot \cos p'}; \quad A = \frac{a \cdot \sin p + a' \cdot \sin p'}{\sin P}
\]

or,

\[
A = \sqrt{a^2 + 2a a' \cdot \cos (p - p') + a'^2}
\]

Thus we have \( X = A \cdot \cos (\theta + P) \), and, similarly, \( Y = B \cdot \cos (\theta + Q) \), and \( Z = C \cdot \cos (\theta + R) \), and a process exactly similar gives us the corresponding expressions for the velocities.

Thus we see that the same rules of composition and resolution apply to dissimilar as to similar vibrations. Each vibration must first be resolved into three rectilinear vibrations in three fixed planes at right angles to each other. These must be separately compounded to produce new rectilinear vibrations in the coordinate planes, which together represent the resulting elliptic vibration, and will have the same period as the component ones. By inverting the process, a vibration of this kind may be resolved into any number of others we please, having the same period.

A great variety of particular cases present themselves, of which we shall examine some of the principal. And first, when the interfering vibrations are both rectilinear.

Since the choice of our coordinate planes is arbitrary, let us suppose that of the \( x, y \) to be that in which both the vibrations are performed. Of course the resulting one will be performed in the same. Therefore we may put \( z = 0 \), or \( c = 0 \), \( c' = 0 \), and content ourselves with making

\[
\begin{align*}
x &= a \cdot \cos (\theta + p) ; \quad y = b \cdot \cos (\theta + p) \\
x' &= a' \cdot \cos (\theta + p') ; \quad y' = b' \cdot \cos (\theta + p')
\end{align*}
\]

because \( \frac{x}{y} \) and \( \frac{x'}{y'} \) are constant in this case, and \( X, Y, A, B, P, Q \), denoting as in the general case, we have

\[
X = A \cdot \cos (\theta + P) ; \quad Y = B \cdot \cos (\theta + Q) ;
\]

and, by elimination of \( \theta \),

\[
\left( \frac{X}{A} \right)^2 + \left( \frac{Y}{B} \right)^2 - 2 \cos (P - Q) \cdot \frac{XY}{AB} = \sin (P - Q); \quad (9)
\]

where \( A, B, P, Q \), are determined as in equations, (7.) In the general case, then, the resulting vibration is elliptic.

The ellipse degenerates into a straight line by the diminution of its minor axis when \( P = Q \). Now this gives \( \tan P = \tan Q \), or

\[
\frac{a \cdot \sin p + a' \cdot \sin p'}{a \cdot \cos p + a' \cdot \cos p'} = \frac{b \cdot \sin p + b' \cdot \sin p'}{b \cdot \cos p + b' \cdot \cos p'}
\]

which, reduced, takes the form

\[
\left( \frac{a'}{a} - \frac{b'}{b} \right) \cdot \sin (p - p') = 0.
\]

There are, therefore, two cases, and two only in which the resulting vibration is rectilinear. The first, when \( p - p' = 0 \), or when the component vibrations have a common origin, or are in complete accordance; the other, when \( \frac{a'}{a} = \frac{b'}{b} \), that is, when they are both performed in one plane, and in the same direction. For if we call \( m \) and \( m' \) the amplitudes, and \( \psi, \psi' \) the angles they make with the axis of the \( x \), we have

\[
a = m \cdot \cos \psi; \quad b = m \cdot \sin \psi; \quad a' = m' \cdot \cos \psi'; \quad b' = m' \cdot \sin \psi',
\]

so that the above equation is equivalent to \( \tan \psi = \tan \psi' \), or \( \psi = \psi' \).

The latter case we have already fully considered. In the former, we have \( \cos (p - p') = 0 \), and, therefore,

\[
A = a + a'; \quad B = b + b'; \quad P = p; \quad Q = p
\]
and, finally,

\[
\frac{Y}{X} = \frac{b + b'}{a + a'} = \tan \phi \quad ; (10)
\]

which is the tangent of the angle made by the resulting rectilinear vibration with the axis of the \(x\).

If we put \(M\) for the amplitude of the resulting vibration, we have \(M \cdot \cos \phi = A\); \(M \cdot \sin \phi = B\); therefore,

\[M^2 = (\cos \phi + \sin \phi)\cos \phi = (\cos \phi + \sin \phi)\sin \phi\]

Now,

\[
A' = (a + a')^2 = (m \cdot \cos \psi + m' \cdot \cos \psi')^2
\]

\[
B' = (b + b')^2 = (m \cdot \sin \psi + m' \cdot \sin \psi')^2
\]

and, therefore, adding these values together, and reducing

\[M'^2 = m^2 + 2 m m' \cos (\psi - \psi') + m'^2; \quad (11)\]

Now, \(\psi - \psi'\) is the angle between the directions of the component vibrations, so that this equation expresses that the amplitude of the resultant vibration is in this case also the diagonal of a parallelogram, whose sides are the amplitudes of the component ones; and it is easily shown, by substituting in \(\tan \phi = \frac{b + b'}{a + a'}\) the above values of \(a + a', b + b'\), that the diagonal has also the position of the resultant line of vibration.

**Corol. 1.** Any rectilinear vibration may be resolved into two other rectilinear vibrations, whose amplitudes are the sides of any parallelogram, of which the amplitude of the original vibration is the diagonal, and which are in complete accordance, or have a common origin with it.

**Corol. 2.** Hence any rectilinear vibration may be readily reduced to the directions of two rectangular coordinates, or, if necessary, into those of three, by the rules of the resolution of forces, and the component vibrations, however numerous, will be in complete accordance with the resultant.

The ellipse degenerates into a circle when \(\cos (P - Q) = 0\), or \(P - Q = 90^\circ\), and, also, \(A = B\). Now the former condition gives \(\tan P - Q = 0\), that is

\[
\frac{a \cdot \sin \psi + a' \cdot \sin \psi'}{a \cdot \cos \psi + a' \cdot \cos \psi'} + \frac{b \cdot \cos \psi + b' \cdot \cos \psi'}{b \cdot \sin \psi + b' \cdot \sin \psi'} = 0
\]

or reducing

\[
\cos (p - p') = \frac{a b + a' b'}{a b'} + \frac{a' b}{a b} = \frac{m^2 \cdot \sin 2 \psi + m'^2 \cdot \sin 2 \psi'}{m^2 \cdot \sin (\psi + \psi')} \quad (12)
\]

The condition \(A = B, \text{ or } A^2 = B^2\), gives

\[
a^2 + 2 a a' \cdot \cos (p - p') + a'^2 = b^2 + 2 b b' \cdot \cos (p - p') + b'^2
\]

whence we, in like manner, obtain

\[
\cos (p - p') = \frac{(a^2 + a'^2) - (b^2 + b'^2)}{2 a a' \cdot 2 b b'} = \frac{m^2 \cdot \sin 2 \psi + m'^2 \cdot \sin 2 \psi'}{\cos (\psi + \psi')} \quad (13)
\]

and, equating the values of \(\cos (p - p')\), we find the following relation between \(a, a', b, b'\), which must subsist when the vibrations are circular.

\[
\left(\frac{a}{b} - \frac{a'}{b'}\right) (a^2 + b^2 - a'^2 - b'^2) = 0.
\]

The vanishing of the first factor gives no circular vibration, it being introduced with the negative root of the equation \(A^2 = B^2\), with which we have no concern. The other gives

\[
a^2 + b^2 = a'^2 + b'^2, \text{ or } m = m',
\]

which shows that the component vibrations must have equal amplitudes. Now, if for \(a\) and \(b\) we write their values \(m \cdot \cos \psi\) and \(m \cdot \sin \psi\), and for \(a'\) and \(b'\), respectively, \(m \cdot \cos \psi'\) and \(m \cdot \sin \psi'\), in either of the expressions for \(\cos (p - p')\), it will reduce itself to

\[
\cos (p - p') = - \cos (\psi - \psi'); \text{ or } p - p' = 180^\circ - (\psi - \psi').
\]

Hence it appears, that the *interference of two equal rectilinear vibrations* will produce a resultant circular one, provided the difference of their phases be equal to the *supplement* of the angle their directions make with each other, so that when the molecule is just commencing its motion towards its centre, in virtue of one vibration, it shall be receding from it at an obtuse angle with this motion, in virtue of the other.

**Corol.** Hence, if two vibrations have equal amplitudes, but differ in their phases by a quarter of an undulation, their resultant vibration will be circular.

We are now in a condition to explain what becomes of the portions of the secondary waves which diverge obliquely from the molecules of the primary ones, as alluded to in Art. 595, and to explain the mode in which Fig. 130. those which do not conspire with the primary wave mutually destroy each other. To this end, conceive the surface of any wave \(A B C\) to consist of vibratory molecules, *all in the same phase of their vibrations*. Then will the motion of any point \(X\) (fig. 130) be the same, whether it be regarded as arising from the original motion of \(S\), or as the resultant of all the motions propagated to it from all the points of this surface. Conceive the surface \(A B C\) divided into an infinite number of elementary portions, such that the difference of distance of each consecutive pair from \(X\) shall be constant, or \(= d\); putting the distance of any one from that point \(= f\); and let \(A B, B C, C D, \text{ &c.},\) and \(A, b, c, d, \text{ &c.}\) be finite portions of the surface containing each the same number of
these elements, and in each of which the corresponding values of \( f \) are exactly half an undulation \( (\frac{1}{2} \lambda) \) greater than in the preceding, so that (for instance) \( B X = A X + \frac{1}{2} \lambda, C X = B X + \frac{1}{2} \lambda, \) &c. Then it is evident, that the vibrations which reach \( X \) simultaneously from the corresponding portions of any two consecutive ones, as of \( A B \) and \( B C \), will be in exactly opposite phases; and, therefore, were they of equal intensity, and in precisely the same direction, would interfere with, and destroy each other. Now, first, with regard to their intensity, this depends on the magnitudes of the elements of the wave \( A B \), from which they are derived, and on the law of lateral propagation. Of the latter, we know little, \( \text{a priori} \); but all the phenomena of light indicate a very rapid diminution of intensity, as the direction in which the secondary undulations are propagated deviates from that of the primary. With respect to the former, it is evident that the elements in the immediate vicinity of the perpendicular \( A X \), corresponding to a given increment \( d f \) of the distance from \( X \), are much larger than those remote from it; so that all the elements of the portion \( A B \) are much larger than those in \( B C \), and these again than in those of \( C D \), and so on. Thus the motion transmitted to \( X \) from any element in \( A B \) will be much greater than that from the corresponding one in \( B C \), and that again greater than that from the element in \( C D \), and so on. Thus the motion arriving at \( O \), from the whole series of corresponding elements, will be represented by a series such as \( A - B + C - D + E - F + \&c. \), in which each term is successively greater than that which follows. Now it is evident that the terms approach with great rapidity to equality; for if we consider any two corresponding elements as \( M, N \) at a distance from \( A \) at all considerable, the angles \( XM \) and \( XN \) make with the surface approach exceedingly near to equality, so that the obliquity of the secondary wave to the primary, and of course its intensity, compared with that of the direct wave, is very nearly alike in both; and the elements \( M, N \) themselves, at a distance from the perpendicular, approach rapidly to equality, for the elementary triangles \( M o \), \( M n \) are in this case very nearly similar, and have their sides \( m o, n p \) equal by hypothesis. Finally, the lines \( M X, N X \) approach nearer to each other in direction so as to produce a more complete interference, as their distance from \( A \) is greater.

Thus we see that the terms of the series \( A - B + C - D + \&c. \), at a distance from its commencement, have on all accounts (viz. their smallness, near approach to equality, and disposition to interfere) an extremely small influence on its value; and as the same is true of every set of corresponding elements into which the portions \( A B, B C, \&c. \) are divided, it is so of their joint effect, so that the motion of the molecule \( X \) is governed entirely by that of the portion of the wave \( A B C \) immediately contiguous to \( A \), the secondary vibrations propagated from parts at a distance mutually interfering and destroying each others effect.

It is obvious, that in the case of refraction or reflexion, we may substitute for the wave \( A M \) the refracting or reflecting surface; and for the perpendicular \( X A \) the primary refracted ray, when the same things, mutatis mutandis, will hold good. See M. Fresnel's Paper entitled Explication de la Réfraction dans le Système des Ondes, published in the Bulletin de la Société Philomatique, October, 1821.

This is the case when the portion of the wave \( A B C D \) whose vibrations are propagated to \( X \) is unlimited, or at least so considerable, that the last term in the series \( A - B + C - D + \&c. \) is very minute compared with the first. But if this be not the case, as, if the whole of a wave except a small part about \( A \) be intercepted by an obstacle, the case will be very different. It is easy on this supposition to express by an integral the intensity of the undulatory motion of \( X \), compared with what it would be on the supposition of no obstacle existing. For this purpose, let \( d^2 s \) be the magnitude of any vibrating element of the surface, \( f \) its distance from \( X = M X \), and let \( \phi(\theta) \) be the function of the angle made by a laterally-divergent vibration with the direct one, which expresses its relative intensity, and which is unity when \( \theta = 0 \), and diminishes with great rapidity as \( \theta \) increases. Then if \( t \) be the time since a given epoch, \( \lambda \) the length of an undulation, \( S A = a \), the phase of a vibration arriving at \( X \) by the route \( S M X \) will be \( 2 \pi \left( \frac{t}{T} - \frac{a + f}{\lambda} \right) \), and the velocity produced in \( X \) thereby will be represented by \( a \cdot d^2 s \cdot \phi(\theta) \cdot \sin 2 \pi \left( \frac{t}{T} - \frac{a + f}{\lambda} \right) \), so that the whole motion produced will be represented by

\[
\int \int a \cdot d^2 s \cdot \phi(\theta) \cdot \sin 2 \pi \left( \frac{t}{T} - \frac{a + f}{\lambda} \right)
\]

the integral being extended to the limits of the aperture.

Corol. 1. If but a very small portion of the wave be permitted to pass, as in the case of a ray transmitted through a very small hole, and received on a distant screen, \( \theta \) and \( \phi(\theta) \) are very nearly constant, so that the motion excited in \( X \) is in this case represented by

\[
a \cdot \phi(\theta) \int \int d^2 s \cdot \sin 2 \pi \left( \frac{t}{T} - \frac{a + f}{\lambda} \right).
\]

We shall have occasion to revert to these expressions hereafter.

§ IV. Of the Colours of Thin Plates.

Every one is familiar with the brilliant colours which appear on soap-bubbles; with the iridescent hues produced by heat on polished steel or copper; with those fringes of beautiful and splendid colours which appear in the cracks of broken glass, or between the laminae of fissile minerals, as Iceland spar, mica, sulphate of lime, &c. In all these, and an infinite variety of cases of the same kind, if the fringes of colour be examined
with care they will be found to consist of a regular succession of hues, disposed in the same order, and determined, obviously, not by any colour in the medium itself in which they are formed, or on whose surfaces they appear, but solely by its greater or less thickness. Thus a soap-bubble (defended from currents of air by being placed under a glass) at first appears uniformly white when exposed to the dispersed light of the sky at an open window; but, as it grows thinner and thinner by the subsidence of its particles, colours begin to appear at its top where thinnest, which grow more and more vivid, and (if kept perfectly still) arrange themselves in beautiful horizontal zones about the highest point as a centre. This point, when reduced to extreme tenuity, becomes black, or loses its power of reflecting light almost entirely. After which the bubble speedily bursts, its cohesion at the vertex being no longer sufficient to counteract the lateral attraction of its parts.

But as it is a matter of great delicacy to make regular observations on a thing so fluctuating and unmanageable as a soap-bubble, the following method of observing and studying the phenomena is far preferable. Let a convex lens, of a very long focus and a good polish, be laid down on a plane glass, or on a concave glass lens having a curvature somewhat less than the convex surface resting on it; so that the two shall touch in but a single point, and so that the interval separating the surfaces in the surrounding parts shall be exceedingly small. If the surfaces be very carefully cleaned from dust before placing them together, and the combination be laid down before an open window in full daylight, the point of contact will be seen as a black spot in the general reflexion of the sky on the surfaces, surrounded with rings of vivid colours. A glass of 10 or 12 feet focus laid on a plane glass, will show them very well. If one of shorter focus be used, the eye may be assisted by a magnifying glass. The following phenomena are now to be attended to:

**Phenomenon 1.** The colours, whatever glasses be used, provided the incident light be white, always succeed each other in the very same order; that is, beginning with the central black spot, as follows:

- First ring, or first order of colours—black, very faint blue, brilliant white, yellow, orange, red.
- Second ring, or second order—dark purple or rather violet, blue, green, (very imperfect, a yellow-green), vivid yellow, crimson red.
- Third ring, or third order—purple, blue, rich grass green, fine yellow, pink, crimson.
- Fourth ring, or fourth order—green, (dull and bluish), pale yellowish pink, red.
- Fifth ring, or fifth order—pale bluish green, white, pink.
- Sixth ring, or sixth order—pale blue-green, pale pink.
- Seventh ring, or seventh order—very pale bluish green, very pale pink. After these, the colours become so faint that they can scarcely be distinguished from white.

On these we may remark, that the green of the third order is the only one which is a pure and full colour, that of the second being hardly perceptible, and of the fourth comparatively dull and verging to apple green; the yellow of the second and third order are both good colours, but that of the second is especially rich and splendid; that of the first being a fiery tint passing into orange. The blue of the first order is so faint as to be scarce sensible, that of the second is rich and full, but that of the third much inferior; the red of the first order hardly deserves the name, it is a dull brick colour; that of the second is rich and full, as is also that of the third; but they all verge to crimson, nor does any pure scarlet, or prismatic red, occur in the whole series.

**Phenomenon 2.** The breadths of the rings are unequal. They decrease, and the colours become more crowded, as they recede from the centre. Newton (to whom we owe the accurate description and investigation of their phenomena) found by measurement the diameters of the darkest (or purple) rings, just when the central black spot began to appear by pressure, and reckoning it as one of them to be as the square roots of the even numbers 0, 2, 4, 6, &c.; and those of the brightest parts, of the several orders of colours, to be as the square roots of the odd numbers 1, 3, 5, 7, &c. Now the surfaces in contact being spherical, and their radii of curvature very great in proportion to the diameters of the rings, it follows from this that the intervals between the surfaces at the alternate points of greatest obscurity and illumination are as the natural numbers themselves 0, 1, 2, 3, 4, &c. The same measurements, when the radii of curvature of the contact surfaces are known, give the absolute magnitudes of the intervals in question. In fact, if \( r \) and \( r' \) be the curvatures of two spherical surfaces, a convex and concave, in contact, and \( D \) the diameter of any annulus surrounding their point of contact, the interval of the surfaces there will be the difference of the versed sines of the two circular arcs having a common chord \( D \). Now (fig. 180) if \( AE \) be the diameter of the convex spherical surface \( AD \), we have \( EA : AD :: AD : DB = \frac{AD^2}{AE} = \frac{D^2}{8} r \), and in like manner \( BC = \frac{D^2}{8} r' \), so that \( \frac{1}{8} D^2 (r - r') = D C \), the interval of the surfaces at the point \( D \). Thus Newton found, for the interval of the surfaces at the brightest part of the first ring, one 178000th part of an inch; and this distance, multiplied by the even natural numbers 0, 2, 4, 6, 8, &c., gives their distance at the black centre and the darkest parts of the purple rings, and by the odd ones 1, 3, 5, &c., their intervals at the brightest parts.

**Phenomenon 3.** If the rings be formed between spherical glasses of various curvatures, they will be found to be larger as the curvatures are smaller, and vice versa; and if their diameters be measured and compared with the radii of the glasses, it will be found, that, provided the eye be similarly placed, the same colour is invariably produced at that point, or that distance from the centre where the interval between the surfaces is the same. Thus, the white of the first order is invariably produced at a thickness of one 178000th of an inch; the purple, which forms the limit of the first and second orders, at twice that thickness. So that there is a constant relation between the tint seen and the interval of the surfaces where it appears. Moreover, if the glasses be distorted by violent and unequal pressure, (as is easily done if thin lenses be used,) the rings lose their circular figure, and extend themselves towards the part where the irregular pressure is applied, so as to form a species of level lines each marking out a series of points where the surfaces are equidistant. Thus, too, if a
cylinder be laid on a plane, the rings pass into straight lines arranged parallel to its line of contact, but following the same law of distance from that line as the rings from their dark centre, and if the glasses be of irregular curvature, as bits of window glass, the bands of colour will follow all their inequalities; yet more, if the pressure be very cautiously relieved, so as to lift one glass from the other, the central spot will shrink and disappear, and so on; each ring in succession contracting to a point, and then vanishing, so as to bring all the more distant colours successively to the centre, as the glasses recede from absolute contact. From all these phenomena it is evident, that it is the distance between the surfaces only at any point which determines the colour seen there.

Phenomenon 4. This supposes, however, that we observe them with the eye similarly placed, or at the same angle of obliquity. For if the obliquity be changed by elevating or depressing the eye, or the glasses, the diameters (but not the colours) of the rings will change. As the eye is depressed, the rings enlarge; and the same tint which before corresponded to an interval of the 178000th of an inch, now corresponds to a greater interval. This distance is determined by measures taken nearly at, and reduced by calculation exactly to, a perpendicular incidence. At extreme obliquities, however, the diameters of the several rings suffer only a certain finite dilatation, and Newton’s measures led him to the following rule: viz. “That the interval between the surfaces at which any proposed tint is produced, is proportional to the secant of an angle whose sine is the first of 106 arithmetical mean proportionals between the sines of incidence and refraction, into the glass from the air, or other medium included between the surfaces, beginning with the greater;” or, in algebraic language, the relative index of refraction being ρ, and θ the angle of incidence, and ρ that of refraction of the ray as it passes out of the rarer medium into the denser; then, if t be the interval corresponding to a given tint at the oblique incidence θ, and T at a perpendicular incidence, we shall have

\[ t = T \cdot \sec \theta \text{ where } \sin \theta = \sin \frac{1}{107} \cdot \left(\sin \theta - \sin \rho\right) \]

but \( \sin \rho = \frac{1}{\mu} \cdot \sin \theta \), consequently we have

\[ t = T \cdot \sec \theta \text{ where } \sin \theta = \frac{106 + \frac{1}{\mu}}{107} \cdot \sin \theta = \frac{106 \mu + 1}{107 \mu} \cdot \sin \theta \]

To see the rings conveniently at extreme obliquities, a prism may be used, laid on a convex lens, as in fig. 182. If the eye be placed at K, the set of rings formed about the point of contact E will be seen in the direction KH, and as the eye is depressed towards the situation I, where the ray IG intromitted from I would just begin to suffer total reflexion, the rings are seen to dilate to a certain considerable extent. When the eye reaches I, the upper half of the rings disappears, being apparently cut off by the prismatic iris of Art. 555, which is seen in that situation, but the black central spot and the lower half of the rings remains; but when the eye is still further depressed the rings disappear, and leave the central spot, like an aperture seen in the silver whiteness of the total reflexion on the base of the prism, and dilated very sensibly beyond the size of the same spot seen in the position KH: thus proving, that the want of reflexion on that part of the base extends beyond the limits of absolute contact of the glasses, and that, therefore, the lower surface interferes with the action of the upper, and prevents its reflexion while yet a finite interval (though an excessively minute one) intervenes between them. Euler has made this an objection to the undulatory theory, but the objection rests on no solid grounds, as it is very reasonable to conclude, that the changes of density or elasticity in the ether within and without a medium is not absolutely perpendicular, but gradial. If so, and if the change take place without the media, the approach of two media within that limit, within which the condensation of the ether takes place, will alter the law of reflexion from either into the interval separating them.

In order, however, to see to the greatest advantage the colours reflected by a plate of air at great obliquities, the following method, first pointed out by Sir William Herschel, may be employed. On a perfectly plane glass or metallic mirror, before an open window, lay an equilateral prism, having its base next the glass or mirror very truly plane, and looking in at the side AC, fig. 133, the reflected prismatic iris, a, b, c, will be seen as usual in the direction EF, where a ray from E would just be totally reflected. Within this iris, and arranged parallel to it, are seen a number of beautiful coloured fringes, whose number and distances from each other vary with every change of the pressure; their breadths dilating as the pressure is increased, and vice versa. They do not require for their formation, that the surfaces should be exceedingly near, being seen very well when the prism is separated from the lower surface by the thickness of thin tissue paper, or a fine fibre of cotton wool interposed, but in this case they are exceedingly close and numerous. If the pressure be moderate, they are nearly equal, and are lost, as it were, in the blue iris, without growing sensibly broader as they approach it. As the intervals of the surfaces is diminished, they dilate and descend towards the eye, appearing, as it were, to come down out of the iris. They do not require for their formation a perfect polish in the lower surface. An emerald glass, so rough as to reflect no regular image at any moderate incidence, shows them very well. The experiment is a very easy one, and the phenomena so extremely obvious and beautiful, that it is surprising it should not have been noticed and described by Newton, especially as it affords an excellent illustration of his law above stated. To understand this, let EH, EK, EL be any rays from E incident at angles somewhat less than that of total reflexion on the base; they will therefore be refracted, and, emerging at the base BC, will be reflected at MN, (the obliquity of the reflexion being so great, that even rough surfaces reflect copiously and regularly enough for the purpose, Art. 555,) and will pursue the courses HDP, KFQ, LGIR, &c. entering the prism again at P, Q, R. Reciprocally, then, rays r P, q Q, &c. incident at P, Q, &c. in these directions,
Light will enter the eye at $E$ after traversing the interval $BCNM$, and being reflected at $MN$, and will affect the eye with the colour corresponding to that obliquity and that interval between the surfaces which is proper to each. If then we put, as above, $\theta$ for the exterior angle of incidence of the ray $DH$ on the base of the prism, and take

$$\sin \theta = \frac{106 \mu + 1}{107 \mu} \cdot \sin \rho = \frac{106 \mu + 1}{107} \cdot \sin \rho = k \cdot \sin \rho,$$

the tint seen in the direction $EH$ will (abstraction made of the dispersion at the surface $AC$) be the same with that reflected at a perpendicular incidence, by a plate of air of the thickness $T = t \cos \mu = t \sqrt{1 - k^2} \sin \rho^2$, where $t$ is the distance between the surfaces $BC$, $MN$. There will, therefore, appear a succession of colours in the several consecutive situations of the line $EH$, analogous to those of the coloured rings, (except in so far as the dispersion of the side $AC$ alters the tints by separating their component rays.)

But the whole series of colours will not be seen, because those which require greater obliquities than that at which total reflection takes place, cannot be formed. In fact, the angle, reckoned from the vertical at which a tint corresponding to a thickness $T$ in the rings would be formed, is given by the equation

$$\sin \rho = \frac{1}{k} \cdot \sqrt{1 - \left(\frac{T}{t}\right)^2} = \frac{214}{320} \cdot \sqrt{1 - \left(\frac{T}{t}\right)^2},$$

taking $\mu = \frac{3}{2}$ for glass, which it is very nearly. Now, according to this, the central tint, or black of the first order, which is formed when $T = 0$, requires that

$$\sin \rho = \frac{1}{k} = \frac{1}{\mu - \frac{1}{107}},$$

which being greater than $\frac{1}{\mu}$ shows that this tint lies above the situation of the iris, and cannot therefore be seen. The first visible tint will be that close to the iris, where $\sin \rho = \frac{1}{\mu}$ which gives

$$T = t \sqrt{1 - \left(\frac{k}{\mu}\right)^2} = t \sqrt{1 - \left(\frac{1 - \mu - 1}{107 \mu}\right)^2} = t \sqrt{\frac{2(\mu - 1)}{107 \mu}} = 0.079 t$$

nearly, or $\frac{t}{12.25}$. Hence it appears, that these fringes would be seen, by an eye immersed in the prism, when the interval between its base and the glass it rests on is more than 12 times that at which colours are formed at a perpendicular incidence, i.e. at $12.25 \times \frac{13}{178000}$, or about $\frac{1}{1100}$ of an inch, which is about the thickness of fine tissue paper. Moreover, from this value of $T$, we see that the first tint immediately visible below the iris ascends in the scale of the rings (i.e. belongs to a point nearer their centre) as the value of $t$ diminishes, or as the prism is pressed closer to the glass; and this explains why the fringes become more numerous, and appear to come out of the iris by pressure. With regard to their angular breadth, (still to an eye immersed in the prism.) If we put $e = \frac{1}{89000}$ we have, putting $\rho_0, \rho_1, \&c.$ for the values of $\rho$, corresponding to the several orders of visible tints,

$$\sin \rho_0 = \frac{1}{\mu}; \quad \sin \rho_1 = \frac{1}{k} \sqrt{1 - \left(\frac{T + e}{t}\right)^2} = \frac{1}{\mu} \sqrt{1 - \frac{\mu^2}{k^2} \cdot 0.079 \cdot \frac{2e}{t}} = \frac{1}{\mu} \left(1 - 0.079 \times \frac{e}{t}\right)$$

very nearly, $\sin \rho_2 = \frac{1}{\mu} \left(1 - 0.079 \cdot \frac{2e}{t}\right)$ and so on. The sines then of the incidences at which the several orders of colours are developed, beginning at the iris, increase in arithmetical progression, so that the fringes must be disposed in circular area parallel to the iris, and their breadths must be nearly equal, and greater the greater the pressure or the less $t$ is, all which is conformable to observation. The refraction of the side of the prism between the eye and the base, however, disturbs altogether the succession of colours in the fringes, and in particular multiplies the number of visible alternations to a great extent, in a manner which will be evident on consideration. We have been rather more particular in explaining the origin of these fringes, and referring them to the general phenomena observed by Newton, because up to the present time we believe no strict analysis of them has been given, as well as on account of the great beauty of the phenomenon itself. If we hold the combination up to the light, and look through the base of the prism and the glass plate, so as to see the transmitted iris of Art. 556, its concavity will, in like manner, be seen fringed with bands of colours of precisely similar origin. To return now to the rings seen between convex glasses.

Phenomenon 5. If homogeneous light be used to illuminate the glasses, the rings are seen in much greater...
number, and the more according to the degree of homogeneity of the light. When this is as perfect as possible, as, for instance, when we use the flame of a spirit lamp with a salted wick, as proposed by Mr. Talbot, they are literally innumerable, extending to so great a distance that they become too close to each other to be counted, or even distinguished by the naked eye, yet still distinct on using a magnifier, but requiring a higher and higher power as they become closer, till we can pursue them no farther, and disappearing from their closeness, and not from any confusion or running of one into the other. Moreover, they are now no longer composed of various colors, but are wholly of the colour of the light used as an illumination, being mere alternations of light and obscurity, and the intervals between them being absolutely black.

Phenomenon 6. When the illuminating light is changed from one homogeneous ray to another, as when, for instance, the colours of the prismatic spectrum are thrown in succession on the glasses at their point of contact, containing rings as to be reflected to the eye, the rings seen to dilate and contract in magnitude as the illumination shifts. In red light they are largest, in violet least, and in the intermediate colours of intermediate size. Newton, by measuring their diameters, ascertained that the interval of the surfaces or thickness of the plate of air, where the corresponding red ring of the same order is formed, nearly as 9:14; and, determining by this method, the thickness of the plate of air where the brightest part of the first ring was formed, when illuminated in succession by the several rays proceeding from the extreme red to the extreme violet, he ascertained those thicknesses to be the halves of the numbers already set down in the second column of the Table, p. 458, expressed in parts of an inch, and which answer to the values of \( \frac{\lambda}{2} \) or the lengths of a semiundulation for each ray.

This phenomenon may be regarded as an analysis of what takes place when the rings are seen in white light; for in that case they may be regarded as formed by the superposition one on the other of sets of rings of all the simple colours, each set having its own peculiar series of diameters. The manner in which this superposition takes place, or the synthesis of the several orders of colours, may be understood by reference to fig. 134, where the abscissae or horizontal lines represent the thicknesses of a plate of air between two glasses, supposed to increase uniformly, and where \( R R' \), \( R R'' \), etc. represent the several thicknesses at which the red, in the system of rings illuminated by red rings only, vanishes, or at which the darkness between two consecutive red rings is observed to happen, while \( R \), \( R' \), \( R'' \), etc. represent those at which the brightness is a maximum. In like manner, let \( 0^\circ, 0^\circ \), etc. be taken equal to the several thicknesses at which the orange vanishes, or at which the black intervals in the system of orange rings are seen, and so on for the yellow, green, blue, indigo, and violet rings. So that \( R R', 0^\circ, Y Y', \) etc. are to each other in the ratio of the numbers in column 2 of the above Table, (Art. 575.) Then if we describe a set of undulating curves as in the figure, and at any point, as in \( C \) in \( A E \), draw a line parallel to \( AV \), cutting all these curves; their several ordinates, or the portions of this line intercepted between the curves and their abscissae, will represent the intensity of the light of each colour, sent to the eye by that thickness of the plate of air. Hence, the colour seen at that thickness will be that resulting from the union of the several simple rays in the proportions represented by their ordinates.

The figure being laid down by a scale, we may refer to it to identify the colours of particular points. Thus, first at the thickness 0, or at \( A \) the origin of the tints, all the ordinates vanish, and this point, therefore, is black. As the thickness of the plate of air increases from 0 while yet very small, it is evident, on inspection, that the ordinates of the several curves increase with unequal rapidity; those for the more refrangible rays more rapidly than those for the less, so that the first feeble light which appears at a very small thickness \( A_1 \), will have an excess of blue rays, constituting the pure but faint blue of the first order, (Art. 635.) At a greater thickness, however, as \( A_2 \), the common ordinate passes nearly through the maxima of all the curves, being a little short of that of the red, and a little beyond that of the violet. The difference, however, is so small, that the several colours will all be present nearly in the proportions to constitute whiteness, and being all nearly at their maximum, the resulting tint will be a brilliant white. This agrees with observation; the white of the first order being, in fact, the most luminous of all; beyond this the violet falls off rapidly, the red increases, and the yellow is nearly at its maximum, so that at the thickness \( A_3 \) the white passes into yellow, and at a still greater thickness, \( A_4 \), where the violet, indigo, blue, and green, are all nearly evanescent, the yellow falling off, and the orange and red, especially the latter, in considerable abundance, the tint resulting will be a fiery orange, growing more and more ruddy. At \( B \) is the minimum of the yellow, i.e. of the most luminous rays. Here then will be the most sombre tint. It will consist of very little either of orange, green, blue, or even indigo; but a moderate portion of violet and a little red will produce a sombre violet purple, which, since the more refrangible rays are here all on the increase, while the less are diminishing, will pass rapidly to a vivid blue, as at the thickness denoted by \( A_5 \). At 6, where the ordinate passes through the maximum of the yellow, there is almost no red, very little orange, a good deal of green, very little blue, and hardly any indigo or violet. Here then the tint will be yellow verging to green, but the green is diminishing and the orange increasing, so that the yellow rapidly loses its green tinge, and becomes pure and lively. At 7 the predominant rays are orange and yellow, being so copious that the little red and violet with which they are mixed does not prevent the tint from being a rich, high-coloured yellow. At 8 a full orange and copious red are mixed with a good deal of indigo and a maximum of violet, thus producing a superb crimson. At \( C \) we have again a minimum of yellow; but here being at the same time a maximum of red and indigo, this point, though dark in comparison to those on either side, will still ruddy purple. This completes, and as we see faithfully represents, the second order of colours. At 9, 10 we see the origin of the vivid green of the third order, in the comparative copiousness of green, yellow, and blue rays at the former point, and of yellow, green,
and violet at the latter, while the red and orange are almost entirely absent, and thus we may pursue all the tints in the scale enumerated in Art. 635 with perfect fidelity.

As the thickness increases, however, it is clear that rays differing but little in refrangibility will differ much in intensity, as the smallest difference in the lengths of the bases of their curves being multiplied by the number of times they are repeated, will at length bring about a complete opposition, so that the maximum of one ray will fall at length on a minimum of another differing little in refrangibility, and not at all in colour. Thus, at considerable thicknesses, such as the 10th or 20th order, there will coexist both maxima and minima of every colour; since each colour, in fact, consists not of rays of one definite refrangibility, but of all gradations of refrangibility between certain limits. In consequence, the tints, as the thickness increases, will grow less and less pure, and will at length merge into undistinguishable whiteness, which, however, for this very reason, will be only half as brilliant as the white of the first order, which contains all the rays at their maximum of intensity.

Phenomenon 7. Such are the phenomena when a plate of air is included between two surfaces of glass. It is not however as air, but as distance, that it acts; for in the vacuum of an air-pump the rings are seen without any sensible alteration. If, however, a much more refracting medium, as water or oil, be interposed, the diameters of the rings are observed to contract, preserving, however, the same colours and the same laws of their breadths; and Newton found by exact measurements, that the thicknesses of different media interposed, at which a given tint is seen, are in the inverse ratio of their refractive indices. Thus, the white of the first order being produced in vacuo or air at the 178000th of an inch, will be produced in water at 13987 part of that thickness.

He found, moreover, that the law stated in Art. 639 for the dilatation of the rings by oblique incidence, holds equally good, whatever be the nature of the interposed medium. Hence it follows, that in dense media the dilatation at great obliquities is much less than in rare ones, and that in consequence a given thickness will reflect a colour much less variable by change of obliquity when the medium has a high refractive power than when low. Thus, the colours of a soap bubble vary much less by change of incidence than those of a film of air, and much more, on the other hand, than the iridescent colours on polished steel, which arise from a film of oxide formed on the heated surface.

Phenomenon 8. Surfaces of glass, or other denser medium enclosing the thin plate of a rarer, are not however necessary to the production of the colours; they are equally, and indeed more brilliantly, visible when any very thin laminae of a denser medium is enclosed in a rarer, as in air, or in vacuo. Thus, soap bubbles, excessively thin films of mica, &c. exhibit the same succession of colours, arranged in fringes according to the variable thickness of the plates. The following very beautiful and satisfactory mode of exhibiting the fringes formed by plates of glass of a tangible thickness has been imagined by Mr. Talbot. If a bubble of glass be blown so thin as to burst, and the glass films which result be viewed in a dark room by the light of a spirit lamp with a salted wick, they will be seen to be completely covered with striae, alternately bright and black, in undulating curves parallel to each other according to the varying thickness of the film. Where the thickness is tolerably uniform, the striae are broad; where it varies rapidly, they become so crowded as to elude the unassisted sight, and require a microscope to be discerned. If the film of glass producing these fringes be supposed equal to the thousandth of an inch in thickness, they must correspond to about the 89th order of the rings, and thus serve to demonstrate the high degree of homogeneity of the light; for if the slightest difference of refrangibility existed, its effect multiplied eighty-nine times would become perceptible in a confusion and partial obliteration of the black intervals. In fact, the thickness of a plate at which alternations of light and darkness or of colour can no longer be discerned, is the best criterion of the degree of homogeneity of any proposed light, and is, in fact, a numerical measure of it. This experiment is otherwise instructive, as it shows that the property of light on which the fringes depend is not restricted to extremely minute thicknesses, but subsists while the light traverses what may be comparatively termed considerable intervals.

Phenomenon 9. When the glasses between which the reflected rings are formed are held up against the light, a set of transmitted coloured rings is seen, much fainter however, than the reflected ones, but consisting of tints complementary to those of the latter, i.e., such as united with them would produce white. Thus the centre is white, which is succeeded by a yellowish tinge, passing into obscurity, or black, which is followed by violet and blue. This completes the series of the first order. Those of the second are white, yellow, red, violet, blue of the third, green, yellow, red, bluish green, after which succeed faint alternations of red and bluish green, the degradation of tints being much more rapid than in the reflected rings.

It was to explain these phenomena that Newton devised his doctrine of the fits of easy reflexion and transmission, mentioned in the 9th postulate of Art. 526. This doctrine we shall now proceed to develop further, and apply, as he has done, to the case in question. In addition then to the general hypothesis there assumed, it will be necessary to assume as follows:

The intervals at which the fits recur, differ in different rays according to their refrangibilities, being greatest for the red and least for violet rays, and for these, and the intermediate rays, in vacuo, and at a perpendicular incidence, are represented in fractions of an inch by the halves of the numbers in column 2 of the Table, Art. 375.

In other media, the lengths of the intervals in the course of a molecule at which its fits recur are shorter, in the ratio of the index of refraction of the medium to unity.

At oblique incidences, or when a ray traverses a medium after being intromitted obliquely, (at an angle \( \theta \) with the internal perpendicular,) the lengths of the fits are greater than at a perpendicular incidence, in the ratio of radius to the rectangle between the cosine of \( \theta \) and the cosine of an arc \( u \), given by the equation

\[
\sin u = \frac{106 \theta}{107} \sin \theta.
\]
Let us now consider what will happen to a luminous molecule, the length of whose fits in any medium is \( \frac{1}{2} \lambda \), which, having been intromitted perpendicularly at the first surface, and traversing its thickness \((= t)\), reaches the second. First, then, if we suppose \( t \) an exact multiple of \( \frac{1}{2} \lambda \), it is evident that the molecule will arrive at the second surface in precisely the same phase of its fit of transmission as at the first. Of course it is placed in the very same circumstances in every respect, and having been transmitted before must necessarily be so again. Thus every ray which enters perpendicularly into such a lamina must pass through it, and cannot be reflected at its second surface. On the other hand, if the thickness of the lamina be supposed an exact odd multiple of \( \frac{1}{2} \lambda \), &c. every molecule intromitted at its first surface will on its arrival at the second be in exactly the contrary phase of its fits, and, having been before in some phase of a fit of transmission, will now be in a similar phase of a fit of reflection. It will, therefore, not necessarily be transmitted; but a reflexion, more or less copious, will take place at the second surface in this case, according to the nature of the medium and its general action on light. For it will be remembered, that every molecule in a fit of reflexion is not necessarily reflected. It is disposed to be so; but whether it will or no, will depend on the medium it moves in and that on which it impinges, and on the phase of its fit. Now conceive an eye placed at a distance from a lamina of unequal thickness, so as to receive rays reflected at a very nearly perpendicular incidence from it. It is evident, that in virtue of the reflexion from the first surface, which is uniform, it will receive equal quantities of light from every point. But with regard to the light reflected from the second the case is different; for in all those parts where the thickness of the lamina is an exact even multiple of \( \frac{1}{2} \lambda \), none will be reflected, while in all those where it is an exact odd multiple of \( \frac{1}{2} \lambda \), a reflexion will take place; and since each molecule so reflected retraces the path by which it arrived, and therefore describes again the same multiple of \( \frac{1}{2} \lambda \); its total path described within the lamina, when it has reached the first surface again, will be an exact multiple of \( \frac{1}{2} \lambda \), and therefore it will penetrate that surface and reach the eye. In consequence, in virtue of the reflexion at the second surface alone, the lamina would appear black in every part where its thickness \( = 0 \), or \( \frac{2}{4}, \frac{4}{4}, \frac{5}{4}, \frac{6}{4} \), &c., and bright in those parts where its thickness \( = \frac{1}{4}, \frac{3}{4}, \frac{5}{4}, \frac{7}{4} \), &c. ad infinitum. In the intermediate thicknesses it would have a brightness intermediate between these and absolute obscurity; so that on the whole, the lamina would appear marked all over with dark and bright alternating fringes, just as we see it actually does in the experiment described, (Art. 649.) The uniform reflexion from the first surface superposed on these, will not prevent their inequality of illumination from being distinctly seen.

Hence it is evident, that if we take the abscissa of a curve equal to thickness of the lamina at any point, and the ordinate proportional to the intensity of the light reflected from the second surface, and returned through the first, this curve will be an undulating line, such as we have represented in fig. 134, touching the abscissa at equal distances equal to the length of a whole fit of a ray of the colour in question. Now these distances for rays of different colours being supposed such as we have assumed in Art. 652, the construction of Art. 645 holds good, and when white light falls on the lamina, its second surface will reflect a series of colours of the composition there demonstrated, and such as we actually observe, but diluted with the light uniformly reflected from every point of the first surface.

If the lamina instead of a vacuum be composed of any refracting medium, the tints will manifestly succeed each other in a similar series, but the thickness at which they are produced will be that in a lamina of vacuum, in the ratio of the lengths of the fits in the two cases, that is, in the proportion of \( 1 : \) the index of refraction of the medium. Thus the rings seen between two object glasses including air, ought to contract when water, oil, &c. is admitted between them, as they are found to do, and, by measure, in that precise ratio.

At oblique incidences, \( \theta \) being the angle of intromission into the lamina, \( \frac{2 \pi}{\lambda} \cdot \sec \theta \) is the whole path of the ray between the first and second surfaces, and since \( \frac{1}{2} \lambda \cdot \sec \theta \cdot \sec u \) is the length of the fits of the given ray at this obliquity, in order that the luminous molecule may arrive at the second surface in the same phase, and therefore be reflected with equal intensity, it must in this space have passed over the same number of these fits; hence we must have \( \frac{2 \pi}{\lambda} \cdot \sec \theta \cdot \sec u \) = constant, or \( t \) proportional to \( \sec u \), which agrees with observation.

All the light which is not reflected at the second surface passes through it, and forms the transmitted series of colours. These, therefore, consist of the whole incident light (= 1) minus that reflected at the first surface, (which will be a small fraction, and which we will call \( a' \)) minus that reflected at the second surface. Now this last will be a periodical function whose minimum is 0, and its maximum can never exceed \( a \), because the reflexion at the second surface of a medium cannot be stronger than at the first at a perpendicular incidence.

We may then represent it by \( a \left( \sin \frac{2 \pi u}{\lambda} \right) \), and thus we have \( 1 - a \left[ 1 + \left( \sin \frac{2 \pi u}{\lambda} \right)^2 \right] \) for the intensity of this particular coloured ray in the transmitted series, and \( a \left( \sin \frac{2 \pi u}{\lambda} \right) \) in the reflected. Hence it is evident, that owing to the smallness of \( a \), the difference between the brightest and darkest part of the transmitted series will be small in comparison with the whole light, and thus the alternations in homogeneous light ought to be (as they are) much less sensible than in the reflected rings, and the tints in white light much more pallid and dilute.
Thus we see that the Newtonian hypothesis of the fits affords a satisfactory-enough explanation, or rather
represents with exactness all the phenomena above described. It has been even asserted, that this doctrine is
really not an hypothesis, but nothing more than a pure statement of facts; for that, first, in point of mere fact, the
second surface of the lamina does send light to the eye, in the bright parts of the fringes, and does not send
it in the dark parts; and, secondly, that this is the same thing with saying that the light which has traversed a
thickness \( t = \left(2n + 1\right) \frac{\lambda}{4} \) is, and that which has traversed \( 2n \frac{\lambda}{4} \) is not susceptible of being reflected. And,
in truth, if only one ray could be regarded as being concerned, and were the light reflected at the first surface
of the lamina altogether out of the question, this way of stating it would be strictly correct. But, if it can be
shown, that, on any other hypothesis of the nature of light, (as the undulatory,) the second link of this argument
is invalid; and that though the second surface, like the first, may reflect in every part, without regard to its
thickness, its full average portion of the light that is incident on it; yet that afterwards, by reason of the
interference of rays reflected from the first surface, such light does not reach the eye (being destroyed in every
point of its course) from those parts where the thickness is an even multiple of \( \frac{\lambda}{4} \), then it is evident, that the
Newtonian doctrine is something more than a mere aliter statement of facts, and is open to examination as a
theory.

Let us now see, therefore, what account the undulatory theory gives of these phenomena. We will begin,
for a reason which will presently appear, with the transmitted rings. Conceive, then, a ray, the length of Explanation
whose undulations in any medium is \( \lambda \), to be incident perpendicularly on the first surface of a lamina of that of
medium whose thickness is \( t \); and (for simplicity) let its surfaces be supposed parallel, then it will be
divided into two portions, the first \( (= a) \) reflected, and the second \( (= 1 - a) \) transmitted. Let \( \theta \) be the phase
of this portion at reaching the second surface. Here it will be again divided into two portions, the one
reflected back into the medium and equal to \( (1 - a) \cdot a \), or \( (a \text{ being small}) \) very nearly to \( a \), and the remainder
\( (1 - a) - a (1 - a) \), or nearly \( 1 - 2a \), transmitted. These portions, supposing no undulation, or part of an
undulation, gained or lost in the act of transmission or reflexion, will both be in the phase \( \theta \). The reflected
portion will again encounter the first surface in the phase \( \theta + 2\pi \cdot \frac{t}{\lambda} \), will there be again partially reflected,
with an intensity equal to \( a \cdot a' = a'' \), and the portion so reflected will reach the second surface in the phase
\( \theta + 2\pi \cdot \frac{2t}{\lambda} \), and will there be transmitted with an intensity \( = (1 - a) \cdot a'' \), or nearly \( = a'' \). Now, the
reflexions being all perpendicular, this portion will be confounded with the portion \( 1 - 2a \) transmitted
without any reflexion; and putting \( a = \sqrt{1 - 2a} = 1 - a \) nearly, \( a' = \sqrt{a''} = a \), \( a \) and \( a' \) will represent
the amplitudes of vibration of the ethereal molecule at the posterior surface, which each of these rays tend to
impress on it. Hence, its total excursion from rest will be represented by
\[
a \cdot \cos \theta + a' \cdot \cos \left( \theta + 2\pi \cdot \frac{2t}{\lambda} \right).
\]
that is
\[
(1 - a) \cdot \cos \theta + a \cdot \cos \left( \theta + 2\pi \cdot \frac{2t}{\lambda} \right).
\]
\[
= 1 \cos \theta + a \cdot \cos \left( \theta + 2\pi \cdot \frac{2t}{\lambda} \right) - a \cdot \cos \theta.
\]
The first term of this is independent of \( t \), and represents, in fact, the incident ray in the state in which it would
arrive at the second surface, had no reflexions taken place. The other two terms represent rays the former of
which evidently is in complete discordance with the latter, and destroys it when \( t \) is any odd multiple of \( \frac{\lambda}{4} \), (or of
the half length of one of Newton's fits, a fit being, as we have seen above, equal to half an undulation,) thus
leaving the ray at its emergence of the same intensity as it would have had were the lamina away; but when, \( t \)
is any odd multiple of half a fit, then the value of \( \cos \left( \theta + 2\pi \cdot \frac{2t}{\lambda} \right) = - \cos \theta \); and the emergent ray
is in this case represented by \( (1 - 2a) \cdot \cos \theta \), being less than the incident ray by twice the light reflected at
the first surface.

Thus if the thickness of the plate be different in different parts, the light transmitted through it to
the eye will not be uniform, but will have alternate maxima and minima corresponding to the thicknesses 0,
\( \frac{\lambda}{4} \), \( 2\frac{\lambda}{4} \), \( 3\frac{\lambda}{4} \), \&c.

If we apply to the expression above given, the general formula Art. (613) for the composition of rays in one
plane, we shall find for the intensity \( A'' \) of the ray finally emergent,
which shows that the several maxima are equal to the incident ray, and the minima to that ray diminished by four times the light reflected at the first surface. The difference of phase between the simple and composite emergent ray, or the value of $B$ in the formulas cited, is given by the equation,

$$\sin B = \frac{a}{\alpha} \sin \left(2\pi \frac{t}{\lambda}\right) = a \sin \left(2\pi \frac{t}{\lambda}\right),$$

so that for such media as have not a very high refractive power, this difference is always small. It is, however, periodical, and differs for different thicknesses.

Suppose now, instead of homogeneous light, white light to fall on the lamina, and let us represent a ray of such light, as in Art. 488, by $C + C' + C'' + \&c.$, or by $S(C)$, $C$, $C'$, &c. being the intensity of the several elementary rays of all degrees of refrangibility, then will the transmitted compound beam be represented in tint and intensity by

$$C \left\{1 - 4a \sin \left(2\pi \frac{t}{\lambda}\right)\right\} + C' \left\{1 - 4a \sin \left(2\pi \frac{t}{\lambda}\right)\right\} + \&c.$$

or by

$$S \cdot C \left\{1 - 4a \sin \left(2\pi \frac{t}{\lambda}\right)\right\}.$$

Now this is the same with

$$S \left\{C (1 - 4a) + C (4a - 4a \sin \left(2\pi \frac{t}{\lambda}\right))\right\} =$$

$$= (1 - 4a) \cdot S (C) + 4a \cdot S \left\{C \cdot \cos \left(2\pi \frac{t}{\lambda}\right)\right\}.$$
Light.

...but with the same velocity \( V \) till it reaches \( D \), having described a space \( BC + CD = 2AB \) with that velocity. At \( D \) it undergoes another partial reflexion, and only a portion \( = (1 - a) (1 - a) \cdot a \) is transmitted, which sets off from \( D \) along the line \( DI \) (parallel to \( BH \)) with the velocity \( V \), that is, with the same velocity as the wave along \( BH \). This wave may also be regarded as a plane of indefinite extent perpendicular to \( DI \), and therefore parallel to the former. But they are not coincident; for the former, having the start of the latter, will have come into a position \( IHK \) in advance of the position \( DLM \) taken by the latter, and both the waves moving forwards now with the same velocity \( V \) will preserve this distance for ever unaltered. The interval \( LH \) we may term the interval of retardation. To determine it, we have to consider that the space \( BH \) is described by the former wave with a velocity \( V \), while the latter describes \( BC + CD \) with the velocity \( V' \), and therefore

\[
BH = (BC + CD), \quad \frac{V}{V'} = 2AB, \quad \frac{V}{V'} = 2t \cdot \sec \rho \cdot \rho,
\]

putting \( \mu \) for the relative index of refraction of the lamina, \( \rho \) for the angle of refraction \( \alpha \), and \( t \) for the thickness \( A \), because

\[
V : V' :: \mu : 1.
\]

Again, \( BL = BD \cdot \cos DBL = DB \cdot \sin \phi (\phi \text{ being the angle of incidence corresponding to } \rho \text{ the angle of refraction}) = 2AB \cdot \sin \phi = 2t \cdot \tan \rho \cdot \sin \phi. \]

Therefore the whole interval of retardation is equal to

\[
2t \cdot \left( \mu \cdot \sec \rho - \tan \rho \cdot \sin \phi \right) = \frac{2t \cdot \mu}{\cos \rho} (1 - \sin \rho) = 2 \mu t \cdot \cos \rho,
\]

because \( \sin \phi = \mu \cdot \sin \rho \).

Thus, in virtue of the two internal reflexions, each wave which before entering the medium was single, will after quitting it be double, being followed at the constant interval \( 2t \cdot \cos \rho \) by a feebler wave of the intensity above determined. The same being true of every wave of the system of which the ray consists, these two systems (considered as of indefinite duration) will be superposed on, and interfere with each other, according to the general principles before laid down.

Let \( \lambda \) be the length of an undulation in the lamina, then \( \mu \cdot \lambda \) represent that of an undulation in the surrounding medium. This is obvious, because the velocity in the latter being to that in the former as \( \mu : 1 \); and undulations of the same length being propagated in the same time through a given point in both cases, they must be more crowded, and therefore occupy less space in the one than the other in the ratio of the velocities.

Hence the differences of phases between the interfering systems at any point will equal

\[
2\pi \cdot \frac{\text{interval of retardation}}{\mu \cdot \lambda} = 2\pi \cdot \frac{2t \cdot \cos \rho}{\lambda} = 2\pi \cdot \frac{2t'}{\lambda}, \quad \text{putting } t' = t \cdot \cos \rho,
\]

and therefore the final resulting wave will be expressed by the equation

\[
X = \sqrt{(1 - a) (1 - a)} \left\{ \cos \theta + a \cdot \cos \left( \theta + 2\pi \cdot \frac{2t'}{\lambda} \right) \right\},
\]

which being resolved into the fundamental form \( A \cdot \cos (\theta + B) \), as before, gives

\[
A' = (1 - a) (1 - a) \left\{ 1 + 2a \cdot \cos \left( 2\pi \cdot \frac{2t'}{\lambda} \right) \right\} + a^2,
\]

and

\[
\sin B = \frac{a \cdot \sin \left( 2\pi \cdot \frac{2t'}{\lambda} \right)}{\sqrt{1 + 2a \cdot \cos \left( 2\pi \cdot \frac{2t'}{\lambda} \right) + a^2}}.
\]

Such are the general expressions for the intensity and change of origin of the compound transmitted ray. It is evident, however, that when \( a \) and \( a \) are small, which they always necessarily are in any but extreme cases, this value of \( A' \) reduces itself by neglecting their powers and products to

\[
(1 - a + a) - 4a \cdot \sin \left( 2\pi \cdot \frac{t'}{\lambda} \right),
\]

which is exactly analogous to the expression in Art. 662, for the case of perpendicular incidence; and shows, that with the exception of a very trifling difference in the degree of dilution, the same laws of alternation in brightness, in homogeneous light, and of tint in white light, must hold good in both cases.

But there is one essential difference. The same tints will arise in the case of oblique incidence at the thickness \( t \), which in that of perpendicular incidence is produced at the thickness \( t \cdot \cos \rho \), because \( t' = t \cdot \cos \rho \). Dilution at the thickness \( t' \) in that of perpendicular incidence is produced at the thickness \( t' \cdot \cos \rho \), because \( t' \cdot \cos \rho \). Dilution is always less than \( t \), and therefore the tint produced at oblique incidences at the given thickness of the rings will be higher in the scale (or correspond to a less thickness) than in perpendicular; and, consequently, the explained rings, or fringes, so seen by transmission should dilate by inclining the lamina to the eye. The law of dilution evidently, at moderate incidences, coincides nearly with Newton's rule; for this gives, on reduction, neglecting \( \sin \rho \),
which does not deviate very greatly from $\sec \rho$ at moderate incidences.

At great incidences the case is different, and the noncoincidence of the results of the undulatory doctrine with experiment might be drawn into an argument against it, were we sure that the law of refraction at extreme incidences, and with very thin laminae, does not vary sensibly from that of the proportional sines. This is, indeed, highly probable, as M. Fresnel has remarked, (Mém, sur la Diffraction, &c.) and as we have before had occasion to observe. The inquiry into which this would lead, is, however, one of the most delicate and difficult in physical optics, and the reader must content with this general notice of a possible explanation of one of the many difficulties which still beset the undulatory doctrine.

The origin of the reflected rings may be accounted for in a similar way from the partial transmission of the waves reflected from the second surface back through the first, and their interference with the waves reflected immediately from the first. The relative intensities of these waves, (in general,) are $a$ and $(1 - a) (1 - a) \cdot a$; or, in the case where $a$ and $a$ are both small, nearly in the ratio of $a : a$, and at a perpendicular incidence, very nearly in the ratio of equality. Hence their mutual destruction in the case of complete discordance will be much more complete than in the transmitted rings, and the colours arising, much less dilute than those of the latter, agreeably to observation.

There is, however, one consideration of importance to be attended to in the application of the undulatory doctrine to the reflected rings, which at first sight appears in the light of a powerful argument against its admissibility, viz. that if we apply the same reasoning to the reflected, as we have already done to the transmitted, rings, we should arrive at the conclusion, that their tints should be precisely the same and in the same order, beginning with a bright white in the centre; because here, the path traversed by the ray within the lamina vanishing, the waves reflected from the two surfaces ought to be in exact accordance, whereas it appears, by observation, that the reverse is the case, the central spot being black instead of white. It becomes necessary, then, to suppose, that in this case, half an undulation is lost or gained either by the wave reflected from the first or second surface. If this hypothesis be made, the phenomena of the reflected rings are completely represented on the undulatory system, for the compound wave reflected by the joint action of the two surfaces should be represented by the equation,

$$ X = \sqrt{a} \cdot \cos \theta + \sqrt{a} (1 - a) (1 - a) \cdot \cos \left\{ \theta + 2 \pi \cdot \frac{2 t}{\lambda} - \frac{1}{2} \lambda \right\}, $$

and if this be put equal to $A \cdot \cos (\theta + B)$ we get

$$ A^2 = a + a (1 - a) (1 - a) - 2 \sqrt{a} a (1 - a) (1 - a) \cdot \cos \left( 2 \pi \cdot \frac{2 t}{\lambda} \right), $$

and in the case of $a$ and $a$ both very small

$$ A^2 = (\sqrt{a} - \sqrt{a})^4 + 4 \cdot \sqrt{a} a \cdot \sin \left( 2 \pi \cdot \frac{t}{\lambda} \right)^2 $$

and at a perpendicular incidence, where $t' = t$, and where $a$ and $a$ may be supposed equal

$$ A^2 = 4 a \cdot \sin \left( 2 \pi \cdot \frac{t}{\lambda} \right)^2. $$

Thus we see, that in this case the total intensity of the compound reflected wave $+$ that of the transmitted (Art. 662) make up 1, the intensity of the incident wave; and thus, this supposition of the loss or gain of half an undulation is in no contradiction with the law of the conservation of the vis viva.

In fact, however, if we consider the mode in which the undulations are propagated, at the limit between two media, we shall see nothing contrary to dynamical principles in the loss of half or any part of an undulation in the transfer—for it cannot be supposed, that the density or elasticity of the ether changes abruptly at the surfaces of media, but that there intervenes some very minute stratum in which it is variable. In this stratum, therefore, the length of an undulation is neither exactly that corresponding to the denser, nor to the rarer medium, but intermediate, and of a magnitude perpetually varying. Therefore the number of undulations to be reckoned as added to the phase of the ray in traversing this stratum, will differ from what it would be if one medium terminated, and the other commenced abruptly. Without knowing the law of density, the limits between which it undergoes its change, or the exact mode in which the partial reflexion of a wave traversing it is performed, it is impossible to subject the point to strict calculation, we must rather submit to be taught by experiment, and content ourselves with such conclusions as we can deduce from observation. In the case before us, all that observation teaches us is, that there is half an undulation more of difference in the phases of two rays that have been reflected in the manner last considered, than in those of the two whose interference forms the transmitted rays. From some curious experiments of Dr. Young, too, we may gather that it is not in all cases strictly half an undulation of difference to be reckoned, but rather a variable fraction depending on the nature of the contiguous media.

The formula of Art. 672 show that it is only in the case of perpendicular incidence that the tints are pure, and that in all others, and especially at great obliquities, where $a$ and $a$ differ considerably, there will be a
§ V. Of the Colours of Thick Plates.

Under certain circumstances rings of colours are formed by plates of transparent media of considerable thickness. The circumstances under which they appear, in one principal case, are thus described by Newton, who first observed them, and who has applied his doctrine of the fits of easy reflection and transmission to explain them, with singular ingenuity.

"Admitting a bright sunbeam through a small hole of a third of an inch in diameter into a dark room, it was received perpendicularly on a concavo-convex glass mirror one quarter of an inch thick, having each surface ground to a sphere of six feet in radius, and the back silvered. Then holding a piece of white paper in the centre of its concavity, having a small hole in the middle of it to let the sunbeam pass, and after reflection at the speculum to repass through it, the hole was observed to be surrounded with four or five coloured concentric rings or irises, just as the rings seen between object-glasses surround their central spot—but larger and more dilute in their colours". . . . "If the paper was much more distant from the mirror, or much less than six feet, the rings became more dilute and gradually vanished." . . . "The colours of these rings succeeded each other in the order of those which are seen between two object glasses, not by reflected but by transmitted light, viz. white, tawny white, black, violet, blue, greenish yellow, yellow, red, purple," &c. . . . "The diameters of these rings preserved the same proportion as those between the object-glasses, the squares of the diameters of the alternate bright and dark rings, reckoning the central white as a ring of the diameter 0, forming an arithmetical progression, beginning at 0. And in the case described, the diameter of the bright ring measured respectively 0, 0.46, 0.81, 0.92, 1.34." . . . "Lastly, in the rings so formed by reflectors of different thicknesses, their diameters were observed to be reciprocally as the square roots of the thicknesses. If the back of the mirror was silvered, the rings were only so much the more vivid." . . . These various phenomena, and a variety of similar ones, some of more, some of less complexity, according to the variation of the distance, and obliquity of the mirror, and the curvature of its surfaces, Newton has explained very happily, by considering the fits of easy reflection and transmission of that faint portion of the light which is regularly scattered in all directions at the first surface of the glass, and which serves to render it visible. But for this explanation we must refer to his Optics, as our object here is more particularly explained very happily, by considering the fits of easy reflection and transmission of that faint portion of the light which is regularly scattered in the air as it passes through it, nearly in its own direction, that the rings in question are attributed to the undulatory doctrine.

There is no surface, however perfectly polished, so free from small scratches and inequalities as not to reflect and transmit, besides those principal rays which obey the regular laws of reflection and refraction, as dependant on the general surface, other, very much feeble, portions scattered in all directions, by which the surface is rendered visible to an eye anywhere placed, but most copiously in and about the direction of the regularly reflected and transmitted rays. It is the interference of these portions, scattered at the first surface by the ray in passing and repassing through it, nearly in its own direction, that the rings in question are attributed in the undulatory doctrine.

Let F A D, E B G be the parallel surfaces of any medium exposed perpendicularly to a homogeneous ray emanating from a luminous point C, and incident at A. The chief portion will pass straight through A, and be reflected back from B to A again. But at A a scattering takes place, and the transmitted ray A B is accompanied by a diverging cone of faint rays A, B, A, C, &c., all which set out from A in the same phase of their undulations with the principal one from which they originate, so that A may be regarded as their common origin. Take Q, the focus of rays reflected at the second surface conjugate to A (if the surfaces be plane, Q and A are equidistant from B) and the cone of scattered rays, with the regularly reflected ray in its axis, will after reflection diverge as from Q. Again, when they pass into the air again, if we take q the focus conjugate to Q of rays refracted at the surface F D, they will after refraction diverge from q, and by the nature of foci on the undulatory hypothesis, the undulations will be propagated in the air as if they had a common origin q placed in air; because, after refraction, the waves have the form of spheres diverging from q, and therefore every portion of their surfaces are equidistant from q; had they, therefore, really emanated from q, as separate rays, they must at the moment of such emanation have been all in one phase. Now, when the reflected beam reaches A a portion of it will again be scattered in a cone, having the regularly transmitted ray A G in its axis; and the rays A O, A N, A M, &c. of this cone will all have A for their origin, and will be in the same phase at their departure from A with the ray A G; but this is in the phase it would have had as emanated from q; hence, if we consider any point M out of the directly transmitted ray A G, it will be reached at once by a wave belonging to each diverging cone, the one along q M from q and the other along A M from A, and the difference of routes is equal to q A + A M – q M. Therefore, when M is very nearly coincident with G, this is very small and at G vanishes, or the waves are in exact accordance. As M recedes from G it increases, and when it becomes
Light.

half an undulation, the waves are in complete discordance and annihilate each other, and so on alternately. Therefore, as this is true of all rays in conical surfaces round $AG$ as an axis, equally inclined with $AM$, $QM$, if we place a white screen at $G$, it will appear marked with alternate dark and bright rings round a bright centre. To determine their diameters we need only put $qA + AM - qM = n$. or, if we take $qA = a$, $AG = r$, $GM = y$,

$$a + \sqrt{r^2 + y^2} - \sqrt{(a + r)^2 + y^2} = n \frac{\lambda}{2}$$

If we resolve this equation neglecting $y^2$, we find

$$y = \sqrt{n} \cdot \sqrt{\frac{\lambda}{a}} \cdot r (s + r)$$

which, on substituting 0, 1, 2, 3, &c. in succession for $n$, shows that the successive diameters of the alternate dark and bright rings are in the progression of the square roots of those numbers.

If the thickness of the plate be small compared to the distance of the screen, $a$ will also be small, and the value of $y$ becomes

$$y = r \cdot \sqrt{n} \cdot \sqrt{\frac{\lambda}{a}}$$

which shows that for rays of a given refrangibility the diameters of the rings are as the distance of the screen directly, and the square root of the thickness of the plate inversely.

Lastly, the diameter of a ring of the same order in different homogeneous lights, are as the square roots of the lengths of their undulations. Now, this is the very same law that governs the diameters of the rings formed between object-glasses. Consequently, if instead of homogeneous we consider white light, we ought to have a succession of coloured rings whose tints agree precisely with the transmitted series in that experiment.

But the rays so formed, by rays scattered from a single point $A$, would be too feeble to be visible. If, however, we suppose the surfaces to be concentric spheres having $G$ in their common centre, as in fig. 137, then any rays $GA$, $GA'$ falling on any points whatever of their surfaces will depict, on screens $GM$, $GM'$ respectively perpendicular to them as $G$, equal systems of rings having $G$ in their common centre; and, when the arc $AA'$ is not very great, the screens may be regarded as coincident (for in that case $BM - MA = BM' - MA'$) and the rings from every point of the surface, exactly superposed on each other, and being thus increased in intensity in proportion to the area of the exposed surface, become visible.

Now this is exactly Newton's case, for the sun being a luminary of a considerable diameter, the hole in the centre of the spheres may be regarded as a portion of the sun of that size, actually placed there. Of this, every indivisible point may be regarded as the origin of a system of waves, and as depicting on the screen its own set of rings. These, were the hole infinitely small, would be infinitely more clear and pure in their tints than the transmitted rings between object-glasses, because they are not (as in those rings) diluted with the great quantity of white light which escapes interference. But owing to the size of the hole, their centres are not exactly coincident, and therefore their tints mix and dilute each other, and that the more the larger the hole is.

If $c$ be the thickness of the glass, since $Q$ is the conjugate focus of $A$, on the surface $B$ whose radius we will call $r + c$ putting $GA = r$, we have, by Art. 249, $BQ = \frac{r + c}{r - c}$, $A Q = \frac{2c}{r - c}$; and, by Art. 248,

$$A q = a = \frac{2c \rho}{2c - \mu (r + c)}$$

taking $\mu$ for the refractive index; and when $c$ is small compared with $r$, we get

$$a = \frac{2c}{\mu} ; \ y = r \cdot \sqrt{n} \cdot \sqrt{\frac{\mu}{2c}}$$

showing that the diameters of the rings are in this case in the subduplicate ratio of the refractive index of the glass directly, and of its thickness inversely.

If we reduce this value to numbers, taking $\mu = \frac{3}{2}$, $n = 4$, $r = 6$ feet = 72 inches, and $\lambda = \frac{2}{90000}$ the length of an undulation for yellow rays nearly, we find, for the diameter of the second bright ring in yellow light, (which corresponds to the brightest part of the same ring in white),

$$2y = 72 \times \sqrt{4 \cdot \frac{3}{4} \cdot \frac{2}{90000} \cdot 4} = 2.35$$

which agrees almost precisely with Newton’s measure 2.5, or 2.375.

When the mirror is inclined to the incident beam the phenomena become more complicated, and have been elegantly described by Newton, (Optics, book ii. part iv. obs. 10.) In this case, the axes of the two interfering cones of scattered rays, which are always the incident and reflected rays, are no longer coincident. But the same principles apply equally to this case in all other respects, and the reader may exercise himself in tracing their consequences.

The Duke de Chaulnes found similar rings to be exhibited when the surface of the mirror was covered with a thin film of milk dried on it, so as to make a delicate semitransparent coating, or even when a fine gauze or muslin was stretched before it; see the account of his experiments in the Méms Acad. Sci. Paris, 1705; and
Light.

Sir William Herschel (Phil. Trans. 1807) describes a pleasing experiment, in which rings were produced by strewing hair powder in the air before a metallic mirror on which a beam of light is incident, and intercepting the reflected ray by a screen. The explanation of these phenomena seems, however, to depend on other applications of the general principle, and will be better conceived when we come to speak of the colours produced by diffraction.

Dr. Brewster, in the Transactions of the Royal Society of Edinburgh, has described a series of coloured fringes produced by thick plates of parallel glass, which afford an excellent illustration of the laws of periodicity observed by the rays of light in their progress, whether, as in the Newtonian doctrine, we consider them as subjected to alternate fits of easy reflection and transmission, or, as in the undulatory hypothesis, as passing through a series of phases of alternately direct and retrograde motions in the particles of ether, in whose vibrations they consist. We may here remark, once for all, that the explanations which the undulatory doctrine affords of phenomena of this description, may, for the most part, be translated into the language of the rival hypothesis; so as to afford, with more or less plausibility and occasional modifications, a result corresponding with observation. It is not, therefore, among phenomena of this class that we must look for the means of deciding between them. We shall adopt, therefore, in the remainder of this essay, the undulatory system, not as being at all satisfied of its reality as a physical fact, but regarding it as by far the simplest means yet devised of grouping together, and representing not only all the phenomena explicable by Newton's doctrine, but a vast variety of other classes of facts to which that doctrine can hardly be applied without great violence, and much additional hypothesis of a very gratuitous kind.

The fringes in question are seen when two parallel plates of glass of exactly equal thickness (portions of the same plate) are slightly inclined to each other, and through them both, at nearly a perpendicular incidence, a circular luminary of 1° or 2° in diameter (a portion of the sky, for instance) is viewed. There will in this case be seen, besides the direct image, a series of lateral images reflected between the glasses, and growing fainter and fainter in succession as they are formed by 2, 4, 6, or more internal reflexions; and of which all but the first is so faint as scarcely to be visible, except in very strong lights. The direct image is colourless; but the reflected one is observed to be crossed with fifteen or sixteen beautiful bands of colour, parallel to the common section of the surfaces of the plates. Their breadth diminishes rapidly as the inclination of the plates increases.

When the plates employed were 0.121 inch in thickness, and inclined at an angle of 1° 11' to each other, the breadth of each fringe measured 29' 50", and at all other inclinations their breadth was inversely as the inclination. At oblique incidences its fringes are seen when the plane of incidence is at right angles to the principal section of the plates, but are at their maximum of distinctness when parallel to it.

To understand their production, let us call the surfaces of the plates in order, reckoning from that on which the incident light first falls, A, a, B, b; and let us consider a ray, or system of waves emanating from a common origin at an infinite distance. Then, when this ray falls on the plates it will at every surface undergo a partial reflexion, and the remainder will be transmitted; each of the several portions will be again subdivided whenever it meets either surface. So that either image will, in fact, consist of several emergent rays, parallel in their final directions, but which have traversed the glasses by very different routes. Thus the direct or principal image will consist of:

1. The chief portion of the whole incident light, refracted at A, at a, at B, and at b, and emergent parallel to the incident ray, which we will represent by A a B b.

2. A portion refracted at A, reflected at a, reflected again at A, refracted again at a, at B and at b, and emergent parallel to the incident beam. This we will denote thus, A a' A' a B b; the letters denoting the surfaces, the accent reflexion, and its absence reflexion.

3. A portion which has undergone two similar reflexions in the interior of the second plate, and which in the same manner may be represented by A a B b' B' b.

4. Other portions which have undergone respectively four, six, &c. reflexions to infinity within either of the plates, and which may be represented by such combinations as A a' A' a B b, A a B b' B' b, or, for brevity, by A (a' A') a B b, A a B (b' B') b, &c.; but these latter portions are too faint to have any sensible influence on the light of the direct image with which they are confounded.

The first lateral reflected image will consist of four principal portions which have undergone two reflexions each, viz.

\[ A a B' a' B b; \quad A a B' a A' a B b; \quad A a B' B' a B b; \quad A a B' a A' a B b; \]

all which will emerge parallel. Besides these there are infinite others, formed by a greater number of reflexions, and by the portions A a' A' a of the incident beam reflected within the first glass; but these are all too faint materially to affect the image in question, which therefore we may regard as composed solely of the four rays just enumerated. Now if we cast our eye on the figure, (188,) we see the course pursued by each of these portions 1, 2, 3, 4; and it is evident that the first portion has traversed the thickness twice, and the interval between the glasses three times, or nearly; neglecting at present all consideration of the inclination of the plates 2 t + 3 i. In like manner, the portion 2 will have traversed 4 t + 3 i; the portion 3, 4 t + 3 i; and the portion 4, 6 t + 3 i. Hence it appears that the portions 1 and 4 differ in their routes by nearly four times the thickness of the glass, and can therefore produce no colours; but the other portions, at a perpendicular incidence, would not differ at all, and at very small inclinations of the plates, and of the incident ray, will only differ by reason of the small differences of the inclinations at which they traverse their respective thicknesses and intervals. They will, therefore, interfere so as to produce colour; and this will be dependent on the interval of retardation of one ray behind the other, arising from the varying obliquity of the ray which enters the eye.

Now when we look at a luminous image of sensible magnitude, the rays by which we see its several points...
are incident in all planes, and at all inclinations. Hence, the image seen will appear of different colours in its different points, and the disposition of these colours will follow the law, whatever it be, which regulates the interval of retardation. The colours, therefore, will be arranged in bands, circles, or other forms, according to the form of the curves arising geometrically from the consideration of equal intervals of retardation prevailing in every point of their course. Such curves, now and hereafter, we shall term isochromatic lines, or lines of equal tint, measuring in all cases the tint numerically by the number of undulations, or parts of an undulation of mean yellow light to which the interval of retardation is equal.

Let us, then, first consider the case when the ray is incident in a plane perpendicular to the common section.

In this case, fig. 139, let KLMN be a ray formed by the union of two rays SАаВbIKL and SСЕFГКL, whose courses through the system are similar to 3 and 3, fig. 139. Draw AD perpendicular to SC, then will the interval of retardation be equal to

\[ \{ DC + CE + EF + FG + GH + HK \} - \{ Aа + aB + Bb + bI + IK \} \]

= \[ D C + (EF - aB) + (FG - IK) + 2(KH - bB) \],

the first three terms being performed in air, the last in glass. Now, without entering into a trigonometrical calculation, it is evident that this will be very small at a perpendicular incidence, and will increase rapidly as the angle of incidence varies; and that (the inclination of the plates remaining constant) it will increase by nearly equal increments, as the incidence varies by equal changes from 0 on either side of the perpendicular. Therefore, in a direction at right angles to the common section of the surfaces the tints will vary rapidly, increasing on either side of the perpendicular incidence; and at very moderate obliquities on either side, the interval of retardation will become too great for the production of colour. On the other hand, if we conceive the rays SА, SС, to be incident in a plane very nearly parallel to the principal section, then will the points K and G be situated, not, as in the figure, at different distances from P, but at very nearly the same; so that (whatever be the incidence) KI will very nearly equal GF, and for the same reason FE will very nearly equal aB. Moreover, in this case GK will be very nearly equal to FI, and the angles of internal incidence will be also very nearly equal, so that HG + GK will differ very little from Bb + bI, and IB will be very nearly equal to GK, and therefore to IF, so that the point F will almost exactly coincide with B, and the rays SАаВb, SСЕFГЛ will coincide almost precisely, making DC = 0; and these approximate equalities and coincidences will continue for great variations in the angle of incidence, provided the plane of incidence be unaltered. The interval of retardation, then, will in this case depend very little on the angle of incidence; so that in a direction parallel to the common section of the surfaces, the tints will vary but little. Hence it appears that they will be arranged in the manner described by Dr. Brewster, viz. in fringes parallel to that line. Their general analytical expression is, however, rather too complex to be here set down, though very easily investigated from what has been said.

By intercepting the principal transmitted beam in the direct image, and receiving on the eye only those portions of the rays going to form it whose courses are as in fig. 140, or the portions Aа’A’аBb, and AаBb’B’b, Dr. Brewster succeeded in rendering visible a set of coloured fringes, which in general are diluted and concealed in the overpowering light of the direct beam. They originate evidently in the interference of these two rays, whose courses are each represented by \( 4t + i \), and would therefore be strictly equal were the plates exactly parallel. Their theory, after what has been said, will be obvious on inspection of the figure, as well as those of all the rest of the systems of fringes which he has described in that highly curious and interesting memoir.

Mr. Talbot has observed, when viewing films of blown glass in homogeneous yellow light, and even in common daylight, that when two films are superposed on each other, bright and dark stripes, or coloured bands and fringes of irregular forms, are produced between them, though presented by neither separately. These are obviously referable to the same principle, the interference taking place here between rays respectively twice reflected within the upper lamina, and once reflected at the upper surface of the lower lamina, or else between rays one of which is thrice reflected in the mode represented by AаBаBа, and the other in that represented by AаBаBаа, the interval between the glasses being supposed to be exactly equal to the thickness of the upper one in both cases, a condition which is sure to obtain somewhere when the laminae are curved. Still more curious and delicate case of the production of similar fringes has been noticed by Professor Ampere, who take place when two of the blue feathers of the wing of the Rapilio Jasus (a species of butterfly) are laid on each other in the field of his powerful and exquisite microscope. These fringes he describes as small plates of perfect transparency, and uniformly and delicately striated over their whole surface. The fringes in question are formed between them, and vary in breadth, form, and situation, according to the manner in which the feathers are superposed. Their origin seems to be independent of the striae however, and is easily understood on the principles above explained. The same may be said of the colours observed by Mr. Nicholson in combinations of parallel glasses of unequal thickness. Suppose, for instance, that instead of the plates having exactly equal thicknesses, their thicknesses \( t, t' \) differ by a very minute quantity, then the course of the rays Aа’A’аBb and AаBb’B’b will (at a perpendicular incidence) be respectively \( 3t + t' + \ell \) and \( t + t' + 3t' \), (supposing the plates strictly parallel,) and the difference of their routes is \( 2t - 2t' \); so that if this be exceedingly minute, colours will arise, or, if not, may be produced by a slight inclination of the plates to each other, and so of an infinite variety of cases which may arise.
§ VI. Of the Colours of Mixed Plates.

The colours hitherto described have been referred to the interference of rays rigorously coincident with each other throughout their whole course, after the point where they begin to be superimposed. Such interfering rays, or systems of waves, being united into a point on the retina, that point is agitated by the sum or difference of rays not of their actions, and the sensation produced is according. But if this coincidence be only approximate, as, if strictly coincident, two systems of waves be propagated from origins so nearly coincident in angular situation from the eye, that their images formed on the retina shall be too close to be distinguished by the mind from the image of a single point, the impressions produced will still be confounded together; or, rather, we ought to say, the mechanical action on one point will be propagated through the substance of the retina to the other, and a sensation corresponding to their mean or average effect will be produced. If, then, the rays concentrating on contiguous points of the retina be in exact discordance, and of equal intensity, a mutual destruction will take place, as if they fell on one mathematical point; if in exact accordance, they will increase each other’s effects, and so for the intermediate states.

To apprehend this more fully, we must consider that the impression of light appears to spread on the retina to a certain extremely minute distance all around the mathematical focus of the rays concentrated by the lenses of the eye. Thus the image of a star is never seen as a point, but as a disc of sensible size, and that the larger as the light is stronger. Thus, too, the bright part of the new moon is seen, as it were, larger than the faintly illuminated portion of its disc projecting beyond it as an acorn cup beyond the fruit, &c. This effect is termed irradiation, and is manifestly the consequence of an organic action such as we have described.

It follows from this, that when waves emanate from origins undistinguishably near, they may be regarded in their effects on the eye as emanating from origins strictly in one and the same right lines, the direction of the joint ray; and the laws of their interferences will be precisely the same, considered in their effect on vision, as if the lenses of the eye were away, and the retina a mere screen of white paper, on a single physical point of which (viz. the point where the images concentrated by the lenses would have fallen) the interfering undulations propagated simultaneously from the two origins fell, and agitated it with a vibration equal to their resultant.

This premised, we are in a condition to appreciate the explanation afforded by the undulatory doctrine of the phenomena of mixed plates. They were first noticed (says Dr. Young) by him “in looking at a candle through two pieces of plate glass with a little moisture between them. He thus observed an appearance of fringes resembling the common colours of thin plates; and upon looking for the fringes by reflexion, found that the new fringes were always in the same direction as the others, but many times larger. By examining the glasses with a magnifier, he perceived, that wherever the fringes were visible, the moisture was intermixed with portions of air producing an appearance similar to dew.” It was easy to find two portions of light sufficient for the production of the fringes; for the light transmitted through the water moving in it with a velocity different from that of light passing through the interstices filled only with air, the two portions would interfere with each other and produce effects of colour according to the general law. The ratio of the velocities in water and air is that of three to four; the fringes ought therefore to appear where the thickness is six times as great as that which corresponds to the same colour in the common case of thin plates; and upon making the experiment with a plane glass and a lens slightly convex, he found the sixth dark circle actually of the same diameter as the first in the new fringes. The colours are also easily produced when butter or tallow is substituted for water, and the rings then become smaller in consequence of the greater refractive density of the oils; but when water is added so as to fill up the interstices of the oil, the rings are very much enlarged; for here the difference of velocities in water and in oil is to be considered, and this is much smaller than the difference between air and water. All these circumstances are sufficient to satisfy us of the truth of the explanation, and is still more confirmed by the effect of inclining the plates to the direction of the light; for then, instead of dilating like the colours of thin plates, these rings contract, and this is the obvious consequence of an increase of the lengths of the paths of the light which now traverses both media obliquely, and the effect is everywhere the same as that of a thicker plate. It must, however, be observed, that the colours are not produced in the whole light that is transmitted through the media; a small portion only of each pencil passing through the water contiguous to the edges of the particle is sufficiently coincident with the light transmitted through the neighbouring portions of air to produce the necessary interference; and it is easy to show that a considerable portion of the light that is beginning to pass through the water will be dissipated laterally by reflexion at its entrance, on account of the natural concavity of the surface of each portion of the fluid adhering to the two surfaces of the glass, and that much of the light passing through the air will be scattered by refraction at the second surface. For these reasons the fringes are seen when the plates are not directly interposed between the eye and the luminous object.” (Young, Phil. Trans. 1802; Account of some Cases of the Production of Colours.) To see the phenomena to advantage, we may add, it is only necessary to rub up a little froth of soap and water almost dry between two plane glasses, and hold them at a distance from the eye between it and a candle, or the reflexion of the sun on any polished convex object. If two slightly convex glasses, or a plane and a convex one be used, the colours are seen arranged in rings.
§ VII. Of the Colours of Fine Fibres and Striated Surfaces.

If two points supposed capable of reflecting light in all directions (as two infinitely small spheres, &c.) be so near each other as to appear to the eye as one, and if rays from a common origin reflected from them reach the eye, they will interfere; and if the light be homogeneous, its intensity will vary periodically, with an interval of retardation corresponding to the difference of their paths; if white, the colour of the mixed reflected ray will be the same as if it had been transmitted through a plate of air of a thickness equal to that difference, but deprived of its diluting white. Suppose two exceedingly fine cylindrical polished fibres to be placed at right angles to the line of sight, and parallel to each other, as in fig. 141, as ABC, abc; and let S be a luminous point very distant with respect to the interval of the fibres, and E the eye, placed so as to receive the reflected rays BE, bE, which, by supposition, are near enough to interfere. Then the differences of phases of the rays on the retina is evidently equal to
\[ 2\pi \times \frac{(Sb + bE) - (SB + BE)}{\lambda} = 2\pi \times \frac{bx + by}{\lambda}, \]

supposing Bx and By perpendicular to Sb and bE. If, then, we suppose \( \theta \) and \( \phi \) to be the angles of incidence of the rays \( SB, EB \) on the plane in which the axes of the two cylinders AC, aC lie, and put \( Bb \) their distance equal to \( a \), we have for the difference of phases
\[ 2\pi \times \frac{a}{\lambda} \sin(\theta + \phi). \]

Hence, if \( a \) remain the same, this will vary with the obliquity both of the incident and reflected ray to the plane of the axes of the fibres; and, therefore, if that plane be turned about an axis parallel to the fibres, a succession of colours analogous to the transmitted series of those of their plates, but much more vivid, will be seen, as if reflected on them.

Any extremely fine scratch on a well polished surface may be regarded as having a concave, cylindrical, or, at least, a curved surface capable of reflecting the light equally in all directions; this is evident, for it is visible in all directions. Two such scratches, then, drawn parallel to each other, and then turned round an axis parallel to both in the sunshine, ought to affect the eye in succession with a series of colours analogous to those of thin plates. This is really the case. Dr. Young found, on examining the lines drawn on glass in Mr. Coventry's micrometric scales, each of them to consist of two or more finer lines exactly parallel, and at a distance of about one 10,000th of an inch. Placing the scale so as to reflect the sun's light at a constant angle, and varying the inclination of the eye, he found the brightest red to be produced at angles whose sines were in the arithmetical progression 1, 2, 3, 4.

In the beautiful specimens of graduation on glass and steel produced by Dr. Wollaston, Mr. Barton, and M. Fraunhofer, single lines exactly parallel to each other, and distant in some cases not more than one 10,000th of an inch, at precisely equal intervals, are drawn with a diamond point. If the eye be applied close to a reflecting or refracting surface so striated, so as to view a distant, small, bright light reflected in it, it will be seen accompanied with splendid lateral spectra, which evidently originate in this manner. They are arranged in a straight line passing through the reflected, colourless image, and at right angles to the direction of the striae. Their angular distances from each other, the succession of their colours, and all their other phenomena, are in perfect agreement with the above explanation. Their vividness depends on the exact equality of distance between the parallel lines, which causes the lateral images produced by each pair to coincide precisely in distance from the principal image, and thus to produce a multiplied effect. If the distance of the lines be unequal, the images from different pairs, not coinciding, blend their colours, and produce a streak, or ray of white light. This is the origin of the rays seen darting, as it were, from luminous objects reflected on irregularly polished surfaces. These colours may be transferred, by impression from the surface originally graduated, to sealing wax, or other soft body; or from steel, by violent pressure, to softer metals. It is in this way that those beautiful striated buttons and other ornaments are produced, which imitate the splendour and play of colours of the diamond.

Dr. Young has assimilated the colour thus produced when a beam of white light strikes on a succession of parallel equidistant lines, to the musical tone heard when any sudden sound is echoed in succession by a series of equidistant bars having flat surfaces situated in a direction perpendicular to the line in which they are arranged, for instance, an iron railing. It is evident that such echoes will reach the ear in succession, at precisely equal intervals of time, each being equal to the time taken by sound to traverse twice the space separating the bars; and thus producing on the ear, if the bars be sufficiently numerous, the effect of a musical sound. (Phil. Trans. 1801; On the Theory of Light and Colours.) This explanation, however, appears to us, we confess, more ingenious than satisfactory. The pitch of the musical tone produced by the echoes is independent of the sound echoed, which may be a single blow, or a noise, (i.e. a sound consisting of non-periodic vibrations,) and requires for its production a number of echoing bars sufficient to prolong the echoes a sensible time. On the other hand, the light reflected from parallel striae depends for its colour wholly on the incident ray, being red in red light, yellow in yellow, &c.; and is produced equally well from two or from twenty, as from a million of such reflecting lines. The intensity, not the colour,—the magnitude, not the frequency of the impression made on the retina by the reflected rays, is modified by their interference. We think it necessary to point out this defect in the illustration in question, inasmuch as it has become popular for its ingenuity, and primâ facie plausibility; while, in reality, it is calculated to give very erroneous impressions of the analogy between sound and light.
A single scratch or furrow in a surface may, as that eminent philosopher has himself remarked, produce colours by the interference of the rays reflected from its opposite edges. A spider's thread is often seen to gleam in the sunshine with the most vivid colours. These may arise either from a similar cause, or from the thread itself as spun by the animal, consisting of several, agglutinated together, and thus presenting not a cylindrical, but a furrowed surface.

The phenomena exhibited by light reflected from and refracted through the polished surface of mother of pearl, are, no doubt, referable in great measure to the same principle, so far as they depend on the structure of the surface. Dr. Brewster has described them in a most curious and interesting Paper, (published in the Phil. Trans. 1814, p. 397;) and a writer in the Edinburgh Philosophical Journal, vol. ii. p. 117, has added some further particulars illustrative of the curious and artificial structure of this singular body. Every one knows that mother of pearl is the internal lining of the shell of a species of oyster. It is composed of extremely thin laminae of a tough and elastic, yet at the same time hard and shelly substance, disposed parallel to the irregular concavity of the interior of the shell. When, therefore, any portion of it is ground and polished on a plane tool, the artificial surface so produced intersects the natural surfaces of the laminae in a series of undulating curves, or level-lines, which are nearer or farther asunder, according to the varying obliquity of the artificial to the natural surfaces. As these laminae adhere imperfectly to each other, their feather-edges become broken up by the action of the powders, &c. used in grinding and polishing them, so as to present a series of ridges or escarpments arranged (when any very small portion of the surface only is considered) nearly parallel to, and equidistant from each other, which are distinctly seen with a microscope, and which no polishing in the least degree obliterates or impairs. The light reflected, therefore, or dispersed on their edges, will interfere and produce coloured appearances in a direction perpendicular to that of the striae. This is, in fact, their situation; but the phenomena are modified in a very singular manner by the peculiar form of the edges and hollows, which results, no doubt, from the crystalline structure of the pearl. That it is the configuration only of the surface on which they depend, is evident from the remarkable fact, that, like the colours described in Art. 702, they may be transferred, by impression, to sealing wax, gum, resin, or even metals, with little or no diminution of their brilliancy; and the impression so transferred, if examined by the microscope, is found to exhibit a faithful copy of the original striae, though sometimes so minute as hardly to exceed one 3000th of an inch in their distance from each other. For a particular description of this very curious and beautiful class of phenomena, however, our limits oblige us to refer to the original memoirs already cited, especially as their theory is still accompanied with some obscurity.

§ VIII. Of the Diffraction of Light.

When an object is placed in a very small beam of light, or in the cone of rays diverging from an extremely small point, such as a sunbeam admitted through a small pin-hole into a dark chamber, or, still better, through an opening of greater size, behind which a lens of short focus is placed, so as to form an extremely minute and brilliant image of the sun from which the rays diverge in all directions, its shadow is observed to be bordered externally by a series of coloured fringes which are more distinct the smaller the angular diameter of the luminous point, as seen from the object. If this be much increased, the shadow and fringes formed by its small beam several points, regarded each as an independent luminary, overlap and confuse each other, obliterating the light colours, and producing what is called the penombre of the object; but when the luminous point is extremely minute, the shadow is comparatively sharp, and the fringes extremely well defined.

These fringes (which were first described by Father Grimaldi in a work entitled Physico-Mathesis de Luminis, Bologna, 1665, and afterwards more minutely by Newton in the third book of his Optics) surround the shadow of bodies of all figures, preserving the same distance from every part, like the lines along the sea-coast in a map, only, where the object forms an acute, salient angle, the fringe curve round it; and where it makes a sharp, reentering one they cross, and are carried up to the shadow at each side, without interfering or obliterating each other. In white light three only are to be seen, whose colours, reckoning from the shadow, are black, violet, deep blue, light blue, green, yellow, red, blue, yellow, red; pale blue, pale yellow, pale red. In homogeneous light they are, however, more numerous, and of different breadths, according to the colours of the light, being narrowest in violet and broadest in red light, as in the coloured rings between glasses; and it is by the mutual superposition of the different sets of fringes for all the coloured rays that their tints are produced, and their obliteration after a few of the first orders caused.

The fringes in question are absolutely independent of the nature of the body whose shadow they surround, and of the form of its edge. Neither the density or rarity of the one, nor the sharpness or curvature of the other, having the least influence on their breadth, their colours, or their distance from the shadow; thus it is indifferent whether they are formed by the edge or back of a razor, by a mass of platinum or by a bubble in a plate of glass (which, though transparent, yet throws a shadow by dispersing away the light incident on it,) circumstances which make it clear that their origin has no connection with the ordinary refractive powers of bodies, or with any elective attraction or repulsions exerted by them on light; for such forces cannot be conceived as independent of the density of the body exerting them, however minute we might regard the sphere of their action.

To see the fringes in question, they may be received on a smooth, white surface, and examined and measured thereon by contrivances which readily occur; this was the mode pursued by Newton. M. Fresnel, however, having (to avoid the inconvenience of intercepting the light by the interposition of the observer) received them on an emeryed glass plate, was enabled, by placing himself behind it, to approach near enough to examine and measure...
Light. them with a magnifier. In so doing, however, he observed, that when thus once brought under inspection, they continued visible, and were indeed much brighter and more distinct in the focus of the lens (as if depicted in the air) even when the emerald glass was altogether withdrawn; and this fortunate observation, by enabling him to avoid the use of a screen altogether, and to perform all his measurements of their dimensions by the aid of a micrometer, put it in his power to examine them with a degree of minuteness and precision no other way attainable, and fully adequate to the delicacy of the inquiry: for it is manifest that the fringes, being seen as they would be formed if received on a screen in the focus, may be regarded as any other optical image formed in the focus of a telescope, viewed with any magnifier, and treated in all respects as such images.

When ever mode of examining them we adopt, however, we shall observe the following facts:

**Phenomenon 1.** That, instead of rays, which are deflected from each other and from the border of the shadow diminishing as the screen on which they are received, or the plane in the focus of the lens in which they are formed, it approaches the border of the opaque body, and ultimately coincides with it, so that they seem to have their origin close to the edge of the body.

It will be noticed also that the border of the visible shadow is not coincident with B, that of the geometrical one, which lies in the straight line OA, grazing the edge of the object. The deviation is difficult to perceive in the shadow of a large body, having nothing to measure from; but if we examine those of very narrow bodies, of a hair, for instance, in such a beam of light as described, we shall find on measuring the total breadth of the shadow a full proof of this. This fact was observed by Grimaldi. The limits of the visible shadow also follows the same law of curvilinear propagation as the fringes. Thus, Newton found the shadow of a hair one 280th of an inch in diameter placed at 12 feet distance from the luminous point, to measure at 4 inches from the hair $\frac{1}{3}$ inch, or upwards of 4 diameters of the hair, at two feet, $\frac{1}{3}$ inch, or 10 diameters; while at 10 feet it measured only $\frac{1}{4}$ inch, or 35 diameters, instead of 120, which it should have done if the rays terminating the shadow had proceeded in straight lines; or rather, to speak more correctly, if the shadow were bounded by straight lines.

To account for these remarkable facts, Newton supposes that the rays passing at different distances from the edges of bodies are turned aside outwards, as if by a repulsive force; and that those nearest are turned more outwards than those more remote, as in fig. 143, where X is a section of the hair, and A D, B E, C F, &c. rays which passed at different distances from the opaque body much more rapidly at first, and less so as we recede, than according to the law of proportionality; and if the locus of each fringe be laid down from such measures, it will be found to be an hyperbolic curve having its convexity outwards or from the shadow. Thus in fig. 142 O is the luminous point, A the edge of the body, and G H a screen perpendicular to the straight line O A, C the visible shadow, and D, E, F the places of the successive minima of the fringes in a line at right angles to the edge of the shadow. If the screen be brought nearer to the body A as at g h, and if c, d, e, f be the points corresponding to C D E F, their loci will be the hyperbolas A c C, A d D, &c.

**Phenomenon 2.** That they are not, however, propagated in straight lines from the edge of that body to a distance, but in hyperbolic curves, having their vertices at that edge; and therefore that it is not one and the same light which forms one and the same fringe at all distances from the opaque body. To explain this, conceive the distances of the fringes from each other and from the shadow measured accurately at a great variety of distances from the edge of the body; then, were they propagated in straight lines, and were each fringe really the axis of a pencil of rays emanating from a point at that edge, their intervals and distances from the shadow ought to be proportional to the distances from the edge of the body; but it is not so, in fact,—the former distances increasing as we recede from the opaque body much more rapidly at first, and less so as we recede, than according to the law of proportionality; and if the locus of each fringe be laid down from such measures, it will be found to be an hyperbolic curve having its convexity outwards or from the shadow. Thus in fig. 142 O is the luminous point, A the edge of the body, and G H a screen perpendicular to the straight line O A, C the visible shadow, and D, E, F the places of the successive minima of the fringes in a line at right angles to the edge of the shadow. If the screen be brought nearer to the body A as at g h, and if c, d, e, f be the points corresponding to C D E F, their loci will be the hyperbolas A c C, A d D, &c.

The visible shadow differs from the geometrical one, which lies in the straight line O A, grazing the edge of the object. The deviation is difficult to perceive in the shadow of a large body, having nothing to measure from; but if we examine those of very narrow bodies, of a hair, for instance, in such a beam of light as described, we shall find on measuring the total breadth of the shadow a full proof of this. This fact was observed by Grimaldi. The limits of the visible shadow also follows the same law of curvilinear propagation as the fringes. Thus, Newton found the shadow of a hair one 280th of an inch in diameter placed at 12 feet distance from the luminous point, to measure at 4 inches from the hair $\frac{1}{3}$ inch, or upwards of 4 diameters of the hair, at two feet, $\frac{1}{3}$ inch, or 10 diameters; while at 10 feet it measured only $\frac{1}{4}$ inch, or 35 diameters, instead of 120, which it should have done if the rays terminating the shadow had proceeded in straight lines; or rather, to speak more correctly, if the shadow were bounded by straight lines.

To account for these remarkable facts, Newton supposes, that the rays passing at different distances from the edges of bodies are turned aside outwards, as if by a repulsive force; and that those nearest are turned more outwards than those more remote, as in fig. 143, where X is a section of the hair, and A D, B E, C F, &c. rays which passed at different distances from the opaque body much more rapidly at first, and less so as we recede, than according to the law of proportionality; and if the locus of each fringe be laid down from such measures, it will be found to be an hyperbolic curve having its convexity outwards or from the shadow. Thus in fig. 142 O is the luminous point, A the edge of the body, and G H a screen perpendicular to the straight line O A, C the visible shadow, and D, E, F the places of the successive minima of the fringes in a line at right angles to the edge of the shadow. If the screen be brought nearer to the body A as at g h, and if c, d, e, f be the points corresponding to C D E F, their loci will be the hyperbolas A c C, A d D, &c.

This will be the boundary of the visible shadow. To account for the fringes, he supposes (Optics, book iii. question 3) that each ray in its passage by the body undergoes several flexures to and fro, as in fig. 144 at a, b, c; and that the luminous molecules, of which that ray consists, are thrown off at one or other of the points of contrary flexure, or other determinate points of the serpentine curve described by them according to the state of their fits in which they there happen to be, or other circumstances; some upwards, as in the directions a A, b B, c C, d D, and others we may suppose inwards, as a a, b b, c c, &c. With the latter we have here no concern. The former, it is evident, will give rise to as many such caustics as above described, as there are deflected rays, and within which none can enter, will be convex outwards; and its curvature will be greatest at the vertex W, and will diminish continually as it recedes from X, being, in fact, the caustic of all the deflected rays.

This theory accounts then perfectly for the curvilinear propagation of the fringes, for their rapid degradation, for their apparently originating in the very edge of the body, (since each caustic will actually come up to that edge, as at A, fig. 142,) and for the remarkable brightness of the fringes, especially the first, which really contains in itself all the light which would have passed into the region B C between the visible and geometrical shadows. It should appear, therefore, that M. Fresnel, in the objections he has taken against these points of the Newtonian doctrine of inflexion in his excellent work Sur la Diffraction de la Lumière, (§ 1, p. 15, 17, 19,) must have formed a very inadequate conception of the doctrine he opposes, which, if viewed in the light he has there placed it in, would indeed deserve no other epithet than puerile, and must be looked upon as quite unworthy of his illustrious author; and were these the only difficulties to be explained, we should certainly not be justified.
in passing a hasty sentence on it. Other objections advanced by the same eminent philosopher, however, are more serious, and refer to a phenomenon of which the doctrine of deflective forces seems incapable of giving any account; but of which, in justice to Newton we ought to add, it does not appear that he was aware, or its importance could not fail to have struck him.

**Phenomenon 3.** All other things remaining the same, let the opaque body A be brought nearer the luminous point O, (fig. 142.) The fringes then, formed at the same distance as before behind A, are observed to dilate considerably in breadth,—preserving, however, the same relative distances from each other, and from the border of the shadow. This fact is evidently incompatible with the idea of their being caused by any deflecting force emanating from the opaque body, since it is inconceivable that such a force should depend on the distance the light has travelled from another point no way related to the body.

To explain the diffracted fringes on the undulatory doctrine, Dr. Young conceived the rays passing near the edge of the opaque body to interfere with those reflected very obliquely on its edge, and which in the act of reflexion had lost half an undulation, as in the case of the reflected rings. This supposition would, in fact, lead us to conclude the existence of a series of fringes propagated hyperbolically, and perfectly resembling those really existing. M. Fresnel, however, has shown that a minute though decided difference exists between their places, as given by this theory and by direct measurement; and has, moreover, remarked, that were this the true explanation, they could hardly be supposed absolutely independent of the figure of the edge of the opaque body, which experience shows they are; and that in cases where this edge is extremely sharp, the small quantity of light which could be reflected from it would be insufficient to interfere with that passing by it, so as to form fringes so bright as we see them. These objections appear conclusive, especially as the supposition of a reflexion on the edge of the body is unnecessary, since a more strict application of the undulatory doctrine, assisted by the principle of interferences, will be found to afford a full and precise explanation of all the facts, regarding the opaque body as merely an obstacle bounding the waves propagated from the luminous point on one side.

To show this, let us consider a wave AMF propagated from O, and of which all that part to the right of A (fig. 145) is intercepted by the opaque body AG; and let us consider a point P in a screen at the distance AB from the point A, as illuminated by the undulations emanating simultaneously from every point of the portion AMF, according to the theory laid down in Art. 628, et seq. For simplicity, let us consider only the propagation of undulations in one plane. Put AO = a, AB = b, and suppose λ = the length of an undulation; and drawing PN any line from P to a point near M, put PF = f, NM = s, PB = s; then, supposing P very near to B, and with centre P radius PM describing the circle QM, we shall have f = PQ + QN = \(\sqrt{(a+b)^2 + x^2 - a + QN = b + \frac{x^2}{2(a+b)}} + QN\). Now, QN is the sum of the versed sines of the arc s to radii OM and PM, and is therefore equal to \(\frac{s^2}{2OM} + \frac{s^2}{2PM} = \frac{s^2}{2} \left(\frac{1}{a} + \frac{1}{b}\right) = \frac{a+b}{2ab} \cdot s^2\); so that, finally,

\[f = b + \frac{x^2}{2(a+b)} + \frac{(a+b)x^2}{2ab}\]

Now, if we recur to the general expression demonstrated in Art. 632, for the motion propagated to P from any limited portion of a wave, we shall have in this case \(\alpha \cdot \phi (\theta) = 1\), because we may regard the obliquity of all the undulations from the whole of the efficacious part of the surface AMN as very trifling, when P is very distant from A in comparison with the length of an undulation. And as we are now only considering undulations propagated in one plane, that expression becomes merely \(V = \int ds \cdot \sin 2\pi \left(\frac{t}{T} - \frac{f}{\lambda}\right)\), and the corresponding expression for the excursions of a vibrating molecule at P will be

\[X = \int ds \cdot \cos 2\pi \left(\frac{t}{T} - \frac{f}{\lambda}\right)\].

If then we put for \(f\) its value, and take

\[2\pi \left(\frac{t}{T} - \frac{b}{\lambda} - \frac{x^2}{2\lambda(a+b)}\right) = \theta; \quad s \cdot \sqrt{\frac{2(a+b)}{a b \lambda}} = \nu,\]

and consider that in those expressions \(t\) and \(x\) remain constant, while \(s\) only varies, the latter will take the form

\[X = \sqrt{\frac{a b \lambda}{2(a+b)}} \cdot \left\{\cos \theta \cdot \int dv \cos \left(\frac{\nu}{2} x^2\right) + \sin \theta \cdot \int dv \cdot \sin \left(\frac{\nu}{2} x^2\right)\right\}^3\]

which shows that the total wave on arriving at P may be regarded as the resultant of two waves \(X'\), \(\cos \theta\) and \(X''\), \(\sin \theta\), differing in their origin by a quarter-undulation, and whose amplitudes \(X'\) and \(X''\) are given by the expression

\[X' = \sqrt{\frac{a b \lambda}{2(a+b)}} \cdot \int dv \cos \left(\frac{\nu}{2} x^2\right); \quad X'' = \sqrt{\frac{a b \lambda}{2(a+b)}} \cdot \int dv \cdot \sin \left(\frac{\nu}{2} x^2\right)\]

the integrals being taken between limits of \(\nu\) corresponding to \(s = -AM\), and \(s = +\infty\). Consequently,
Hence, to determine the intensity of the light at any point \( P \) on the screen, we must first of all calculate the values of these integrals; and having thus determined \( X' \) and \( X'' \), the square root of the sum of their squares will represent the amplitude of a single vibration, the resultant of both, (Art. 615;) and the sum of theirsquares simply \((X'^2 + X''^2)\), the intensity of the light, or the sensation produced in the eye.

M. Fresnel, in the work already cited, has given a table of the values of these integrals for limits successively increasing from 0 up to \( \infty \), (at which latter limit each is equal to \( \frac{1}{2} \), as may readily be proved;) and, calculating on this, he finds that the intensity of the light, without the limit of the geometrical shadow, passes through a series of maxima and minima according to the following table:

</table>

In this it is to be remarked, that no minimum is zero, and that the difference between the successive maxima and minima diminishes very rapidly as the values of \( s \) increase, which explains the rapid degradation of their tints.

If the point \( P \) be situated on the very edge of the geometrical shadow, its illumination should on this theory be \((\frac{1}{2})^2 + (\frac{1}{2})^2 = \frac{1}{4}\). To compare this with the illumination of the same point, were the opaque body removed, we have only to consider, that at a great distance from the shadow the light must be the same, whether the body be there or not. Now the limit to which the maxima and minima approximate is 2, which therefore represents the uniform illumination beyond the fringes; so that the light on the border of the geometrical shadow is equal to \( \frac{1}{2} \) of the full illumination from the radiant point.

Within the shadow we have only to make \( s \) or \( v \) negative. This does not alter the values of the integrals, but it does their limits, which must in that case be taken not from \( v = -x \sqrt{\frac{2a}{(a + b)b\lambda}} \to +\infty \), but from \( v = +x \sqrt{\frac{2a}{(a + b)b\lambda}} \to +\infty \). The computations have been executed by M. Fresnel, who finds that no periodical increase or decrease here takes place, but that the light degrades rapidly and constantly within the geometrical shadow to total darkness.

The actual visible shadow then is marked by no sudden defalcation of light, and it will depend on the judgment of the eye where to establish its termination. If we regard all that part as shadow which is less illuminated than the general light of the screen beyond the fringes, then the visible shadow will extend considerably beyond the geometrical one, and this explains why the shadows of small bodies are so much dilated, as we have seen they are.

If we would know the breadths of the several fringes, we have only to find the values of \( x \) in the equation

\[ x = s \cdot \sqrt{\frac{(a + b)b\lambda}{a}} \]

where \( x \) has in succession the several values set down in the foregoing table. If we consider the variation of \( x \) for successive values of \( a \) and \( b \), we shall see the origin both of the curvilinear propagation of the fringes, and of their dilatation on the approach of the luminous point. In fact if we regard, first, the relation between \( b \) and \( x \), or the locus of any fringe regarded as a curve, having the line \( AB \) for an abscissa and \( BP \) as an ordinate, we have

\[ x^2 = \frac{\lambda}{2} \left( b + \frac{b^2}{a} \right) \]

which is the equation of an hyperbola having its convexity outwards and passing through \( A \). Secondly, on the other hand, if we regard \( a \) as the variable quantity and \( b \) as constant, we see that for one and the same distance from the screen, the breadths of the fringes increase as \( a \) diminishes; the increments of
The shadows of bodies which afford peculiarly apt illustrations of the principle of interferences. The first class of phenomena of this kind was noticed by Grimaldi, who found that when a long, narrow body is held in a small diverging beam of light, the shadow received on a screen at a distance will be marked in the direction of its length with alternate streaks or fringes brighter and darker than the rest. These are more or less numerous, according as the distance of the shadow from the body is smaller or greater in proportion to the breadth of the shadows. To study the phenomena more minutely, Dr. Young passed a sunbeam through a hole made with a fine needle in thick paper, and brought into the diverging beam a slip of card one-thirtieth of an inch in breadth, and observed its shadow on a white screen at different distances. The shadow was divided by parallel bands, as above described, but the central line was always white. That these bands originated in the interference of the light passing on both sides of the card, Dr. Young demonstrated beyond all controversy, by simply intercepting the light on one side by a screen interposed between the card and the shadow, leaving the rays on the other side to pass freely, in the manner represented in fig. 146, where O is the hole, A B the card, E F its shadow, and C D the intercepting body receiving on its margin the margin of the shadow of the edge B of the body. In this arrangement all the fringes which had before existed in the shadow E F immediately disappeared, although the light deflected on the edge A was allowed to retain its course, and must have necessarily undergone any modification it was capable of receiving from the proximity of the other edge B. The same result took place when the intercepting screen was placed as at c d before the edge E of the body, so as to throw its own shadow on the margin B of the card.

Without entering minutely into the rationale of this phenomenon, which, however, the formula of the preceding articles enable us fully to do, by considering the illumination of any point X between E and F as explained from the whole wave a A B b, minus the portion A B, and which M. Fresnel has done at full length, nation.

Besides the exterior fringes above described, there are others formed in certain circumstances within the shadows of bodies which afford peculiarly apt illustrations of the principle of interferences. The accordance of this theory with experiment, so far as it regards the distances of the fringes from the shadow and from each other, has been put to a severe test by M. Fresnel, and found perfect. It were to be wished, however, that he had stated somewhat more precisely the instrumental means by which he determined the place of the border of the geometrical shadow, from which his measures are all stated to be taken; and which, being marked by no phenomenon of maximum or minimum, might be liable to uncertainty if judged of by the eye alone. This, however, in no way invalidates the accuracy of the final conclusions, as the intervals between the fringes are distinctly marked, and susceptible of exact measurement. The dilatation of the fringes on the approach of the luminous point is, perhaps, the strongest fact in favour of the undulatory doctrine, and in opposition to that of reflection, which has yet been added. It seems hardly reconcilable to any received ideas of the action of corpuscular forces, to suppose the force of deflection exerted by the edge of a body on a passing ray, to depend on the distance which the ray has passed over before arriving at that edge from an arbitrarily assumed origin. M. Fresnel has placed this argument in a strong light, in his work already cited.

Grimaldi's crested fringes. When a shadow is formed by an object having a rectangular termination; besides the usual external fringes there are two or three alternations of colours, beginning from the line which bisects the angle, disposed, within the shadow on each side of it, in curves which are convex towards the bisecting line, and which converge towards it as they become remote from the angular point. These fringes are the joint effect of the light spreading into the shadow from each outline of the object, and interfering as above; and that they are so, is proved by placing a screen within a few inches of the object, so as to receive only one edge of the shadow, when the whole of the fringes disappear. If, on the other hand, the rectangular point of the shadow be opposed to the point of the shadow, so as barely to receive the angle of the shadow on its extremity, the fringes will remain undisturbed.

Case of diffraction through a small aperture. The image of the hole will be seen through the lens as a brilliant spot, encircled by rings of colours of great vividness, which contract and dilate, and undergo a singular and beautiful alternation of tints, as the distance of the hole from the luminous point on the one hand, or on the eye-glass on the other, is changed. When the latter distance is considerable, the central spot is white, and the rings follow nearly the order of the colours of thin plates. Thus, when the diameter of the hole was about \( \frac{2}{3} \) of an inch, its distance...
(a) from the luminous point about 6 feet 6 inches, and its distance (b) from the eye-lens 24 inches, the series of colours was observed to be,

1st order. White; pale yellow; yellow; orange; dull red.
2nd order. Violet; blue (broad and pure); whitish; greenish yellow; fine yellow; orange red, very full and brilliant.
3rd order. Purple; indigo blue; greenish blue; pure, brilliant green; yellow green; red.
4th order. Good green, but rather sombre and bluish; bluish white; red.
5th order. Dull green; faint bluish white; faint red.
6th order. Very faint green; very faint red.
7th order. A trace of green and red.

730. When the eye-lens and hole are brought nearer together, the central white spot contracts into a point and vanishes, and the rings gradually close in upon it in succession, so that the centre assumes in succession the most surprisingly vivid and intense hues. Meanwhile the rings surrounding it undergo great and abrupt changes in their tints. The following were the tints observed in an experiment made some years ago, (July 12, 1819,) the distance between the eye-glass and luminous point (a + b) remaining constant, and the hole being gradually brought nearer to the former.

731. Fresnel's analysis of this case.

The series of tints exhibited by the central spot is, evidently, so far as it goes, that of the reflected rings in the colours of thin plates. The surrounding colours are very capricious, and appear subject to no law. They depend, indeed, on very complicated and unmanageable analytical expressions, with which we shall not trouble the reader, but content ourselves with presenting the explanation given by M. Fresnel of the changes of tint of the central spot in white light, and its alternations of light and total darkness observed by him in an homogeneous illumination. Let then a and b be the distances of a small hole whose radius is r from the luminous point, and a screen placed behind the hole perpendicularly to the ray passing directly through its centre. Then if we consider any infinitely narrow annulus of the hole whose radius is z, and breadth dz, this annulus will send to the central point of the screen a system of waves whose intensity is proportional to the area of the annulus, or \( \pi z dz \), but whose phase of undulation differs from that of the central ray, by reason of the difference of the paths described by them. Now, calling f the distance of each point in the annulus from the centre of the screen, we have \( f^2 = b^2 + z^2 \), and, in like manner, if \( f' \) be the distance of the luminous point from the same annulus, \( f'^2 = a^2 + z^2 \), so that \( (f + f') - (a + b) \) the difference of paths, or interval of retardation, is equal to \( \frac{z^2}{2} \left( \frac{1}{a} + \frac{1}{b} \right) = \frac{z^2 (a + b)}{2ab} \). Hence, the general expression in Art. 632 for the amplitude of the total wave, incident on the centre of the screen in this particular case, is equivalent to

\[
X = \int \sin 2\pi \frac{z^2 (a + b)}{2ab},
\]

\[
\left( \frac{1}{a} + \frac{1}{b} \right)
\]
or, integrating, which from the peculiar form of the differential is in this case easy,

\[ X = \frac{a \cdot b \cdot \lambda}{a + b} \left\{ \text{const} + \cos 2 \pi \left( \frac{t}{T} - \frac{r^2(a + b)}{2 a \cdot b \cdot \lambda} \right) \right\} \]

which, extended from \( z = 0 \) to \( z = r \), gives

\[ X = \frac{a \cdot b \cdot \lambda}{a + b} \left\{ \cos \lambda \left( \frac{t}{T} - \frac{(a + b) \cdot r^2}{2 a \cdot b \cdot \lambda} \right) - \cos 2 \pi \left( \frac{t}{T} \right) \right\} \]

\[ = \frac{a \cdot b \cdot \lambda}{a + b} \left\{ \sin \left( \frac{\pi (a + b) \cdot r^2}{a \cdot b \cdot \lambda} \right) \sin 2 \pi \left( \frac{t}{T} \right) + \left( \cos \left( \frac{\pi (a + b) \cdot r^2}{a \cdot b \cdot \lambda} \right) - 1 \right) \cos 2 \pi \left( \frac{t}{T} \right) \right\}. \]

This expresses, as we have before remarked in a similar case, (Art. 718,) two partial waves differing by a quarter-undulation, and expressing it, as in that case, by \( X = X' \cdot \cos \theta + X'' \cdot \sin \theta \), where \( \theta = \frac{t}{T} \), we find for the intensity \( A^* \) of their resultant

\[ A^* = X'^2 + X''^2 = 4 \left( \frac{a \cdot b \cdot \lambda}{a + b} \right) \left( \frac{\sin \left( \frac{\pi (a + b) \cdot r^2}{2 a \cdot b \cdot \lambda} \right)}{\frac{a \cdot b \cdot \lambda}{a + b}} \right)^2. \]

To make use of this, however, we must compare it with what would be the direct illumination of the centre of the screen, if the aperture were infinite, i.e., if the direct light from the luminous point shone full upon it. To this case, however, neither our formula nor our reasoning are applicable; for if we make \( r \) infinite in this expression, it becomes illusory, and presents no satisfactory sense, and in our reasoning we have neglected to consider the law of diminution of the intensity of the oblique waves, or regarded \( \phi (\theta) \) in Art. 631 as invariable, which in this extreme case is far from the truth. We must, therefore, have recourse to another method. Now, M. Fresnel has demonstrated (and our limits oblige us to take his demonstration for granted) that this total illumination is equal to one-fourth of that which the centre of the screen would receive from an opening of such a radius, that the difference of routes of a ray passing through the centre, and one diffracted at the circumference, shall be an exact semi-undulation, i.e., in which \( \frac{r^2(a + b)}{2 a \cdot b} = \lambda \), or \( r = \sqrt{\frac{a \cdot b \cdot \lambda}{a + b}} \). If then we substitute this for \( r \) in the above formula, and put \( C \) for the whole illumination, we get, on the same scale,

\[ C = \left( \frac{a \cdot b \cdot \lambda}{a + b} \right)^2 \left( \frac{\sin \pi}{2} \right)^2 = \frac{(a \cdot b \cdot \lambda)}{(a + b)} \]

and, consequently,

\[ A^* = 4 \cdot C \left( \frac{\sin \left( \frac{\pi (a + b) \cdot r^2}{2 a \cdot b \cdot \lambda} \right)}{\frac{a \cdot b \cdot \lambda}{a + b}} \right)^2. \]

In this expression, \( a, b \) are independent of \( \lambda \), and therefore the value of \( A^* \) is of the form \( 4 \cdot C \left( \sin 2 \pi \cdot \frac{2 \cdot \sqrt{\lambda}}{\lambda} \right)^2 \) where \( B = \frac{(a + b) \cdot r^2}{4 a \cdot b} \). Hence, if we suppose light of all colours to emanate from the luminous point, the compound tint produced in the central point of the screen will be represented by \( S \left\{ 4 \cdot C \left( \sin 2 \pi \cdot \frac{2 \cdot \sqrt{\lambda}}{\lambda} \right)^2 \right\} \) and will therefore, by Art. 673, be the same with that reflected by a plate of air whose thickness is \( B \), or \( \frac{(a + b) \cdot r^2}{4 a \cdot b} \) which increases as \( b \) diminishes when \( a + b \) remains constant. Thus we see the origin of the succession of colours of the central spot in the Table above recorded, which is the more satisfactory, as that experiment was made without reference to, and indeed in ignorance of, this elegant application of M. Fresnel's general principles, the merit of which is due (as he himself states) to M. Poisson.*

Another very curious result of M. Poisson's researches is this, that the centre of the shadow of a very small circular opaque disc, exposed to light diverging from a single point, is precisely as much illuminated by the diffracted waves as it would be by the direct light, if the disc were altogether removed. We cannot spare room for the demonstration of this singular theorem. It has been put to the test of experiment by M. Arago, with a small metallic disc cemented on a very clear and homogeneous plate of glass, and with full success.

When the light is transmitted through two equal apertures, placed very near each other, the rings are formed about each as in the case of one; but besides these arise a set of narrower, straight, parallel fringes bisecting the interval between their centres, and at right angles to the line joining them. If the apertures be unequal, these fringes assume the form of hyperbolas, having the aperture in their common focus. Besides these also two other sets of parallel rectilinear fringes (in the case of equal apertures) go off in the form of a St. Andrew's cross from the centre at equal angles with the first set. See figures 147, 148. When the apertures are more numerous or varied in shape, the variety and beauty of the phenomena are extraordinary; but of this more presently.

M. Fresnel has shown, that when the light from a single luminous point is received on two plane mirrors...
very slightly inclined to each other, so as to form two almost contiguous images, if these be viewed with a lens, there will be seen between them a set of fringes perpendicular to the line joining them. These are evidently analogous to those produced by the two holes in the experiments last described. The experiment is delicate; for if the surfaces of the reflectors at the point where they meet be ever so little, the one raised above or depressed below the other, so as to render the difference of routes of the rays greater than a very few undulations, no fringes will be seen. But it is valuable, as demonstrating distinctly that the borders of the apertures in the preceding experiment have nothing to do with the production of the fringes, the rays being in this case abandoned entirely to their mutual action after quitting the luminous point. An exactly similar set of fringes is formed if, instead of two reflectors, we use a glass, plane on one side, and on the other composed of two planes, forming a very obtuse angle, as in fig. 149. This being interposed between the eye-lens E and the luminous point S, forms two images S and S' of it; and the interference of the rays SE and S'E from these images, forms the fringes in question.

Since the production of the fringes and their places with respect to the images of the luminous point, depends on the difference of routes of the interfering rays, it is evident, that if, without altering their paths, we alter the velocity of one of them with respect to the other, during the whole or a part of its course, we shall produce the same effect. Now, the velocity of a ray may be changed by changing the medium in which it moves. In the undulatory system, the velocity of a ray in a rarer medium is greater than in a denser. Hence, if in the path of one of two interfering rays we interpose a parallel plate of a transparent medium denser than air, (at right angles to the ray's course), we shall increase its interval of retardation, or produce the same effect as if its course had been prolonged. If then a thick plate of a dense medium, such as glass, be interposed in one of the rays which forms the fringes, they will disappear; because the interval of retardation will be thus rendered suddenly equal to a great number of undulations, whereas the production of the fringes requires that the difference of routes shall be very small. If, however, only a very thin lamina be interposed, they will remain visible, but shift their places. Thus, in fig. 150, let S A, S B be rays transmitted through the small apertures A, B from the luminous point S, and received on the screen D C E, these forming a set of fringes of which C, the middle one, will be white.

Let D, E be the dark fringes immediately adjacent on either side; and things being thus disposed, let a thin film of glass or mica G be interposed in one of the rays S A, its thickness being such that the ray in traversing it shall just be retarded half an undulation. Then will the rays A E, B E, which before were in complete discordance, be now in exact accordance, and there will be formed at E a bright fringe instead of a dark one. On the other hand, the ray A C will now be half an undulation behind B C, instead of in complete accordance with it, so that at C there will be formed a dark fringe, and so on. In other words, the whole system of fringes will be formed as before, but will have shifted its place, so as to have its middle in E instead of C, i.e. will have moved on which the plate of the dense medium is interposed. It is evident, that if the plate G be thicker, the same effect will take place in a greater degree.

To make the experiment, however, it must be considered that the refractive power of glass, or indeed of any but gaseous media, is so great, that any plate of manageable thickness would suffice to displace the fringes so far as to throw them wholly out of sight. But we shall succeed, if, instead of a single plate G placed over one aperture A, we place two plates G, g of very nearly equal thicknesses, (such as will arise from two nearly contiguous fragments of one and the same polished plate,) one over each aperture; or we may vary the thickness of the plate traversed by either ray by inclining it, so as to bring it within the requisite limits. This done, the effect observed is precisely that described; the fringes shift their places from the thicker plate, without sustaining any alteration in other respects. This elegant experiment affords a strong indirect argument in favour of the undulatory system, and in opposition to that of emission, since it proves that the rays of light are retarded in their passage through denser media, agreeably to what the undulatory system requires, and contrary to the conclusions of the corpuscular doctrine.

MM. Arago and Fresnel have taken advantage of this property, to measure the relative refractive powers of different gases, or of the same in different states of temperature, pressure, humidity, &c. It is manifest, that if any considerable portion of the path of one of the interfering rays be made to pass through a tube closed at both ends with glass plates, and the other through equal glass plates only, the fringes will be formed as usual. But if the tube be exhausted, or warmed, or cooled, or filled with a gas of different refractive density, a displacement of the fringes will take place, which, (if they be received in the focus of a micrometer) may be measured with the greatest delicacy. Knowing the amount of their displacement, as compared with the breadth of the fringes, we know the number of undulations gained or lost by one ray on the other; and hence, knowing the internal length of the tube, we have the ratio of the refracting power of the medium it contains to that of air. What renders this method remarkable is, that there is actually no conceivable limit to the precision of which it is susceptible, since tubes of any length may be employed, and micrometers of any delicacy.

The phenomena of diffraction, and those arising from the mutual interference of several very minute pencils of rays emanating from a common origin, have been investigated by M. Fraunhofer with great care and extraordinary precision, by the aid of a very delicate apparatus devised and executed by himself.

This apparatus consisted of a repeating, 12-inch theodolite, reading to every 4", carrying, attached to its horizontal circle, a plane circular disc of six inches in diameter, having its axis precisely coincident with that of the theodolite, and having its own particular divisions independent of those of the theodolite. In the centre of this disc was placed vertically a metallic screen, having in it one or more narrow, vertical, rectangular slits, or apertures, and so fixed as to have the middle of its aperture, or system of apertures, exactly coincident with the axis of the instrument. Attached to the great circle of the theodolite, horizontally, was a telescope, having its object-glass three inches and a half from the centre, and its axis directed exactly to it, and precisely parallel to the plane of the limb, and provided with a delicate micrometer, whose parallel threads were exactly vertical.
Light

The instrument being insulated on a support of stone, a beam of solar light was directed by a heliostat, through a very narrow slit, also exactly vertical, having a breadth of one hundredth of an inch, and distant 453 inches from the centre of the theodolite, so as to fall on the screen, and, being transmitted through its apertures, to be received into the telescope. It is manifest that the eye-glass of the telescope will here view the fringes, &c. as they are formed in its focus. The magnifying power of the telescope used by Fraunhofer varied from 30 to 50 times.

M. Fraunhofer first examined the effect produced by the diffraction of the light through a single slit, the breadth of which he first determined with the greatest precision by means of a micrometer-microscope, with which he assures us that he found it practicable to appreciate so minute a quantity as 1-50,000th of an inch. The slit being then placed on the apparatus, and accurately adjusted before the object-glass of the telescope, which was directed exactly to the aperture in the heliostat, the image of the latter was formed in its focus, accompanied by lateral fringes, which by the effect of the magnifying power were diluted into broad and brilliant prismatic spectra. The distances of the red ends of these spectra from the middle point, or white central image, were then measured accurately by means of the micrometer. The result of a great number of experiments with aperture of all breadths from one-tenth to one-thousandth of an inch, agreed to astonishing precision with each other, and with the following laws, viz. that (under the circumstances of the experiment,)

1. The angles of deviation of the diffracted rays, forming similar points of the systems of fringes produced by different apertures, are inversely as the breadths of the apertures.

2. That the distances of similar rays (the extreme red, for instance,) from the middle in the several spectra, constituting the successive fringes, form in each case an arithmetical progression whose difference is equal to its first term.

3. That calling γ the breadth of the aperture, in fractions of a Paris inch, the angular distances L', L'', L''', &c. in parts of a circular arc to radius unity, of the extreme red rays in each fringe from the middle line, are respectively represented by

\[ L' = \gamma, \quad L'' = 2\gamma, \quad L''' = 3\gamma, \quad \text{etc.} \]

where \( \gamma = 0.0000211 \), and a similar law holds for all the other coloured rays, different values being assigned to \( L \) for each.

This conclusion agrees perfectly with the result of an experiment related by Newton in the IIId Book of his Optics. He ground two knife edges truly straight, and placed them opposite to each other, so as to be in contact at one end, and at the other to be at a small distance, such that the angle included between them was about 1° 54', thus forming a slit whose breadth at their intersection was evanescent, and at 4 inches from that point 4th of an inch, and in the intermediate points, of course, of every intermediate magnitude. Exposing this in a sunbeam emanating from a very small hole at 15 feet distance, he received their shadows on a white screen behind them, and observed that when they were received very near to the knife edges, (as at half an inch,) the fringes exterior to the shadow of each edge ran parallel to. The result without sensible variation, till they met and joined without crossing, at angles equal to that contained between the knife edges. But when the shadows were received at a great distance from the knives, the fringes had the form of hyperbolas, having for one asymptote the shadow of the knife to which they respectively belonged, and for the other a line perpendicular to that bisecting the angle of the two shadows, each fringe becoming broader and more distinct from the shadow which it bordered, as it approached the angle. These hyperbolas crossed without interfering, as represented in fig. 151. Their points of crossing, Newton found, however, not to be at a constant distance from the angle included between the projections of the knife edges, but to vary in position with the distance from the knives, at which the shadow is received on the screen; and hence, he says, "I gather that the light which makes the fringes upon the paper, is not the same light at all distances of the paper from the knives; but when the paper is held very near the knives, the fringes are made by light which passes by their edges at a less distance, and is more bent than when the paper is held at a greater distance from the knives." Newton, however, left these curious researches, which could hardly have failed to have led in his hands to a complete knowledge of the principles of diffraction—unfinished; being, as he says, interrupted in and unwilling to the charging and opposition his optical discoveries produced to him. An unmeet reward, it must be allowed, for so noble a work, but one of which, unhappily, the history of Science affords but too many parallels.

The above were the results obtained by M. Fraunhofer when the two edges of the aperture were both in a plane perpendicular to the incident rays; but when the same effective breadth was procured, by inclining a larger aperture obliquely, so as to reduce its actual breadth in the ratio of the cosine of its incidence to radius, or by limiting the incident ray by two opaque edges at different distances from the object-glass of the telescope, the phenomena were very different. To accomplish this, two metallic plates were fixed upright on the horizontal plane of the theodolite, having their edges exactly vertical, and precisely at opposite extremities of a diameter. Then, by turning the plate round on its axis, the passage allowed to the light between them could be increased or diminished at pleasure. The phenomena, then, were as follows. When the opening allowed to the light was considerable, as 0.02 or 0.04 inch (Paris,) the fringes were exactly similar to those observed when the edges were equidistant from the object-glass; but as the opening diminished, they ceased to be symmetrical on both sides of the middle line, those on the side of that edge of the aperture nearest to the telescope becoming broader than those on the other, which, on their part, undergo no sensible alteration. As the aperture contracts, this inequality increases, till at length the dilated fringes begin to disappear in succession, the outermost first, which they do by suddenly acquiring an extraordinary magnitude, so as to fill the whole field of the telescope, and thus, as it were, losing themselves. While these are thus vanishing, those on the other side remain quite unaltered till the last is gone, when they all disappear at once, which happens at the moment that the opening is reduced to nothing by the two edges covering each other.
When the aperture placed before the object-glass, instead of being a straight line, was a small, circular hole, and the aperture of the heliostat, in like manner, a minute circle, the phenomena of the rings were observed, and their diameters could be accurately measured by the micrometer. The results of these measurements led M. Fraunhofer to the following laws: 1st, that for apertures of different diameters, the diameters of the rings are inversely as those of the apertures forming them; 2dly, that the distances from the centre of the maxima of extreme red rays (or of rays of any given refrangibility) in the several rings of one and the same system, form an arithmetical progression, whose difference is somewhat less than its first term. Thus, calling $\gamma$ the diameter of the aperture, and putting $L = \frac{0.0000214}{\gamma}$ and $l = \frac{0.0000257}{\gamma}$, he found $L' = l$, $L'' = l + L$, $L''' = l + 2L$, &c., where $L'/L''$, &c., represent the angular semidiameters of the several rings expressed in arcs of a circle to radius unity. The near coincidence of the value of $L$ in this case, with that in the case of a linear aperture, and the small, but decided difference of the values of the first term of the progression in the two cases, are very remarkable.

When the aperture was a very narrow, circular annulus, such as might be traced with a steel point on a gilt disc of glass, of whatever diameter, the image was a circular spot, surrounded in like manner by coloured rings, the diameters of which depended nowise on the diameter, but only on the breadth of the annulus, being in fact (as might be expected) the very same as the intervals between similar opposite fringes, on both sides of the central line in the image produced by a linear aperture of equal breadth.

But the most curious parts of M. Fraunhofer’s investigations are those which relate to the interference of rays transmitted through a great many narrow apertures at once. When these apertures are exactly equal, and placed at exactly equal distances from one another, phenomena of a totally different kind from those originating in a single aperture are seen. In his first experiments of this kind he formed a grating of wire, by stretching a very fine wire across a frame, in the form of a narrow, rectangular parallelogram, whose shorter sides were screws tapped in the same die, and therefore precisely similar; across these screws in the consecutive intervals between their threads the wires were stretched, and of course could not be otherwise than parallel and equidistant. The diameter of the wire was 0.002021 Paris inch, the intervals between them each 0.003862, and the grating consisted of 260 such wires. When this apparatus was placed precisely vertical before the object-glass of his telescope, and illuminated by a narrow line of light 0.01 inch in breadth, also exactly vertical, forming the aperture of the heliostat, the image of this was seen in the telescope, colourless, well defined, and in all respects precisely as it would have been seen without the interposition of any grate or aperture at all, occupying the centre of the field, only less bright. On either side of this was a space perfectly dark, after which succeeded a series of prismatic spectra, which he calls spectra of the second class, not consisting of tints melting into each other, according to the law of the coloured rings, or any similar succession of hues depending on a regular degradation of light, but of perfectly homogenous colours; so much so, as to exhibit the same dark lines crossing them as exist in the purest and best defined prismatic spectrum. In the disposition of things already described, the first, or nearer spectrum is completely insulated, the space between it and the central image, as well as between it and the second spectrum, being quite dark. The violet ends of the spectra are inwards, and the red outwards; but the violet end of the third spectrum is superposed on the red end of the second, so as in place of a dark interval to produce a purple space; and as we proceed farther from the middle, the spectra become more and more confounded, but not less than thirteen may easily be counted on each side by the aid of a prism refracting them transversely, so as to separate their overlapping portions.

The measurement of the distances of similar points in the several spectra are rendered susceptible of the utmost precision by means of the dark lines which cross them. A very remarkable peculiarity of these spectra must, however, be here noticed, viz. that although the dark lines hold exactly the same places in the order of colours, or, in other words, correspond to precisely the same degrees of refrangibility, as in the prismatic spectra formed by refraction, yet the ratio of the intervals between them, or the breadths of the several coloured spaces, differ entirely in the two cases. Thus, in the diffracted spectra, the interval between the lines C and D (fig. 94) is very nearly double of that between G and H, while in a spectrum formed by a flint-glass prism of an angle of 270, the proportion is reversed, and in a water prism of the same angle C : G H : : 2 : 3.

In the diffracted fringes formed by a single aperture, their distances (as we have seen) from the axis depends only on the breadth of the aperture, being inversely as that breadth. In the spectra formed by a great number, their distances from the central image depends neither on the breadths of the apertures nor on the intervals between them, but on the sum of these quantities, that is, on the distances between the middle points of the consecutive apertures, (or, in the case before us, on the distances between the axes of the wires.) By a series of measures performed with the utmost care and precision on wire gratings of a great variety of dimensions, M. Fraunhofer ascertained the following laws and numerical values.

1. For different gratings, if we call $\gamma$ the breadth of each of the interstices through which the light passes, and $\delta$ that of each of the opaque intervals between them, the magnitudes of spectra of the same order, and the distances of similar points in them from the axis, is inversely as the sum $\gamma + \delta$.

2. The distances of similar points, (i.e. of similar colours or similar fixed lines,) in the several consecutive spectra formed by one and the same grating from the axis, constitute an arithmetical progression whose difference is equal to its first term.

3. For the several refrangibilities corresponding to the fixed lines B, C, D, E, &c. the first term of this progression is numerically represented by the respective fractions which follow, being the lengths of the arcs, or their sines to radius unity.
These results were all, however, deduced from gratings so coarse as to allow of our regarding the angles of
diffraction as proportional to their sines; but when extremely fine gratings are employed, the spectra are Case of
formed at great distances from the axis, and the analogy of other similar cases, as well as theory, would lead us
to substitute \( \sin B, \sin C, \sin D, \&c. \) in the place of \( B, C, D, \&c. \) This, M. Fraunhofer found by experiment to be really the case. The construction of gratings proper for these delicate purposes, however, was no easy
matter. Those employed by him were nothing more than a system of parallel and equidistant lines ruled on Methods of
plates of glass covered with gold-leaf, or with the thinnest possible film of grease; by the former of these
constructing methods he found, that the proximity of the lines might be carried to the extent of placing about a thousand in
* the inch, but when he would draw them still closer, the whole of the gold-leaf was scraped off. When the surface
was covered with a film of grease so thin as to be almost imperceptible to the sight, (although the intervals
were in this case transparent,) no change was produced in the optical phenomena, so far as the spectra
were concerned, only the brightness of the central image being increased. By this means he was enabled to obtain
a system of parallel lines at not more than half the distance from each other that could be produced on gold-
leaf: but beyond this degree of proximity, he found it impossible to carry the ruling of equidistant lines on any
film of grease or varnish. But this being still far short of his wishes, he had recourse to actual engraving with
a diamond point on the surface of the glass itself, and by this means was enabled to rule lines so fine as to be
absolutely invisible under the most powerful compound microscope, and so close that 30,000 of them lie in a single Paris inch. When so excessively near, however, no accuracy of machinery will ensure that perfect equi-
distance which is essential to the production of the spectra now under consideration, and he found it impossible to succeed in placing them nearer than 0.0001223, (or about 8200 to the inch,) with such a degree of precision
as to enable him to distinguish the fixed lines in the spectra; and, if it be considered, that a deviation to the
extent of the hundredth part of the just interval frequently occurring, is sufficient to obliterate these, and that to
produce the spectra in sufficient brightness to affect the eye, some hundreds or even thousands must be ruled,
we shall be enabled to form some conception of the difficulties to be encountered in researches of this kind.

For a detail of some of these, and of the methods employed by him to count their number and measure their dis-
tances, we must refer to his original Memoir, (read to the Royal Bavarian Academy of Sciences, June 14, 1823.)

In the course of these researches, M. Fraunhofer met with a very singular and instructive peculiarity in one
of the engraved glass-gratings used by him; which, although it produced spectra equidistant on either side of
the axis, yet gave always those on one side a much greater degree of brightness than those on the other.

Attributing this to the form of the furrows being sharper terminated on one side than on the other, owing either
to the figure of the diamond point or the manner of its application, he endeavoured to produce a similar struc-
ture of the striae in a film of grease spread on glass, by purposely applying the engraving tool obliquely, and the
attempt proved successful.

When the incident rays from the opening in the heliostat fell obliquely on the grating, it might be supposed
that the phenomena would be the same as those exhibited by a closer grating, having intervals less in proportion
to the cosine of the angle of incidence to radius. But the analogy of the unsymmetrical fringes produced by a
single aperture, whose sides lie in a plane oblique to the incident ray, may lead us to expect a different result,
and experiment confirms the surmise; thus, M. Fraunhofer found, that on inclining a grating, whose intervals
\( (\gamma + \delta) \) were each equal to 0.0001223 inch, so as to make the angle of incidence 55° with the perpendicular,
the distance of the first fixed line \( D \) from the axis on the one side of the axis was 15°6', and on the other no less
than 30°33', or more than double.

The facts deduced by M. Fraunhofer from the above detailed researches are certainly extremely curious. The
most interesting and remarkable point about them is, the perfect homogeneity of colour in the spectra, indicating
a saltus, or breach of continuity, in the law of intensity of each particular coloured ray in the diffracted beam.

For it is obvious, that taking any one refrangibility (that corresponding to the fixed line \( C, \) for example,) the
expression of its intensity in functions of its distance from the axis must be (analytically speaking) of such a
nature as to vanish completely for every value of that distance, excepting for a certain series in arithmetical pro-
gression, or, as it is called, a discontinuous function; so that the curve representing such value, having the distance from the axis for its abcissa, must be a series of points arranged above the axis at equal intervals; or, at
least, a curve of the figure represented in fig. 151, in which certain extremely narrow portions, equidistantly
arranged, start up to considerable distances from the axis, while all the intermediate portions lie so close to that
line as to be confounded with it. The manner in which such a function can be supposed to originate from the
summation of a series of the values of \( \int \frac{d \nu \cdot \sin \frac{\pi \nu}{2}}{\nu^2} \) and \( \int \frac{d \nu \cdot \cos \frac{\pi \nu}{2}}{\nu^2}, \) (Art. 718.) taken successively be-
tween limits corresponding to the boundaries of the several interstices, involves too many complicated consid-
nerations to enter into in this place. M. Fraunhofer, meanwhile, states the following general expression, as the
result of his own investigations founded on the principle of interferences. Let \( n \) indicate the order of any

\[ B = \frac{0.00002541}{\gamma + \delta}; \quad E = \frac{0.00001945}{\gamma + \delta}; \quad H = \frac{0.00001464}{\gamma + \delta}. \]

\[ C = \frac{0.00003422}{\gamma + \delta}; \quad F = \frac{0.00001794}{\gamma + \delta}; \quad &c. \]

\[ D = \frac{0.00002175}{\gamma + \delta}; \quad G = \frac{0.00001587}{\gamma + \delta}; \quad &c. \]
spectra, reckoned from the axis; \( e \) the distance from the middle of one interstice to that of the adjacent one
\( = \gamma + \delta \); \( \lambda \) the length of an undulation of an homogeneous ray; \( \sigma \) the angle of incidence of the ray from the luminous point on the grating; and \( y \) the length of a perpendicular let fall from the micrometer thread of the telescope, (or from the point in the focus of its object-glass, where that particular homogeneous ray in that spectrum is found,) on the plane of the grating. Then, if the angular elongation of that ray from the axis be called \( \theta^{(e)} \), we shall have, in general,

\[
\cotan \theta^{(e)} = \sqrt{\left\{ \frac{e^2 - (e \cdot \sin \sigma + n \lambda)^2}{y^2 + e^2 - (e \cdot \sin \sigma + n \lambda)^2} \right\}}.
\]

In this equation, \( n \) is to be regarded as \( + \) for the spectra which lie on the side of the axis on which the incident ray makes an obtuse angle with the plane of the grating, and negative for the spectra on the other side. This formula he states to be rigorous, and independent of any approximation. When \( y \) is very great (as it, in fact, always is,) compared with \( e \) and \( \lambda \), this reduces itself simply to

\[
\cotan \theta^{(e)} = \frac{e \cdot \sin \sigma + n \lambda}{e \cdot \sin \sigma + n \lambda}, \text{ or } \sin \theta^{(e)} = \frac{e \cdot \sin \sigma + n \lambda}{e}.
\]

756. Lengths of undulations of the rays
B, C, D, &c., assigned by Fraunhofer.

This formula, applied to M. Fraunhofer's measures of the distances of the same fixed lines in successive spectra on either side of the axis, in the case of inclined gratings, represents them with perfect exactness. When the gratings are perpendicular to the ray \( \sigma = 0 \), and the equation becomes \( \sin \theta^{(e)} = n \lambda \), which is the law before noticed for symmetrical spectra. And hence, too, it appears that the values of \( \lambda \), or the lengths of the undulations for the several rays designated by C, D, E, &c., are no other than the numerators of the fractions in Art. 751, expressed in parts of a Paris inch, which thus become data of the utmost value in the theory of light, from the great care and precision with which they have been fixed, and for the possibility of identifying them at all times.

If the unruled surface of the glass grating be covered with black varnish, and the light reflected from the ruled surface be received in the telescope, the very same phenomena are seen as if the light had been transmitted through the glass, and the same analytical expression, according to M. Fraunhofer, applies to both cases.

A curious consequence of this expression is, that if \( e \), the distance between the lines, be less than \( \lambda \), and the light fall perpendicularly on the grating, so that \( \sin \sigma = 0 \), we shall have \( \sin \theta^{(e)} > 1 \), and therefore \( \theta^{(e)} \) imaginary. It appears, therefore, that lines drawn on a surface distant from each other by a less quantity than one undulation of a ray of light, produce no coloured spectra. Hence, such scratches, or inequalities, on polished surfaces, have no effect in disturbing the regularity of reflection or refraction, and produce no dimness or mistiness in the image; if less distant from each other than this limit. M. Fraunhofer seems inclined to conclude further, that an object of less linear magnitude than \( \lambda \) can in consequence never be discerned by microscopes, as consisting of parts: a conclusion which would put a natural limit to the magnifying power of microscopes, but which we cannot regard as following from the premises.

757. Diffracted spectra produced by reflection.

When the intervals of the parallel interstices are unequal, and disposed with no regularity, the light of the diffracted spectra of different combinations is confounded together, and a white misty streak at right angles to the direction of the lines arises; but when they are regularly unequal, so that the same intervals recur in regular periods, if we call \( E (= e' + e'' + e''' + \&c.) \), the period of recurrence of whose similar interstices is \( E = e' + e'' + e''' + \&c. \). Thus, M. Fraunhofer was never able through a simple grating to see the fixed lines C and F in the spectrum of the 12th order, reckoning from the axis, while in a composite grating, consisting of three systems of lines continually repeated, whose intervals \( e', e'', e''' \) were to each other as 25 : 33 : 42, these fixed lines as well as the lines D and E, were distinctly seen in the 12th spectrum, owing to the almost total disappearance of the 10th and 11th. Nay, even the fixed line E in the 24th spectrum could be seen, and its distance from the axis measured with this grating.

Such are the extreme cases of the phenomena as produced by a single aperture, and by an infinite, or, at least, very great number; but the intermediate steps and gradations by which one set of phenomena pass into the other, remain to be traced. When a single interstice is left open in a grating, the spectra are formed as described in Art. 741. These, M. Fraunhofer calls spectra of the first class, and their colours are not homogeneous, but graduate into one another.

When two contiguous interstices are left open, the spectra of the first class appear as before; but between the axis and the first spectrum on either side appear other spectra, which M. Fraunhofer terms imperfect spectra of the second class, their colours being similar to those of the first class, and no fixed lines being visible in them.
L I G H T.

When three adjacent interstices are left open, a third set of spectra, or *spectra of the third class*, are formed between the axis and the nearest of the imperfect spectra of the second class. Besides these, no new *classes of spectra* arise by a further increase of the number of interstices; but these undergo a series of modifications as the interstices grow more numerous. These are chief in:

- The spectra of the third class grow narrower, and approach the axis, till at last they run together and form by their union the colourless, well-defined image of the opening of the heliostat in the axis of the whole phenomenon. By a series of exact measurements, M. Fraunhofer found their breadths to be inversely as the number of interstices by which they are produced in the same grating, and inversely as the intervals of the interstices for different ones; and in general, that \( \gamma + \delta = \varepsilon \) representing this interval, \( m \) the number of interstices used, and \( n \) the order of the spectrum, \( \theta^{(n)} \) the distance of extremity of the red rays in that spectrum is given by the equation:

\[
\theta^{(n)} = m \times \frac{0.000209}{\varepsilon}.
\]

As the spectra of the third class contract into the axis, they leave a dark space between it and the first spectrum of the second class. This and the other spectra of that class meanwhile grow continually more vivid and homogeneous in respect of colour; till at length, when the number of interfering rays is very much increased, the fixed lines begin to appear in them, and they acquire the character of perfect spectra of the second class.

M. Fraunhofer next examined the phenomena produced by immersing in media of different refractive powers the gratings used, when he found all the phenomena precisely similar; but the distances at which the several spectra were formed from the axis, to be less than when in air, in the inverse ratio of the refractive indices.

A very beautiful and splendid class of optical phenomena has been investigated and described by M. Fraunhofer, which arise by substituting for the gratings used in the above experiments very small apertures of regular figures, such as circles and squares, either singly or arranged in regular forms, in great numbers; as, for instance, when two equal wire gratings are crossed at right angles. Fig. 151 is a representation of the phenomenon produced when the light is received on the object-glass of the telescope through two circular holes of the diameter 0.02227 inch, placed at a distance of 0.03531 inch centre from centre. Each compartment is a separate spectrum. In the bands \( a_a, b_b \) we see here plainly the origin and minute structure of the vertical and crossed fringes described in Art. 735. The appearances vary as the number of apertures is increased, the spectra growing purer and more vivid. That which arises when two equal wire gratings are crossed, is figured in Fig. 151. The phenomena are the same whether we consider the figures, such as circles and squares, either singly or arranged in regular forms, in great numbers; as, for instance, when two equal wire gratings are crossed at right angles. Fig. 151 is a representation of the phenomenon produced when the light is received on the object-glass of the telescope through two circular holes of the diameter 0.02227 inch, placed at a distance of 0.03531 inch centre from centre. Each compartment is a separate spectrum. In the bands \( a_a, b_b \) we see here plainly the origin and minute structure of the vertical and crossed fringes described in Art. 735. The appearances vary as the number of apertures is increased, the spectra growing purer and more vivid. That which arises when two equal wire gratings are crossed, is figured in Fig. 151.

When we look at a bright star through a very good telescope with a low magnifying power, its appearance is that of a condensed, brilliant mass of light, of which it is impossible to discern the shape for the brightness; and which, let the goodness of the telescope be what it will, is seldom free from some small ragged appendages or rays. But when we apply a magnifying power from 200 to 300 or 400, the star is then seen (in favourable circumstances of tranquil atmosphere, uniform temperature, &c.) as a perfectly round, well-defined planetary disc, surrounded by two, three, or more alternately dark and bright rings, which, if examined attentively, are seen to be slightly coloured at their borders. They succeed each other nearly at equal intervals round the central disc, and are usually much better seen and more regularly and perfectly formed in refracting than in reflecting telescopes. The central disc, too, is much larger in the former than in the latter description of telescope.

These discs were first noticed by Sir William Herschel, who first applied sufficiently high magnifying powers to telescopes to render them visible. They are not the real bodies of the stars, which are infinitely too remote. S*pluruous, or unreal images, resulting from optical causes, which are still to a certain degree obscurc. Indeed, to any one who has entered into the subject, we have said of the law of interferences, and from the explanation given in Art. 590 and 591 of the formation of foci on the undulatory system, that (supposing the mirror or object-glass rigorously aplanatic) the focal point in the axis will be agitated with the united undulations, in complete accordance, from every part of the surface, and must, of course, appear intensely luminous; but that as we recede from the focus in any direction in a plane at right angles to the axis, this accordance will no longer take place, but the rays from one side of the object-glass will begin to interfere with and destroy those from the other, so that at a certain distance the opposition will be total, and a dark ring will arise, which, for the same reason, will be succeeded by a bright one, and so on. Thus the origin both of the central disc and the rings is obvious, though to calculate their magnitude from the data may be difficult. But this gives no account of one of the most remarkable peculiarities in this phenomenon, viz. that the apparent size of the disc is different for different stars, being uniformly larger the brighter the star. This cannot be a mere illusion of judgment; because when two unequally bright stars are seen at once, as in the case of a close double star, so as to be directly compared, the inequality of their spurious diameters is striking; nor can it be owing to any real difference in the stars, as the intervention of a cloud, which reduces their brightness, reduces also their apparent discs till they become incognizable. Nor can it be attributed to irradiation, or propagation of the impression from the point on the retina to a distance, as in that case the light of the central disc would encroach on the rings, and obliterate them; unless, indeed, we suppose the vibrations of the retina to be performed according to the same laws as those of the ether, and to be capable of interfering with them; in which case, the disc and rings seen on the retina will be a resultant system, originating from the interference of both species of undulations.

Not to enter further, however, on this very delicate question, we shall content ourselves with stating some of the phenomena we have observed, as produced by diaphragms, or apertures of various shapes variously applied to mirrors and object-glasses, and which form no inapt supplement to the curious observations of Fraunhofer on the effect of very minute apertures, of which they are in some sort the converse.
When the whole aperture of a telescope is limited by a circular diaphragm, whether applied near to, or at a distance from the mirror or object-glass, the disc and rings enlarge in the inverse proportion of the diameter of the aperture. When the aperture was much reduced (as to one inch, for a telescope of 7 feet focal length) the central disc was enlarged to a planetary appearance; being well defined, and surrounded by one ring only, strong enough to be clearly perceived, and faintly tinged with colour in the following order, reckoning from the centre of the disc. White, very faint red, black, very faint blue, white, extremely faint red, black. When the aperture was reduced still farther (as to half an inch) the rings were too faint to be seen, and the disc was enlarged to a great size, the graduation of light from its centre to the circumference being now very visible, giving it a hazy and cometic appearance, as in fig. 152.

When annular apertures were used the phenomena were extremely striking, and of great regularity. The exterior diameter of the annulus being three inches, and the interior 1.5, the appearance of Capella was as in fig. 153, and of the double star Castor, as in 154. As the breadth of the annulus is diminished, the size of the disc and breadth of the rings diminish also, (contrary to what took place in Fraunhofer's experiments with extremely narrow annuli, and obviously referring the present phenomena to different principles,) at the same time the number of visible rings increases. Fig. 155, 156, and 157 exhibit the appearance of Capella with annular apertures of 5.5 inch—5 inch (i.e. whose exterior diameter = 5.5 and interior = 5) of 0.7—0.5, of 0.2—0.0. In the last case the disc was reduced to a hardly perceptible round point, and the rings were so close and numerous as scarcely to admit being counted, giving, on an instanteous view, the impression of a mere circular blot of light. When the breadth of the annulus was reduced to half this quantity, the intervals between the rings could no longer be discerned. The dimensions of the rings and disc, generally, seem to be proportional to $r'^{-r}$.

Besides the rings immediately close to the central disc, however, others of much greater diameter and fainter light, like halos, are seen with annular apertures, which belong (in Fraunhofer's language) to spectra of a different class. With a single annulus they are too faint to be distinctly examined, but with an aperture composed of two annuli, as in fig. 158, they are very distinct and striking, presenting the phenomenon in fig. 159, (in which it is to be understood that light is represented in the engraving by darkness, and darkness by light.)

When the aperture was in the form of an equilateral triangle, the phenomenon was extremely beautiful; it consisted of a perfectly regular, brilliant, six-rayed star, surrounding a well-defined circular disc of great brightness. The rays do not unite to the disc, but are separated from it by a black ring. They are very narrow, and perfectly straight; and appear particularly distinct in consequence of the total destruction of all the diffused light which fills the field when no diaphragm is used; a remarkable effect, and much more than in the mere proportion of the light stopped. Fig. 160 is a representation of this elegant appearance. The same arises when, in place of an equilateral triangle, the aperture is the difference of two concentric, equilateral triangles similarly situated.

As a triangle has but three sides and three angles, it seems singular that a six-rayed star should be produced. When out of focus, however, all the rays are precisely alike; but if thrown out of focus, their difference of origin becomes apparent. Fig. 161 represents the phenomenon then seen, in which the alternate branches are seen to consist of a series of fringes parallel to their length, and the others of small arcs of similar fringes immediately adjacent to the vertices of the hyperbolas to which they belong, and which consequently cross the rays in a direction perpendicular to their length. As the telescope is brought better in focus, the hyperbolas approach their asymptotes, and are confounded together in undistinguishable proximity; and thus three rays arise composed of continuous lines of light, and three intermediate ones composed of an infinite number of discontinuous points placed infinitely near each other. To represent analytically the intensity of the light in one of these discontinuous rays would call for the use of functions of a very singular nature and delicate management.

The phenomenon just described affords in certain cases a very perfect position-micrometer for astronomical uses. If the diaphragm be turned round, the rays turn with it; and if a brilliant star (as a Aquilae) have near it a very small one, the diaphragm may be so placed as to make one of the rays pass through the small star, which thus remains like a bead threaded on a string, and may be examined at leisure. If then the position of the diaphragm be read off on a graduated properly contrived, the relative situations of the two stars become known. We have satisfied ourselves by trial of the practicability of this; and by proper contrivances the principle may be made available in cases which at first sight appear to present considerable difficulties.

When three circular apertures, having their centres at the angles of an equilateral triangle, were used, the image consisted of a bright central disc. Six fainter ones in contact with it, and a system of very faint halo-like rings surrounding the whole as in fig. 162. When, however, three equal and similar annular apertures were thus disposed, the appearance when in focus was as in fig. 153, being exactly the same back. If two of them were closed. But when thrown a little out of focus, the difference was perceived. Fig. 163 represents the appearance in this case, each of the apertures then produces its own central disc and system of rings, whose intersections give rise to the system of intersectional fringes there depicted. As the telescope is brought better in focus these disappear, and the phenomenon is as in fig. 164; the centres gradually approaching, and the rings blending till the point of complete coincidence is attained.

An aperture in the form of the difference between two concentric squares produced not an eight, but a four-rayed star. The rays, however, were not, as in the case of the triangular aperture, uninterrupted fine lines, gradually tapering away from the centre to their extremities, but composed of distinct alternating obscure and...
Light bright portions, as represented in fig. 165. The portions nearest the central disc (which is circular) were composed of bands transverse to the direction of the rays, and tinged with prismatic colour. Similar bands, no doubt, existed in the more distant portions, which extended to a great length.

An aperture consisting of fifty squares, each of about half an inch in the side, regularly disposed at intervals so as to leave spaces between them in both directions equal in breadth to the side of each, produced an image totally different from that described by Fraunhofer as resulting from the crossing of two equal very close gratings, though the distribution and shape of the apertures were the same in both cases. It was as represented in fig. 166, consisting of a white, round, central disc, surrounded by eight vivid spectra, disposed in the circumference of a square, beyond which were arranged in the shape of a cross, triple lines of very faint spectra extending to a great distance.

When the aperture consisted of numerous equilateral triangles regularly disposed, as in fig. 167, the image presented the very beautiful phenomenon represented in fig. 168, consisting of a series of circular discs arranged in six diverging rays from the central one, and each surrounded with a ring. The central disc was colourless and bright; the rest more and more strongly coloured and elongated into spectra, according to their degree of remoteness from the centre. These are only a few of the curious and beautiful phenomena depending on the figures of the apertures of telescopes, which afford a wide field of further inquiry, and one at least as interesting to the artist as to the philosopher.
§ I. Of Double Refraction.

When a ray of light is incident on the surface of a transparent medium, a portion of it is reflected, at an angle equal to that of incidence, another small portion (so small, however, that we shall neglect its consideration) is dispersed in all directions, serving to render the surface visible, and the rest enters the medium and is refracted. The law of refraction, or the rule which regulates the path of this portion within the medium, has been explained in the preceding parts; and no exceptions to it, as a general law, have hitherto been noticed. It is, however, very far from general; and, in fact, obtains only where the refracting medium belongs to one or other of the following classes, viz.

1. Gases and vapours.
2. Fluids.
3. Bodies solidified from the fluid state too suddenly to allow of the regular crystalline arrangement of their particles, such as glass, jellies, &c., gums, resins, &c., being chiefly such as in the act of cooling pass through the viscous state.
4. Crystallized bodies, having the cube, the regular octahedron, or the rhomboidal dodecahedron for their primitive form, or which belong to the tessular system of Mohs. A very few exceptions (probably only apparent ones, arising from our imperfect knowledge of crystallography) exist to the generality of this class.

The solid bodies belonging to these classes, moreover, cease to belong to them when forcibly compressed or dilated, either by mechanical violence, or by the unequal action of heat or cold, which brings their particles into a state of strain, such as in extreme cases to produce their disruption, as is familiarly seen in the cracking of a piece of glass by heat too suddenly and partially applied. The class of fluids too admits some exceptions, at least when very minutely considered; but the deviation from the ordinary law of refraction in these cases is of so microscopic a kind, that we shall at present neglect to regard it.

All other bodies, comprehending all crystallized media, such as salts, gems, and crystallized minerals, not belonging to the system above mentioned; all animal and vegetable bodies in which there is any disposition to a regular arrangement of molecules, such as horn, mother of pearl, quill, &c.; and, in general, all solids when in a state of unequal compression or dilatation, act on the intromitted light according to very different laws, dividing the refracted portion into two distinct pencils, each of which pursues a rectilinear course so long as it continues within the medium, according to its own peculiar laws, but without further subdivision. This phenomenon is termed double refraction. It is best and most familiarly seen in the mineral termed Iceland spar, which is, in fact, carbonate of lime in a regular crystalline form. This is generally obtained in oblique parallelepips, easily reduced by cleavage to regular, obtuse rhomboids, and is not uncommonly met with in a state of limpid transparency, on which account, as well as by reason of its remarkable optical properties, it easily attracted attention. Bartholinus, in 1669, appears to have been the first to give any account of its double refraction, which was afterwards more minutely examined by Huygens, the first proposer of the undulatory theory of light, whose researches on this phenomenon form an epoch in the history of Physical Optics little if at all less important than the great discovery of the different refrangibility of the coloured rays by Newton. To Huygens we owe the discovery of the law of double refraction in this species of medium. Newton, misled by some inaccurate measurements, (a thing most unusual with him,) proposed a different one; but the conclusions of Huygens, long and unaccountably lost sight of, were at length established by unequivocal experiments by Dr. Wollaston, since which time a new impulse has been given to this department of Optics; and the successive labours of Laplace, Malus, Brewster, Biot, Arago, and Fresnel present a picture of emulous and successful research, than which nothing prouder has adorned the annals of physical science since the development of the true system of the universe. To enter, however, into the history of these discoveries, or to assign the share of honour which each illustrious labourer has reaped in this ample field forms no part of our plan. Of the splendid constellation of great names just enumerated, we admire the living and revere the dead far too warmly and too deeply to suffer us to sit in judgment on their respective claims to priority in this or that particular discovery; to balance the mathematical skill of one against the experimental dexterity of another, or the philosophical acumen of a third. So long as “one star differs from another in glory,”—so long as there shall exist varieties, or even incompatibilities of excellence,—so long will the admiration of mankind be found sufficient for all who truly merit it. Waving, then, all reference to the history of the subject, except in the way of incidental remark, or where the necessity of the case renders it unavoidable, we shall present the reader with an
Double Refraction. The Huygenian law having been demonstrated to apply rigorously to the case for which he himself devised it, as well as to a very large class of other bodies, we shall begin with that class, and proceed afterwards to consider more complicated cases.

In all crystallized bodies, then, which possess double refraction, it is found that that portion of a ray of ordinary light incident on any natural or artificially polished surface which enters the body is separated into two axes of equal pencils which pursue rectilinear paths, making with each other an angle not of constant magnitude, but varying according to the position which the incident ray holds with respect to the surface, and to certain fixed lines, or axes within the crystal, and which lines are related in an invariant manner to the planes of cleavage, or other fixed planes or lines in the primitive form of the crystal. Now, it is found that in every crystal there is at least one such fixed line, along which one of these two pencils be transmitted the other is so also, so that in this case the two pencils coincide, the angle between them vanishing. Moreover, no crystal has yet been discovered in which two such lines exist. These lines are called the optic axes. All double refracting crystals, then, at present, may be divided into such as have one, and such as have two, optic axes.

When a ray penetrates the surface of a crystal so as to be transmitted undivided along the optic axis; or when, moving within the crystal along that line, it meets the surface and passes out, whatever be the inclination of the surface, its refraction is always performed according to the ordinary law of the proportional sines. Thus, in this particular case, the crystal acts precisely as an uncrystallized medium, (some rare instances excepted, of which more hereafter.)

But in all other cases the law is essentially different, and (for one portion of the divided pencil, at least) of a very singular and complicated nature. This we shall first proceed to explain in the simpler case of crystals with one optic axis. But, first, we must explain somewhat more distinctly, what we mean by axes and fixed lines within a crystal. Suppose a mass of brickwork, or masonry, of great magnitude, built of bricks, all laid parallel to each other. Its exterior form may be what we please; a cube, a pyramid, or any other figure. We may cut it (when hardened into a compact mass) into any shape, a sphere, a cone, or cylinder, &c.; but the edges of the bricks within it lie still parallel to each other; and their directions, as well as those of the diagonals of their surfaces, or of their solid figures, may all be regarded as so many axes, i.e. lines having (so long as the mass remains at rest) a determinate position, or rather direction in space, no way related to the exterior surfaces, or linear boundaries of the mass, which may cut across the edges of the bricks in any angles we please. Whenever, then, we speak of fixed lines, or axes of, or within, a crystal, we always mean directions in space parallel to each of a system of lines drawn in the several elementary molecules of the crystal, according to given geometrical laws, and related in a given manner to the sides and angles of the molecules themselves. We must conceive the axis, then, of a crystallized mass not as a single line having a given place, but as any line whatever having a given direction in space, i.e. parallel to the axis of each molecule, which is a line having a determinate place and position within it.

In the remainder of this section, when we speak of the axis or axes of a crystallized mass or surface generally, we mean the direction of the optic axis or axes of its molecules, or of a crystal similar and similarly situated to any one of them.

Of the Law of Double Refraction in Crystals with One Optic Axis.

This class of crystals comprises all such as belong to Mhah's rhombohedral system, or which have the acute or obtuse rhombo-, or regular six-sided prism, for their primitive form, as well as all which belong to his pyramidal system, or whose primitive form is either the octahedron with a square base, the right prism with a square base, or the bi-pyramidal dodecahedron. All such crystals Dr. Brewster has shown to have but one axis, which is that to which the primitive form is symmetrical, viz. in the rhombohed, the axis of the figure, or line joining the two angles formed by three equal plane angles; in the hexagonal prism, the geometrical axis classes of the prism; in the octahedron, or square based prism, a line drawn through the centre of the base at right angles to it. The cases in accordance with the rule are so numerous, and the exceptions, once believed to be so, have so often disappeared on the attainment of a more perfect knowledge of the crystalline forms of the excepted minerals, that when any case of disagreement seems to occur, we are justified in attributing it rather to our own incorrect determination of this datum, than to want of generality in the rule itself.

In all crystals of this class, one of the two equal pencils into which the refracted ray is divided follows the ordinary law of Snellius and Descartes, having a constant index of refraction (n), or invariable ratio of the sine of incidence to that of refraction, whatever be the inclination of the surface by which it enters; so that its velocity within the medium, when once entered, is the same in whatever direction it traverses the molecules; and with respect to this ray the crystal comports itself as an uncrystallized medium. This, then, is called the ordinary pencil.

To understand the law obeyed by the other, or extraordinary portion of the divided pencil, let us consider it as fairly immersed in the medium, and pursuing its course among the molecules. Then its velocity will not, Huygens's as in the case of the ordinary ray, be the same in whatever direction it traverses them, but will depend on the angle it makes with the axis; being a minimum when its path within the crystal is parallel to the axis, and a maximum when at right angles to it, or vice versa; and in all intermediate inclinations of an intermediate magnitude according to the following law. Let an ellipsoid of revolution, either oblate or prolate, as the case
may be, be conceived, having its axis of revolution coincident in direction with the axis of the crystal, and its polar to its equatorial radius in the ratio of the minimum and maximum velocities above mentioned, i.e. as the velocity of a ray moving parallel to that of one perpendicular to the axis. Then in all intermediate positions, the radius of this spheroid parallel to the ray will represent its velocity on the same scale that its polar and equatorial radii represent the velocities in their respective directions.

This is the Huygenian law of velocities, in its most simple and general form. It does not at first sight appear what this has to do with the law of extraordinary refraction; but the reader who has considered with the requisite attention what has been said in Art. 539, 540, with prospective reference to this very case, will easily perceive that, the law of velocity of the ray within the medium once established, it becomes a mere matter of pure Geometry to deduce from it the law of extraordinary refraction, whether we adopt the Corpuscular theory, and employ Laplace's principle of least action, as in that Article; or whether, preferring the Undulatory hypothesis, we substitute for this principle the equivalent one of swiftest propagation, as explained in Art. 587, 588. We should observe, however, that the Huygenian law, as just stated, is worded in conformity with the undulatory doctrine, in which the velocity in a denser medium is supposed slower than in a rarer. But when we use the principle of least action, we must invert the use of the word, or, which comes to the same thing, suppose the the velocity in the medium to be inversely proportional to the radius of the ellipsoid. The results being necessarily the same in both cases, this shall use at present the language of the Corpuscular system.

788.

Its connection with the law of extraordinary refraction.

789.

Investigation of the latter from the former law.

790.

Introduction of the principle of least action or swiftest propagation.

Fig. 169.

Expression for the radius of the spheroid of refraction.

791.

Suppose, now, the axis of the x to be parallel to HC the projection of the axis of the crystal, and since we may choose the plane of the x, y, as we please, let it coincide with the refracting surface, so that z = 0. Then dropping the perpendiculars A M, M m, B N, N n, and putting \( \lambda = ZP = \angle P = \angle ABC \), the angle between the axis and perpendiculars.

\[ \omega = \angle AM = \angle ABC = \angle \text{incidence} \]

\[ \omega' = \angle Mm = \angle \text{plane of refraction to ditto} \]

\[ \theta = \angle ZCA = \angle ZAB = \angle \text{incidence} \]

\[ \theta' = \angle ZCB = \angle \text{angle of refraction} \]

We shall have as follows:

\[ AC = S; \quad AM = \gamma; \quad CM = (\alpha - x) \]

\[ Mm = (\beta - y) \]

consequently,

\[ a - x = \gamma \cdot \tan \theta \cdot \cos \omega; \quad \beta - y = \gamma \cdot \tan \theta \cdot \sin \omega; \quad S = \frac{\gamma}{\cos \theta} \]

and, similarly,

\[ a' - x = \gamma' \cdot \tan \theta' \cdot \cos \omega'; \quad \beta' - y = \gamma' \cdot \tan \theta' \cdot \sin \omega'; \quad S' = \frac{\gamma'}{\cos \theta'} \]
Now, differentiating these equations, and considering that \( d(a - x) = d(a' - x) \) and \( d(\beta - y) = d(\beta' - y) \)

we get

\[
\begin{align*}
d (\tan \theta \cdot \cos \omega) &= \frac{\gamma'}{\gamma} \cdot d (\tan \theta' \cdot \cos \omega') ; \\
d (\tan \theta \cdot \sin \omega) &= \frac{\gamma'}{\gamma} \cdot d (\tan \theta' \cdot \sin \omega') ;
\end{align*}
\]

which equations, developed and reduced, afford the following,

\[
\begin{align*}
\frac{d \theta}{d \theta'} &= \frac{\gamma'}{\gamma} \left( \cos \theta \cdot \cos (\omega - \omega') \right) ; \\
\frac{d \theta}{d \omega} &= \frac{\gamma'}{\gamma} \left( \cos \theta \cdot \tan \theta \cdot \sin (\omega - \omega') \right) ; \\
\frac{d \omega}{d \theta} &= \frac{\gamma'}{\gamma} \left( \sin (\omega' - \omega) \right) ; \\
\frac{d \omega}{d \omega'} &= \frac{\gamma'}{\gamma} \left( \tan \theta' \cdot \cos (\omega' - \omega) \right) ;
\end{align*}
\]

which are necessary conditions, in order that the point \( C \) may remain on the surface.

But since \( S, S', V' \) may be regarded as functions of \( \theta' \) and \( \omega' \), which are the polar coordinates we propose to use as independent variables, we shall have

\[
d V' = \frac{d V'}{d \theta'} \cdot d \theta' + \frac{d V'}{d \omega'} \cdot d \omega';
\]

and, moreover,

\[
\frac{d S}{d \theta'} = \frac{\gamma}{\cos \theta} \left( \frac{d \theta}{d \theta'} \cdot d \theta' + \frac{d \theta}{d \omega} \cdot d \omega' \right) ;
\]

so that, substituting their values in the equation (2), we get

\[
0 = \left\{ \frac{\gamma}{\cos \theta} \left( \frac{d \theta}{d \theta'} \cdot d \theta' + \frac{d \theta}{d \omega} \cdot d \omega' \right) - V \cdot \frac{\gamma}{\cos \theta} \cdot \frac{d V'}{d \theta'} \right\} d \theta' + \left\{ \frac{\gamma}{\cos \theta} \left( \frac{d \omega}{d \omega'} \cdot d \omega' + \frac{d \omega}{d \theta} \cdot d \theta' \right) - V \cdot \frac{\gamma}{\cos \theta} \cdot \frac{d V'}{d \omega'} \right\} d \omega';
\]

in which the coefficients of each of the two independent differentials being separately made to vanish, we get

\[
\begin{align*}
\frac{d V'}{d \theta'} &= - V \cdot \frac{\gamma}{\cos \theta} \cdot \frac{d \theta}{d \theta'} \cdot \cos (\omega - \omega') - V \cdot \tan \theta' \\
\frac{d V'}{d \omega'} &= - V \cdot \frac{\gamma}{\cos \theta} \cdot \frac{d \omega}{d \omega'} \cdot \cos (\omega - \omega') \\
\end{align*}
\]

In these, substituting the values of \( \frac{d \theta}{d \omega} \) and \( \frac{d \theta}{d \theta'} \) found in equation (4), we obtain the following

\[
\begin{align*}
\frac{d V'}{d \theta'} &= - V \cdot \frac{\sin \theta \cdot \cos \theta}{\cos \theta'} \cdot \cos (\omega - \omega') - V \cdot \tan \theta' \\
\frac{d V'}{d \omega'} &= - V \cdot \sin \theta \cdot \sin \theta' \cdot \sin (\omega - \omega')
\end{align*}
\]

These are the very same equations with those deduced by Laplace and Malus, by a more abstruse and complicated calculus, from the primary dynamical relations of the problem, and from them it is easy to express, in general, the law of refraction corresponding to any given law of velocities, for we have only to put them under the form

\[
\begin{align*}
V \cdot \sin \theta \cdot \cos \omega \cdot \cos \omega' + V \cdot \sin \theta \cdot \sin \omega \cdot \sin \omega' &= - V' \cdot \sin \theta' - \cos \theta' \cdot \frac{d V'}{d \theta'} \\
V \cdot \sin \theta \cdot \cos \omega \cdot \sin \omega' - V \cdot \sin \theta \cdot \sin \omega \cdot \cos \omega' &= \frac{1}{\sin \theta'} \frac{d V'}{d \omega'}
\end{align*}
\]

and multiplying the first by \( \cos \omega' \), and the second by \( \sin \omega' \), and adding, we get

\[
V \cdot \sin \theta \cdot \cos \omega = \frac{\sin \omega'}{\sin \theta'} \frac{d V'}{d \theta'} - \cos \theta' \cdot \cos \omega' \cdot \frac{d V'}{d \theta'} - \sin \theta' \cdot \cos \omega' \cdot V';
\]

and, again, multiplying the first by \( \sin \omega' \), and the second by \( - \cos \omega' \), and adding, we find

\[
V \cdot \sin \theta \cdot \sin \omega = - \frac{\cos \omega'}{\sin \theta'} \frac{d V'}{d \omega'} - \cos \theta' \cdot \sin \omega' \cdot \frac{d V'}{d \omega'} - \sin \theta' \cdot \sin \omega' \cdot V';
\]
Light. Now, the second members of these equations, (when \( V \) the velocity of the extraordinary ray is any function of \( \phi \) and \( \theta \), the angle it makes with the axis, or of its position within the crystal,) is always explicitly given in terms of \( \theta' \) and \( \varpi' \), so that, calling \( P \) and \( Q \) their values so expressed, we have at once

\[
\tan \varpi = \frac{Q}{P} ; \quad \cos \varpi = \frac{P}{\sqrt{P^2 + Q^2}} ; \quad \sin \theta = \frac{\sqrt{P^2 + Q^2}}{a·P + b·Q} ;
\]

so that \( \varpi \) and \( \theta \) are directly expressed in terms of \( \varpi' \) and \( \theta' \); and, therefore, the direction in which a ray, moving anyhow within the crystal will emerge, is known, and vice versa.

793. It only remains to execute these processes in the case before us. To this end (for simplicity) we shall put \( V = 1 \), and suppose (since \( a \) and \( b \), the semiaxes of the spheroid, are arbitrary) \( b = \frac{1}{\mu} \), or \( \mu = \frac{1}{b} \), and put \( W \) for the radical \( \sqrt{a^2 \cdot \cos \varphi^2 + b^2 \cdot \sin \varphi^2} \), when we shall have

\[
W = \frac{a^2 - b^2}{a · b} \cdot \cos \phi \cdot d (\cos \phi).
\]

Now in the spherical triangle \( Z B p \) we have, the side \( Z p = \lambda \); \( Z B = \theta' \), angle \( p Z B = \varpi' \), and side \( p B = \phi' \), therefore, by spherical trigonometry,

\[
\cos \phi = \cos \lambda \cdot \cos \theta' + \sin \lambda \cdot \sin \theta' \cdot \cos \varpi',
\]

and differentiating separately with respect to \( \theta' \) and \( \varpi' \),

\[
\frac{d \cdot \cos \phi}{d \theta'} = - \cos \lambda \cdot \sin \theta' + \sin \lambda \cdot \cos \theta' \cdot \cos \varpi',
\]

\[
\frac{d \cdot \cos \phi}{d \varpi'} = - \sin \lambda \cdot \sin \theta' \cdot \sin \varpi'.
\]

If, then, we write these values in the partial differences of \( V' \) in the equations (8) and (9,) they will become

\[
\sin \theta \cdot \cos \varpi = - \frac{1}{a · b \cdot W} \left\{ W^2 \cdot \sin \theta' \cdot \cos \varpi' + (a^2 - b^2) \cdot \cos \phi \sin \lambda \left( 1 - \cos \varpi^2 \cdot \sin \theta' \right) - \cos \lambda \cdot \sin \theta' \cdot \cos \varpi' \cdot \cos \theta' \cdot \cos \varpi' \right\},
\]

\[
\sin \theta \cdot \sin \varpi = - \frac{1}{a · b \cdot W} \left\{ W^2 \cdot \sin \theta' \cdot \sin \varpi' - (a^2 - b^2) \cdot \cos \phi \sin \lambda \left( 1 - \cos \varpi^2 \cdot \cos \theta' \cdot \sin \varpi' \right) + \cos \lambda \cdot \sin \theta' \cdot \cos \varpi' \cdot \cos \theta' \cdot \sin \varpi' \right\}.
\]

In these, let \( b' + (a^2 - b^2) \cdot \cos \phi' \) be put for \( W^2 \), and, bearing in mind that the value of \( \cos \phi \) is as given in the equation (10,) we shall see that they will reduce themselves respectively to

\[
\sin \theta \cdot \cos \varpi = - \frac{1}{a · b \cdot W} \left\{ b' \cdot \sin \theta' \cdot \cos \varpi' + (a^2 - b^2) \cdot \sin \lambda \cdot \cos \phi \right\},
\]

that is, by reason of (10),

\[
- \sin \theta \cdot \cos \varpi = \frac{(a^2 - b^2) \cdot \cos \lambda \cdot \sin \lambda \cdot \cos \theta' + (a^2 \cdot \sin \lambda^2 + b^2 \cdot \cos \lambda^2) \cdot \cos \varpi' \cdot \sin \theta'}{a · b \cdot W}
\]

and

\[
- \sin \theta \cdot \sin \varpi = \frac{b' \cdot \sin \theta' \cdot \sin \varpi'}{a · b \cdot W}.
\]

794. These equations, conjointly with the equations expressing the value of \( W \) in terms of \( \cos \phi \), and of \( \cos \phi \) in terms of \( \theta' \) and \( \varpi' \), afford a complete solution of the problem in the case when a ray passes out of a crystal into air, and suffice to determine both the inclination of the refracted ray to the surface, and the inclination of the plane in which it lies to the principal section.

For brevity, let us put

\[
a^2 \cdot \sin \lambda^2 + b^2 \cdot \cos \lambda^2 = A ; \quad a^2 \cdot \cos \lambda^2 + b^2 \cdot \sin \lambda^2 = B ; \quad (a^2 - b^2) \cdot \sin \lambda \cdot \cos \lambda = C ;
\]

and, dividing the second of the equations (11) by the first, we find

\[
\tan \varpi = \frac{b' \cdot \tan \theta' \cdot \sin \varpi'}{A \cdot \tan \theta' \cdot \cos \varpi' + C}
\]

which gives immediately the inclination of the plane of emergence to the principal section, or, as it is sometimes termed, the azimuth of the emergent ray.
Light. Reciprocally, if having given the angle of incidence and azimuth of a ray incident externally on the crystal, we would find the angle of refraction and azimuth of the internally reflected ray, we must find $\theta'$ and $\varphi'$ from the above equations in terms of $\theta$ and $\varphi$. This may be thus accomplished:

Take $x = \tan \theta' \cdot \cos \varphi'$, and $y = \tan \theta' \cdot \sin \varphi'$,

then $x^2 + y^2 = \tan \theta' \cdot \cos \varphi'$, and $\cos \theta' = \frac{1}{1 + x^2 + y^2}$;

and, moreover,

$$\tan \varphi = \frac{b^2}{A} \frac{y}{x + C};$$

now, since $W^2 = b^2 + (\alpha^2 - b^2) \cdot \cos \varphi$,

$$= \cos \theta' \left\{ \frac{b^2}{\cos \varphi} + (\alpha^2 - b^2) \cdot (\cos \lambda + \sin \lambda \cdot \tan \theta' \cdot \cos \varphi)^2 \right\};$$

the second of the equations (11) becomes, by squaring,

$$(\sin \theta \cdot \sin \varphi)^2 \left\{ \frac{b^2}{\cos \varphi} + (\alpha^2 - b^2) \cdot (\cos \lambda + \sin \lambda \cdot \tan \theta' \cdot \cos \varphi) \right\} = \frac{b^2}{a^2} (\tan \theta' \cdot \sin \varphi)^2,$$

that is,

$$a^2 (\sin \theta \cdot \sin \varphi)^2 \left\{ b^2 (1 + x^2 + y^2) + (\alpha^2 - b^2) \cdot (\cos \lambda + \sin \lambda)^2 \right\} = b^2 y^2,$$

that is, developing

$$a^2 (\sin \theta \cdot \sin \varphi)^2 \{A x^2 + 2 C x + B + b^2 y^2\} = b^2 y^2.$$

Now we have

$$A x + C = \frac{b^2 y}{\tan \varphi},$$

and substituting this in the value of $x$, we find

$$x = \tan \theta' \cdot \cos \varphi' = \frac{a^2 b^2}{A} \frac{\sin \theta \cdot \cos \varphi}{\sqrt{A - a^2 \cdot \sin \varphi^2} \left\{ A \cdot \sin \varphi^2 + b^2 \cdot \cos \varphi^2 \right\}} - \frac{C}{A}.$$ (15)

These equations are identical with those demonstrated by Malus in his *Théorie de la Double Réfraction*, with some slight differences of notation only, arising from our having reckoned $\varphi$ and $\varphi'$ from the opposite point of the circle.

The values of $A$, $B$, and $C$ depend only on $\alpha$, $\beta$, and $\lambda$, that is, on the peculiar nature of the crystal, which determines the ratio of the axes of the spheroid of double refraction, and on the inclination of the axis to the surface on which the ray is incident. The former are constant for one and the same crystal, however the surface be placed; the latter is constant for any given surface. Hence it appears, that the general law of extraordinary refraction, when we confine ourselves to the consideration of a surface given in position with respect to the axis, resolves itself into an infinite variety of particular laws, some of which we shall now consider.

Case 1. $\lambda = 0$, the surface perpendicular to the axis; $A = \beta^2$; $B = \alpha^2$; $C = 0$, and the equations (14) and (15) become

$$\tan \theta' \cdot \sin \varphi' = \frac{a^2 b^2}{b} \frac{\sin \theta \cdot \sin \varphi}{\sqrt{1 - a^2 \cdot \sin \varphi^2}};$$
$$\tan \theta' \cdot \cos \varphi' = \frac{a^2}{b} \frac{\sin \theta \cdot \cos \varphi}{\sqrt{1 - a^2 \cdot \sin \varphi^2}};$$

these equations (as well as Equation 13) give $\varphi' = \varphi$, so that in this case the plane of refraction is the same with that of incidence, and the extraordinary ray is not deviated out of the vertical plane. Hence, we get simply

$$\tan \theta' = \frac{a^2}{b} \frac{\sin \theta}{\sqrt{1 - a^2 \cdot \sin \varphi^2}};$$ (16)

which expresses the law of extraordinary refraction in this case. If $\theta = 0$, $\theta' = 0$, or the ray incident perpendicularly passes unrefracted along the axis. If $\theta = 90^\circ$, $\tan \theta' = \frac{a^2}{b \sqrt{1 - a^2}}$. Now if we put $b = \frac{1}{\mu}$ and $\alpha = \frac{1}{\mu'}$, this becomes

$$\tan \theta' = \frac{\mu}{\mu' \sqrt{\mu' - 1}};$$ (17)

which, $\mu$ and $\mu'$ being each greater than unity, is always real, so that the ray can enter the crystal however oblique its incidence.
Case 2. When the axis lies in the surface, or \( \lambda = 90^\circ \); \( A = a^2 \); \( B = b^2 \); \( C = 0 \), and the equations become

\[
\tan \theta' \cdot \sin \varphi' = \frac{a \cdot \sin \theta \cdot \sin \varphi}{\sqrt{1 - \sin \theta^2 \{ a^2 \cdot \sin \varphi^2 + b^2 \cdot \cos \varphi^2 \}}}; 
\]

\[
\tan \theta' \cdot \cos \varphi' = \frac{b^2}{a} \cdot \frac{\sin \theta}{\sqrt{1 - \sin \theta^2 \{ a^2 \cdot \sin \varphi^2 + b^2 \cdot \cos \varphi^2 \}}}; 
\]

\[
\tan \varphi' = \frac{a^2}{b^2} \cdot \tan \varphi = \left( \frac{\mu}{\mu'} \right)^2 \cdot \tan \varphi. 
\]
The square of the velocity of the extraordinary ray is therefore (in the corpuscular doctrine) diminished by a quantity proportional to the square of the sine of the inclination of the ray within the crystal, to the axis. We say diminished, in the algebraical sense of the word, supposing \( a > b \), this agrees with common parlance; but if \( a < b \), Division of crystals into positive and negative, which have by some been termed attractive and repulsive: by others, positive and negative, which seems preferable, as the former phrases involve theoretical considerations. Positive crystals are, then, such as have \( a > b \), or in which the spheroid of double refraction is prolate. In these the coefficient \( \left( \frac{1}{b^2} - \frac{1}{a^2} \right) \)

which we call \( k \) is positive, and the square of the velocity, or \( v^2 + k \cdot \sin^2 \theta \), (where \( v = \frac{1}{b} \) = velocity of the ordinary ray within the medium,) is increased by the action of the medium, and is a minimum in the axis. In the negative class the coefficient \( k \) is negative, \( a > b \), or the spheroid of double refraction is oblate, and the velocity of the extraordinary ray is a maximum along the axis. In positive crystals, therefore, the index of ordinary refraction \( (a) \) is less than \( b \), or in which the spheroid of double refraction is prolate. In these the coefficient \( \left( \frac{1}{b^2} - \frac{1}{a^2} \right) \)

In the undulatory doctrine the velocity is the reciprocal of what it is in the corpuscular doctrine, and is therefore directly as the radius of the spheroid of double refraction. Hence a wave propagated within the crystal from any point will run over in the same time in different directions, distances proportional to the radii of the spheroid parallel to those directions; and therefore at any instant the surface of the whole wave will be itself a spheroid similar to the spheroid of double refraction. This is Huygens's conception of the subject. It requires us to regard the crystal, or the ether within the crystal through which the undulation is propagated, as having different elasticities in different directions. As far as regards the molecules of a solid body there is no apparent impossibility or improbability in such an idea, but the contrary; but if we regard the propagation of the light within the medium to take place by the elasticity of the ether only, we must then suppose its molecules in crystallized bodies to be in a very different physical state from what they are in free space, and either to be in some manner connected with the solid particles, (forming atmospheres, for instance, about them,) or as subjected to laws of mutual action which approximate to those governing the molecules of solid bodies; and partaking, themselves, of a regular crystalline arrangement and mutual dependency.

To pursue the particular applications of the general formulae (13), (14), and (15) farther, would be far beyond our limits. The reader who is curious on this very interesting part of Physical Optics, and who wishes to be delighted and instructed by a combination of consummate mathematical skill with sound experimental research, which may deservedly be cited as a model of the kind, will find every thing which relates to the subject in its best form in the work, already so often cited, of Malus, Théorie de la Double Réfraction, which gained the mathematical prize of the French Institute in 1810. To the theory of the internal reflexion of the extraordinary ray which offers many remarkable particularities, as the reader will find on reference to Malus's further researches, we must especially refer him, as well as to his investigation of the foci of lenses formed of doubly refracting crystals, of which we shall here only extract the results, in the single case of a double convex lens having the axis of double refraction in the direction of the axis of the lens.

Let \( r, r' \) be the radii of the anterior and posterior surfaces of the lens, both supposed convex,

\[ d = \text{distance of the radiant point in the axis.} \]
\[ a, b = \text{the equatorial and polar radii of the spheroid of double refraction, as above.} \]
\[ D = \text{distance of the conjugate focus behind the lens for extraordinary rays.} \]
\[ \Delta = \text{extraordinary focal length for parallel rays.} \]
\[ F = \text{ordinary focal length for parallel rays.} \]

Then shall we have for the general expression of \( D \),

\[ D = \frac{a^2 b d r r'}{d (r + r') (2 b^2 - a^2 - a^2 b) - a^2 b r r'}; \]
\[ F = \frac{- b r r'}{(r + r') (1 - b)}; \]

If the lens be equi-convex, or \( r = r' \),

\[ D = \frac{a^2 b d}{2 (2 b^2 - a^2 - a^2 b) d - a^2 b r}; \]
\[ \Delta = - \frac{a^2 b r}{2 (2 b^2 - a^2 - a^2 b)}; \]
\[ F = - \frac{b r}{2 (1 - b)}; \]
\[ \Delta - F = - 2 F = - \frac{a^2 - b^2}{2 b^2 - a^2 - a^2 b}. \]

In the case of Iceland spar, these last equations become

\[ D = - r \cdot 0.88226; \quad F = - r \cdot 0.7642; \quad D - F = - F \cdot 114,4544; \]

and in the case of rock crystal (quartz)

\[ D = - r \cdot 0.9628; \quad F = - r \cdot 0.8958; \quad D - F = - F \cdot 0.0748. \]

To represent, in general, the course of any extraordinarily refracted ray, Huygens has giving the following construction, (fig. 170.) Let \( H E D \) be the elliptic section of the spheroid of double refraction by the surface, and \( R C \) the incident ray falling on \( C \) its centre, and \( B C K \) the orthographic projection of the ray \( R C \) on the
Propagation into the ambient medium, the usual law of perpendicular propagation is restored. The position of plane, and advances with a uniform velocity in a direction oblique to it. Consequently the velocity is also uniform in a direction perpendicular to it. Moreover, its common section with the surface is always parallel to the ordinary ray. This distinction will require to be very carefully kept in view hereafter, when we come to treat of the extraordinary ray. It appears that when a plane wave is incident on a doubly refracting surface, the transmitted extraordinary wave is also plane, and advances with a uniform velocity in a direction oblique to itself. Hence, it is evident, that it moves in the same way as an ordinarily transmitted wave would do, and at any instant has the same position that such a wave would have, provided the index of refraction in the latter case were properly assumed. The only difference is, that the motions of the vibrating molecules, of which they respectively consist, are executed in different planes. Now, when this wave emerges from the medium, it obeys the same laws as on its entry, only reversed; so that it still continues a plane wave, and its common section with the surface of emergence remains unaltered.

Hence it follows, that if we cut a prism of any doubly refracting crystal with one axis, and transmit through it a ray incident in a plane at right angles to the edge of the prism, the ordinary and extraordinary ray will both emerge in that plane, and their separation will take place in a plane containing the incident and ordinarily refracted ray, and will therefore be, apparently, such as would arise from attributing two ordinary refractive powers to the medium. It is only when the edge of the prism is oblique to the plane of incidence, that the extraordinary ray can deviate from the plane containing the incident and ordinarily refracted rays.

We see, then, that in the theory of extraordinary refraction, it is necessary to consider, as distinct, two things, which, in that of ordinary, are one and the same, viz. the velocity of the luminous waves, and the velocity of the rays of light. This distinction will require to be very carefully kept in view hereafter, when we come to treat of the law of refraction in crystals with two axes of double refraction. For this, however, we are not yet prepared, as the knowledge of this law presupposes an acquaintance with a multitude of facts relative to the polarization of light, of which we have yet said nothing. It will suffice here to mention, that the whole doctrine of double refraction has recently undergone a great revolution; one, indeed, which may be said to have changed the face of Physical Optics, in consequence of the researches of M. Fresnel. It had all along been taken for granted, that in crystals possessed of double refraction, one of the pencils followed the ordinary law of proportional sines. It had, moreover, been ascertained, by experiments hereafter to be related, that the difference of the squares of the velocities between the two pencils is in all cases proportional to the product of the sines of the angles contained between the extraordinary ray (as it was termed) and the two axes, or directions in which the refraction is single. It was hence concluded, that the velocity of the extraordinary pencil was in all cases represented by \( \sqrt{\sin^2 \phi + k^2} \), where \( k \) is a constant depending on the nature of the crystal, and \( \phi \), \( \phi' \) the angles in question. This granted, there would be no difficulty in determining the form of the surface of double curvature, which should be substituted for the Huygenian spheroid; so as to render the same construction with that described in Art. 806, or the general formula in Art. 792, applicable to this case. In fact, if we call \( \phi \) the semi-angle between the two axes, and conceive three coordinates \( x, y, z \), of which \( x \) bisects that angle, the plane of the \( x, y \) containing both axes, it is easy to see, by spherical trigonometry, that we must have...
\[
\cos \phi = \frac{x \cdot \cos a + y \cdot \sin a}{\sqrt{x^2 + y^2 + z^2}}; \quad \cos \phi' = \frac{x \cdot \cos a - y \cdot \sin a}{\sqrt{x^2 + y^2 + z^2}}.
\]

Hence, since \( r \sqrt{x^2 + y^2 + z^2} \) the radius of the surface of the wave, is always equal to

\[
\frac{1}{V}, \quad \frac{1}{\sqrt{x^2 + k^2 \cdot \sin \phi' \cdot \sin \phi}},
\]

a simple substitution would give at once the equation of its surface as referred to the three coordinates \( x, y, z \); namely,

\[
0 = (k^2 - v) (x^2 + y^2 + z^2) + 2 (x^2 + y^2 + z^2) - k^2 \cdot x^2 \cdot \cos a - k^2 \cdot y^2 \cdot \sin a + k^2 \cdot \cos a^2 \cdot y^2 \cdot \sin a^2 - 1,
\]

which it would be easy then to transform into functions of \( r, \omega, \) and \( \theta \), as required for the application of the general analytical formulæ by the usual substitutions

\[
s = r \cdot \sin \theta; \quad y = r \cdot \sin \theta \cdot \sin \omega; \quad z = r \cdot \sin \theta \cdot \cos \omega.
\]

The researches of M. Fresnel, however, as before remarked, have destroyed the basis on which this theory rested, by demonstrating the non-existence of an ordinarily refracted ray in the case of crystals with two axes. The theory which he has substituted in its place, however, and which it is impossible to regard otherwise than as one of the finest generalizations of modern science, we must reserve for a more advanced place in this essay.

We shall now proceed to treat

**Of the Polarization of Light.**

The phenomena which belong to this division of our subject are so singular and various, that to one who has only studied the subject of Physical Optics under the relations presented in the foregoing pages, it is like entering into a new world,—so splendid as to render it one of the most delightful branches of experimental inquiry; and so fertile in the views it lays open of the constitution of natural bodies, and the minuter mechanism of the universe, as to place it in the very first rank of the physico-mathematical sciences, which it maintains, by the rigorous application of geometrical reasoning its nature admits and requires. The intricacy as well as variety of its phenomena, and the unexampled rapidity with which discoveries have succeeded each other in it, have hitherto prevented the possibility of embodying it satisfactorily in a systematic form; but, after the rejection of numberless imperfect generalizations, it seems at length to have acquired that degree of consistency as to enable us—not, indeed, to deduce every phenomenon, by distinct steps, from one general cause—but to present them, at least, in something like a regular succession; to show a mutual dependence between their several classes, which is a main step to a complete generalization; and to dispense with the bewildering detail of an immense multitude of individual facts, which, having served their purpose in the inductive process, must in future be considered as having their interest merged in that of the laws from which they flow.

§ II. **General Ideas of the Distinction between Polarized and Unpolarized Light.**

In all the properties and affectations of light which we have hitherto considered, we have regarded it as presenting the same phenomena of reflexion and transmission, both as respects the direction and intensity of the reflected or transmitted beam, however it may be presented to the reflecting or refracting surface, provided the angle of incidence, and the plane in which it lies, be not varied. And this is true of light in the state in which it is emitted immediately from the sun, or from other self-luminous sources. A ray of such light, incident at a given angle on a given surface, may be conceived to revolve round an axis coincident with its own direction; or, which comes to the same thing, the reflecting or refracting surface may be actually made to revolve round the ray as an axis, preserving the same relative situation to it in all other respects, and no change in the phenomena will be perceived. For instance, if in a long cylindrical tube we fix a plate of glass, or any other medium at any angle of inclination to the axis; and then, directing the tube to the sun, turn the whole apparatus round on its axis, the intensity of the reflected or refracted ray will suffer no variation, and its direction (if deviated) will revolve uniformly round with the apparatus, so that if received on a screen connected invariably with the tube, it will continue to fall on the very same point in all parts of its rotation. Or we may receive the light from a piece of white hot iron at any angle on any medium, and its phenomena will be precisely the same, whether the iron be at rest, or be made to revolve round an axis coincident with the direction of the ray.

But, if instead of employing a ray immediately emitted from a self-luminous source, we subject to the same examination a ray that has undergone some reflexions, refractions, or been in any one of a great variety of Polarized ways subjected to the action of material bodies, we find this perfect uniformity of result no longer to hold good. Rays have acquired fixed relations to not the direction of the reflected or transmitted portion, depends materially on the position with respect to these external space.
Various character which distinguishes polarized from ordinary light. We shall, therefore, describe in order, the principal means by which the polarization of light may be performed, and the assemblage of characters which are invariably found to coexist in a ray when polarized.

The chief modes by which the polarization of light may be effected, are:

1st. By reflection at a proper angle from the surfaces of transparent media.
2d. By transmission through a regularly crystallized medium possessed of the property of double refraction.
3d. By transmission through transparent, uncrystallized plates in sufficient number, and at proper angles.
By transmission through a variety of bodies, such as agate, mother-of-pearl, &c. which have an approach to a laminated structure, and an imperfect state of crystallization.

The characters which are invariably found to coexist in a polarized ray, being the chief of those by which it may be most easily recognised as polarized, are:

1. Incapability of being transmitted by a plate of tourmaline, as above described, when incident perpendicularly on it, in certain positions of the plate; and ready transmission in others, at right angles to the former.

2. Incapability of being reflected by polished transparent media at certain angles of incidence, and in certain positions of the plane of incidence.

3. Incapability of undergoing division into two equal pencils by double refraction, in positions of the doubly refracting bodies, in which a ray of ordinary light would be so divided.

Besides which, there might be enumerated a vast variety of other characters, which, however, it will be better to regard as properties at once of polarized light, and of the various media which affect it. It cannot fail to be remarked, that all these characters are of the negative kind, and consist in denying to polarized light properties which ordinary light possesses, and that they are such as affect the intensity of the ray, not its direction. Thus, the direction which a polarized ray will take under any circumstances of the action of media, is never different from what an unpolarized ray might take, and from what a portion of it at least actually does. For instance, when an unpolarized ray is separated by double refraction into two equal pencils, a polarized ray will be divided into two unequal ones, one of which may even be altogether absent, but their directions are precisely the same as those of the pencils into which the unpolarized ray is divided. Hence we may lay it down as a general principle, that the direction taken by a polarized ray, or by the parts into which it may be divided by any reflexions, refractions, or other modifying causes, may always be determined by the same rules as apply to unpolarized light; but that the relative intensities of these portions differ from those of similar portions of unpolarized light, according to certain laws which it is the business of the optical inquirer to ascertain.

§ III. Of the Polarization of Light by Reflexion.

When a ray of direct solar light is received on a plate of polished glass or other medium, a portion more or less considerable is always reflected. The intensity of this portion depends only on the nature of the medium and on the angle of incidence, being greater as the refractive power of the former is greater, and as the ray falls more obliquely on the surface. But it is, moreover, found, that at a certain angle of incidence, (which is therefore called the polarizing angle,) the reflected ray possesses all the characters above enumerated, and is therefore polarized.

This remarkable fact was discovered by Malus in 1808, when accidentally viewing, through a doubly refracting prism, the light of the setting sun reflected from the glass windows of the Luxembourg Palace in Paris. On turning round the prism, he was surprised to observe a remarkable difference in the intensity of the two images, the most reflected alternately surpassing and falling short of the least in brightness, at each quadrant of the revolution. This phenomenon connecting itself in his mind with similar phenomena produced by rays which had undergone double refraction, and with which, from the researches he was then engaged in, he was familiar, led him to investigate the circumstances of the case with all possible attention, and the result was the creation of a new department of Physical Optics. So true it is, that a thousand indications pass daily before our eyes which might lead to the most important conclusions. The seeds of great discoveries are everywhere present and floating around us, but they fall in vain on the unprepared mind, and germinate only where previous inquiry has elaborated the soil for their reception, and awakened the attention to a perception of their value.

To make this new property acquired by the reflected ray evident by experiment, let any one lay down a large plate of glass on a black cloth, on a table before an open window, and placing himself conveniently so as to look obliquely at it, let him view the reflected light of the sky, (or, which is better, of the clouds if not too dark,) from the whole surface, which will thus appear pretty uniformly bright. Then let him close one eye, and apply before the other a plate of tourmaline, cut as above directed, so as to have its axis in a vertical plane. He will then observe the surface of the glass, instead of being as before equally illuminated, to have on it, as it were, an obscure cloud, or a large blot, the middle of which is totally dark. If this be not seen at first, it will come into view on elevating or depressing the eye. If the inclination of a line drawn from the centre of the dark spot to the eye be measured, it will be found to make an angle of about 33° with the surface of the glass. If now, keeping the eye fixed on the spot, the tourmaline plate (which it is convenient to have set in a small circular frame for such experiments) be turned slowly round in its own plane, the spot will grow less and less obscure, and when the axis of the tourmaline is parallel to the reflecting surface, (or horizontal,) will have disappeared completely, so as to leave the surface equally illuminated, and, on continuing the rotation of the tourmaline, will appear and vanish alternately.

It appears from this experiment, that the ray which has been reflected from the surface of the glass at an inclination of 33°, or an incidence of 57°, has thereby been deprived of its power to penetrate a tourmaline plate whose axis lies in the plane of incidence. It has therefore acquired the same character, or (so far as this goes, at least) undergone the same modification as if, instead of being reflected on glass, it had been transmitted through a tourmaline plate, whose axis was perpendicular to the plane of reflexion.

It has, moreover, acquired all the other enumerated characters of a polarized ray. And, first, it has become...
incapable of reflection at the surface of glass, or other transparent media at certain definite angles, and in

certain positions of the plane of incidence. To show this experimentally, let a piece of polished glass have one

of its surfaces roughened, and blackened with melted pitch or black varnish, so as to destroy its internal

reflexion, and let this be fixed on a stand, so as to be capable of varying with will the inclination of its polished

surface to the horizon, and of turning it round a vertical axis in any azimuth. A very convenient stand of this

kind is figured in fig. 171, consisting of a cylindrical support A sliding in a vertical tube B, attached to a round

base F like a candlestick, and carrying an arm C, which can be set to any angle of inclination to the horizon by

means of a stiffish joint D. To this arm the blackened glass E is fixed, having its plane parallel to the

axis of the joint D. Let this apparatus be set on a table, so that the rays reflected from a perfectly large plate of

glass G, at an angle of about 57° (of incidence) shall be received on the glass E, which ought to be inclined

with its polished surface looking downwards, and making an angle of about 73° with the horizon, see Art. 842.

Then let the observer apply his eye near the glass E, so as to see the glass G reflected in it, and slowly turn

the stand F round in a horizontal plane, keeping always the reflected image of G in view. He will then

perceive, that at a certain point of the rotation of the stand, the illumination of this image, which in other

situations is very bright, will undergo a rapid diminution, and at last wholly disappear, and (if the glass G be

large enough) the same appearance of a cloud or large dark spot will then be visible upon it. If the inclination

of the arm C D be correct, it will be easy to find such a position by turning the stand a little backwards and

forwards, as shall make the centre of this spot totally black; if not, bring it to as great a degree of obscurity as

possible by the horizontal motion, then, holding fast the stand, vary a little one way or another the inclination of

the reflector E, and a very complete obscurity will readily be attained.

Another, and, for some experimental purposes, a better way of exhibiting the same phenomenon, is to take

two metallic or pasteboard tubes, open at both ends, and fitting into each other so as to turn stiffly. Into each of

these, at the end remote from their junction, fix with wax, or in a frame, a plate of glass, blackened at the

back as above described, so as to make an angle of 35° with the axis of the tube, as represented in fig. 172.

Then having placed the tube containing one of the plates (A) so that the light from any luminary, reflected at the

plane shall traverse the axis of the tube, fix it there, and the reflected ray will be again reflected at B, and

on its emergence may be received on a screen or on the axis of the eye. Now make the tube containing the reflector B

revolve within the other, so that that reflector shall revolve round the ray A B as an axis, preserving the same

inclination. Then will the twice reflected ray revolve with equal angular motion, and describe a conical

surface. But in so doing, it will be observed to vary in intensity, and at two points of the revolution of the tube

B will disappear altogether. Now if we attend to the position of the reflectors at this moment, it will be found that

the planes of the first and second reflection make a right angle.

By repeating these experiments with all sorts of reflecting media, and determining by exact measurement the

angles at which the original ray must be incident that polarization shall take place, and those at which a

polarized ray ceases to be reflected, the following laws have been ascertained to hold good, previous to

announcing which a definition will be necessary.

Definition. The plane of polarization of a polarized ray is the plane in which it must have undergone

reflexion, to have acquired its character of polarization; or that plane passing through the course of the ray

perpendicular to which it cannot be reflected at the polarizing angle from a transparent medium; or, again, that

plane in which, if the axis of a tourmaline plate exposed perpendicularly to the ray be situated, no portion of

the ray will be transmitted. Also, a polarized ray is said to be polarized in its plane of polarization, as just

defined.

The plane of polarization of any polarized ray is to be considered as one of the sides of the ray which thus, in all its future progress, carries with it certain relations to surrounding fixed space, which must be regarded, while they continue unchanged, as inherent in the ray itself, and as having no further any relation to the particular mode in which they originated.

The laws of polarization by reflexion are these:

Law 1. All reflecting surfaces are capable of polarizing light if incident at proper angles; only, metallic bodies, or bodies of very high refractive powers, appear to do so but imperfectly, the reflected ray not entirely disappearing in circumstances when a perfectly polarized ray would be completely extinguished. Of this more hereafter.

Law 2. Different media differ in the angles of incidence at which they polarize light; and it is found, that these angles may always be determined from the following simple and elegant relation, discovered by Dr. Brewster after a laborious examination of an infinite variety of substances.

The tangent of the polarizing angle for any medium is the index of reflection belonging to that medium.

Thus, the indices of refraction of water, crown-glass, and diamond, being respectively 1.336, 1.535, and 2.4287, their respective polarizing angles will be 58° 11', 56° 55', and 65° 0'. For diamond, however, or bodies of very high refractive powers, we must understand by the polarizing angle, that angle of incidence at which the reflected ray approaches most nearly to the character of a ray completely polarized.

It follows from this law, that one and the same medium does not polarize all the coloured rays at the same angle, and that therefore the disappearance of the reflected pencil can never be total, except when the incident ray is homogeneous. This will account in some degree for the want of complete polarization of a white ray, reflected at any angle from highly refractive media, which are generally also highly dispersive. Of the reality of the fact, it is easy to satisfy oneself by a very simple experiment, which we have often made. Receive a sunbeam on a plane glass, with the back roughened and blackened, at an incidence (θ) nearly equal to the polarizing angle (α) and let the reflected ray pass into a darkened room, and fall on another similar glass, which may be held in the hand, so as to reflect the ray in a plane at right angles to that of the first reflection, and
also at an angle ($\theta$) nearly equal to the polarizing angle ($a'$) of the second plate. It will be easy to find a position where the reflected ray (which must be received on a white screen) very nearly vanishes; but no adjustment of the angles of incidence $\theta$ and $\theta'$ will produce a total disappearance. When the disappearance is most nearly total, the reflected light is coloured of a neutral purple; the yellow, or most luminous rays, being now totally extinguished. In this position, if $\theta$ remain constant, and $\theta'$ the incidence on the second plate be varied a little on one side or the other of the polarizing angle $a'$, the reflected ray assumes on the one hand a pretty intense blue-green, and on the other a ruddy plum colour or amethyst red. The several changes of tint, arising from variations of incidence on both plates, were observed to be as follows:

1. $\theta < a'$; Reflected ray, Strong green.<br>Intermediate, White.<br>2. $\theta = a'$; Strong blue-green.<br>$\theta' = a'$; Neutral purple.<br>3. $\theta > a'$; Strong plum colour.<br>Intermediate, White.<br>$\theta' > a'$; Strong red, or plum colour.

The rationale of these changes of colour will be more evident when we have announced the following law, which expresses one of the most general and distinguishing characters of polarized light.

**Law 3.** When a polarized ray (no matter how it acquired its polarization) is incident on a reflecting surface of a transparent, or other medium capable of completely polarizing light, in a plane perpendicular to that of the ray's polarization, and at an angle of incidence equal to the polarizing angle of the medium, no portion of the ray will be reflected. If the medium be of such a nature as to be capable only of incompletely polarizing light, a portion will be reflected, but much less intense than if the incident ray were unpolarized.

It is evident that this property may be employed to distinguish polarized from common light, as well as that of extinction by a plate of tourmaline. It is, however, much less convenient though better adapted for delicate inquiries.

The polarizing angle for white light is, in fact, the angle for the most luminous or mean yellow rays; and when the two reflexions, in planes at right angles to each other, are made at this angle, the yellow rays only totally escape reflexion, but a very small portion both of the red and blue end of the spectrum are reflected, and form a feeble purple beam, such as above described. The polarizing angle for red rays being less than for violet, it is evident that when either $\theta$ or $\theta'$ is equal to the polarizing angle for red, it will be less than that of yellow, and still less than that of blue and violet rays; thus, the red disappears most completely from the reflected beam in those cases when $\theta$ or $\theta'$ are less than $a$ or $a'$, leaving an excess of the green and blue rays, and vice versa in the converse cases. Thus, too, if $\theta < a$, and at the same time $\theta' < a'$, the colour produced will be a more intense green than if the incidences deviated opposite ways from the polarizing angles; and it is evident, that a compensation may arise from the effect of such opposite deviations giving an intermediate white ray, exactly as we see to have happened.

Some very remarkable consequences follow from the law announced by Dr. Brewster for finding the polarizing angle, which may be presented in the form of distinct propositions. Thus,

**Prop. 1.** When a ray is incident on a transparent surface, so that the reflected portion shall be completely polarized, the reflected and refracted portions make a right angle. For $\theta$ being the angle of incidence, we have

$$\tan \rho = \rho$$

being the angle of incidence also of refraction, $\sin \rho = \frac{\sin \theta}{\mu}$ and $\tan \theta = \cos \theta$. Therefore $\rho = 90^\circ - \theta$, but $\theta$ being the angle of refraction, $\sin \rho = \cos \theta$, and since $\rho$ is also the angle of incidence on the second surface, we shall have $\tan \rho = \cotan \theta = \frac{1}{\tan \theta} = \frac{1}{\mu} = \text{index of refraction out of the medium}$. Hence, $\rho$ is the angle of polarization for rays internally incident, and therefore that portion of the beam which, having penetrated the first surface, falls on the second, being incident at its polarizing angle, the portion reflected here will also be polarized, and being again incident on the first surface, in the plane of its polarization, that part of it which is transmitted will (as we shall see hereafter) suffer no change in its plane of polarization, so that both it and the first reflected ray will come off polarized in the same plane. Q. E. D.

**Corol. 1.** Hence, to obtain a stronger polarized ray, we may dispense with roughening or blackening the posterior surface, provided we are sure that the surfaces are truly parallel.

If a series of parallel plates be laid one on the other so as to form a pile, the portions reflected from the several surfaces all come off polarized in the same plane, and by this means a very intense polarized ray may be obtained. It can never, however, for a reason we shall presently state, contain more than half the incident light, whatever be the number of plates employed.

**Prop. 2.** When a beam of common light is incident at the polarizing angle on a parallel plate of a transparent medium, not only the portion reflected at the first surface, but also that reflected internally at the second, and the compound reflected ray, consisting of both united, are polarized.

Since $\sin \rho = \cos \theta$, and since $\rho$ is also the angle of incidence on the second surface, we shall have $\tan \rho = \cotan \theta = \frac{1}{\tan \theta} = \frac{1}{\mu} = \text{index of refraction out of the medium}$. Hence, $\rho$ is the angle of polarization for rays internally incident, and therefore that portion of the beam which, having penetrated the first surface, falls on the second, being incident at its polarizing angle, the portion reflected here will also be polarized, and being again incident on the first surface, in the plane of its polarization, that part of it which is transmitted will (as we shall see hereafter) suffer no change in its plane of polarization, so that both it and the first reflected ray will come off polarized in the same plane. Q. E. D.

**Law 3.** When a polarized ray (no matter how it acquired its polarization) is incident on a reflecting surface of a transparent, or other medium capable of completely polarizing light, in a plane perpendicular to that of the ray's polarization, and at an angle of incidence equal to the polarizing angle of the medium, no portion of the ray will be reflected. If the medium be of such a nature as to be capable only of incompletely polarizing light, a portion will be reflected, but much less intense than if the incident ray were unpolarized.

It is evident that this property may be employed to distinguish polarized from common light, as well as that of extinction by a plate of tourmaline. It is, however, much less convenient though better adapted for delicate inquiries.

The polarizing angle for white light is, in fact, the angle for the most luminous or mean yellow rays; and when the two reflexions, in planes at right angles to each other, are made at this angle, the yellow rays only totally escape reflexion, but a very small portion both of the red and blue end of the spectrum are reflected, and form a feeble purple beam, such as above described. The polarizing angle for red rays being less than for violet, it is evident that when either $\theta$ or $\theta'$ is equal to the polarizing angle for red, it will be less than that of yellow, and still less than that of blue and violet rays; thus, the red disappears most completely from the reflected beam in those cases when $\theta$ or $\theta'$ are less than $a$ or $a'$, leaving an excess of the green and blue rays, and vice versa in the converse cases. Thus, too, if $\theta < a$, and at the same time $\theta' < a'$, the colour produced will be a more intense green than if the incidences deviated opposite ways from the polarizing angles; and it is evident, that a compensation may arise from the effect of such opposite deviations giving an intermediate white ray, exactly as we see to have happened.

Some very remarkable consequences follow from the law announced by Dr. Brewster for finding the polarizing angle, which may be presented in the form of distinct propositions. Thus,

**Prop. 1.** When a ray is incident on a transparent surface, so that the reflected portion shall be completely polarized, the reflected and refracted portions make a right angle. For $\theta$ being the angle of incidence, we have

$$\tan \rho = \rho$$

being the angle of incidence also of refraction, $\sin \rho = \frac{\sin \theta}{\mu}$ and $\tan \theta = \cos \theta$. Therefore $\rho = 90^\circ - \theta$, but $\theta$ being the angle of refraction, $\sin \rho = \cos \theta$, and since $\rho$ is also the angle of incidence on the second surface, we shall have $\tan \rho = \cotan \theta = \frac{1}{\tan \theta} = \frac{1}{\mu} = \text{index of refraction out of the medium}$. Hence, $\rho$ is the angle of polarization for rays internally incident, and therefore that portion of the beam which, having penetrated the first surface, falls on the second, being incident at its polarizing angle, the portion reflected here will also be polarized, and being again incident on the first surface, in the plane of its polarization, that part of it which is transmitted will (as we shall see hereafter) suffer no change in its plane of polarization, so that both it and the first reflected ray will come off polarized in the same plane. Q. E. D.

**Corol. 1.** Hence, to obtain a stronger polarized ray, we may dispense with roughening or blackening the posterior surface, provided we are sure that the surfaces are truly parallel.

If a series of parallel plates be laid one on the other so as to form a pile, the portions reflected from the several surfaces all come off polarized in the same plane, and by this means a very intense polarized ray may be obtained. It can never, however, for a reason we shall presently state, contain more than half the incident light, whatever be the number of plates employed.
For a great variety of optical experiments, a pile consisting of ten or a dozen panes of common window-glass set in a frame, is of great use and very convenient. Such a pile laid down before an open window affords a dispersed beam, each ray of which is polarized at the proper angle, and of great intensity and very proper for the exhibition of many of the phenomena hereafter to be described.

Prop. 3. If a ray be completely polarized by reflection at the surface of one medium, and the reflected ray completely transmitted or absorbed at that of a second, Required the inclination of the two surfaces to each other?

Let \( a \) and \( a' \) be the polarizing angles of the respective media; then, since the planes of reflection are at right angles to each other, and \( a, a' \) are the angles of incidence, if we call \( I \) the inclination required, we shall have by Art. 104, \( \cos I = \cos a \cdot \cos a' \). Now, if \( \mu, \mu' \) be the refractive indices of the media, we have \( \tan a = \mu \), \( \tan a' = \mu' \), and therefore

\[
\tan I = \sqrt{\mu^2 + \mu'^2} - \mu' \mu^2.
\]

Thus, in the case of crown-glass, \( \mu = 1.535 \) and \( I = 72^\circ 40' \), as in Art. 825.

By the help of this law, connecting the angle of polarization with the refractive index, we may easily deduce the one from the other. This affords a valuable and ready resource in cases to which other methods can hardly be applied, for ascertaining the refractive powers of media, which are either opaque, or in such small or irregularly shaped masses, that they cannot be used as prisms. For ascertaining the angle of polarization, only one polished surface, however small, is necessary, and we have only to receive a ray reflected from it on a blackened glass, or other similar medium of known refractive index, at the polarizing angle, and in a plane perpendicular to that at which it is reflected by the surface under examination. For this purpose it is convenient to have the glass plate (or, which is better, a polished plate of obsidian or dark coloured quartz) set in a tube diagonally, so as to reflect laterally the ray which traverses the axis of the tube. At the other end, the substance to be examined must be fixed on a revolving axis perpendicular to the axis of the tube, and having its plane adjusted as to be parallel to the former, which must then be turned round till the dispersed light of the clouds, reflected by it, is entirely extinguished by the obsidian plate, and the inclination of the reflecting surface to the axis of the tube in this situation may be measured by a divided circle, connecting with the axis of rotation. By this means we may ascertain the polarizing angles, and therefore the refractive indices of the smallest crystals, or of polished stones, gems, &c., set in such a manner as not to admit of other modes of examination. To insure a fixed zero point on the graduated circle, the following mode (among many others) may be resorted to.

Let a polished metallic reflector or small piece of looking-glass be permanently attached to the revolving axis, so that its plane shall be perpendicular to the axis of the tube, when the index of the divided circle marks 0° 0'. This adjustment being made once for all, let the surface to be examined be attached by wax or otherwise, not to the axis itself, but to a ring turning stiffly on it. Then, bringing the image of the sun, or any very distant object, sufficiently bright or well defined, seen in the reflector, to coincide with any other equally well defined, and also at a great distance, alter the attachment of the substance by pressure on the wax, and by turning round the ring, till a similar coincidence is obtained when the eye is transferred to it. Then we are assured that the two surfaces are parallel, and that therefore the reading off on the circle measures the true angle between the axis of the tube and the perpendicular, or the angle of reflection, or at least differs from it only by a constant quantity, which may be ascertained at leisure, and applied as index error. (This method of bringing a movable surface to a fixed position with respect to the divisions of an instrument, is applicable to a great variety of cases, and is at once convenient and delicate.)

Dr. Brewster has remarked, that glass surfaces frequently exhibit remarkable, and apparently unaccountable, deviations from the general law; but on minute examination he found that this substance is liable to a superficial tarnish, or formation of infinitely thin films of a different refractive power from the mass of glass beneath. As the polarized ray never penetrates the surface, its angle of polarization is determined solely by this film, which is too thin to admit of any direct measure of its refractive index. When this tarnish has gone to a great extent, scales of glass detach themselves, as is seen in very old windows, (especially those of stables,) and even in green glass bottles which have long lain in damp situations, and which acquire a coat actually capable of being mistaken for gilding.

In metallic or adamantine bodies, which polarize light but imperfectly, that angle at which the reflected beam approaches nearer in its character to those described as of polarized light, is to be taken for the angle of polarization, and from it the refractive power may still be found. The results deduced by this means for metallic bodies, agree with those obtained from the quantity of light reflected, in assigning very high refractive powers to them. Thus, for steel the polarizing angle is found to be above 71°, and for mercury 76°, and their indices of refraction are, therefore, respectively 2.83 and 4.16. This latter result, indeed, differs greatly from that of Art. 594, but the observations are so uncertain, and the angle of greatest polarization so indefinitely marked, (not to mention the errors to which a determination of the reflective power itself is liable to,) that we cannot expect coincidence in such determinations. Perhaps 5.0 may be taken as a probable index.

The law of polarization announced by Dr. Brewster is general, and applies as well to the polarization of light at the separating surfaces of two media in contact, as at the external or internal surface of one and the same medium. He has attempted to deduce from it several theoretical conclusions, as to the extent and mode of action of the reflecting and refracting forces, for which we must refer the reader to his Paper on the subject. Philosophical Transactions, 1816.
If a ray be reflected at an angle greater or less than the polarizing angle, it is partially polarized, that is to say, when received at the polarizing angle on another reflecting surface, which is made to revolve round the reflected ray without altering its inclination to it, the twice reflected ray never vanishes entirely, but undergoes alternations of brightness, and passes through states of maxima and minima which are more distinctly marked according as the angle of the first reflection approaches more nearly to that of complete polarization. The same is observed when a ray so partially polarized is received on a tourmaline plate, revolving (as above described) in its own plane. It never undergoes complete extinction, but the transmitted portion passes through alternate maxima and minima of intensity, and the approach to complete extinction is the nearer the nearer the angle of reflection has been to the polarizing angle. We may conceive a partially polarized ray to consist of two unequally How intense portions; one completely polarized, the other not at all. It is evident that the former, periodically passing from evanescence to its total brightness, during the rotation of the tourmaline or reflector, while the latter remains constant in all positions, will give rise to the phenomenon in question. And all the other characters of a partially polarized ray agreeing with this explanation, we may receive it as a principle, that when a surface does not completely polarize a ray, its action is such as to leave a certain portion completely unchanged, and to impress on the remaining portion the character of complete polarization. Thus we must conceive polarization as a property or character not susceptible of degree, not capable of existing sometimes in a more, sometimes in a less, intense state. A single elementary ray is either wholly polarized or not at all. A beam composed of many coincident rays may be partially polarized, inasmuch as some of its component rays only may be polarized, and the rest not so. This distinction once understood, however, we shall continue to speak of a ray as wholly or partially polarized, in conformity with common language. We shall presently, however, obtain clearer notions on the subject of unpolarized light, and see reason for discarding the term altogether.

If a ray be partially polarized by reflexion, Dr. Brewster has stated that a second reflexion in the same plane renders this polarization more complete, or diminishes the ratio of the unpolarized to the polarized light in the reflected beam; and that by repeating the reflexion, the ray may be completely polarized, although none of the angles of reflexion be the polarizing angle. Thus he found, that one reflexion from glass at 56° 45' of incidence, two at incidences of 62° 30' or at 50° 20', three at 65° 33' or at 46° 30', four at 67° 33' or 43° 51', and so on, alike sufficed to operate the complete polarization of the ray finally reflected, provided all the reflexions were made in one plane. At angles above 83°, or below 18°, more than 100 reflexions were required to produce complete polarization.

§ IV. Of the Laws of Reflexion of Polarized Light.

When polarized light is reflected at any surface, transparent or otherwise, the direction of the reflected portion is precisely the same as in the case of natural light, the angle of reflexion being equal to that of incidence; the laws we are now to consider are those of the intensity of the reflected light, and of the nature of its polarization after reflexion. One essential character of a polarized ray is, its insusceptibility of reflexion in a plane at right angles to that of its polarization when incident at a particular angle, viz. the polarizing angle of the reflecting surface. In this case, the intensity I of the reflected ray is 0. In all other cases it has a certain value, which we are now to inquire. Let us suppose, then, to begin with the simplest case, that the polarized ray falls on the reflecting surface at a constant angle of incidence, equal to its polarizing angle, and that the reflecting surface is turned round the incident ray as an axis, so that the plane of incidence shall make an angle (= a) of any variable magnitude with the plane of polarization. It is then observed, as we have seen, that when a = 90° or 270°, we have I = 0, and when a = 0°, or 180°, I is a maximum. Hence, it is clear that I is a periodic function of a, and the simplest form which can be assigned to it (since negative values are inadmissible) is I = A. (cos a). This value, which was adopted by Malus on no other grounds than those we have stated, is however found to represent the variation of intensity throughout the quadrant, with as much precision as the nature of photometrical experiments admits, and we must therefore receive it as an empirical law at present, for which any good theory of polarization ought to be capable of assigning a reason a priori.

A remarkable consequence follows from this law. It is that, so far as the intensity of the reflected ray is concerned, an ordinary or unpolarized ray may be regarded as composed of two polarized rays, of equal intensity, having their planes of polarization at right angles to each other. For such a compound ray being incident on a reflecting surface, as above supposed, if a be the inclination of the plane of polarization of one to that of incidence, 90° — a will be that of the other, and, therefore, since

\[ A \cdot (\cos a)^2 + A \cdot (\cos 90° - a)^2 = A, \quad (a) \]

the reflected ray will be independent of a, and therefore no variation of intensity will be perceived on turning the reflecting surface round the incident ray as an axis, which is the distinguishing character of unpolarized light. Any such pair of rays as here described are said to be oppositely polarized.

When the polarized ray is not incident at the polarizing angle, but at any angle of incidence, the law of intensity of the reflected ray is more complicated. M. Fresnel has stated the following as the general expression for it. Let the intensity of the incident ray be represented by unity, and calling, as before, \( a \) the inclination of the plane of incidence to that of primitive polarization, and \( i \) the angle of incidence, \( i \) the corresponding angle of refraction. Then will the intensity of the reflected ray be represented by
This formula is in some degree empirical, resulting partly from theoretical views, of which more hereafter, and being not yet verified, or indeed compared with experiment, except in particular cases, by M. Arago, whose results, so far as they go, are consonant with it. It will be well to examine some of these. And first, then, when \( a = 90^\circ \), and \( i \) the polarizing angle of the reflecting surface, we have by (835 and 836) \( i + i' = 90^\circ \), and therefore \( \tan(i + i') = \infty \), so that \( I = 0 \). In these circumstances, then, the reflected ray is completely extinguished, which agrees with fact. 2dly. When the incidence is perpendicular, we have, in this case, both \( i \) and \( i' \) vanishing, and each term of \( I \) takes the form \( \frac{\mu - 1}{\mu + 1} \). Now at the limit we have (\( \mu \) being the refractive index) \( i = \mu \cdot i' \), and very small arcs being equal to their sines or tangents, we have \( \sin(i - i') = \mu (\mu - 1) \); \( \sin(i + i') = \mu (\mu + 1) \), and so for the tangents. Consequently,

\[
I = \left(\frac{\mu - 1}{\mu + 1}\right)^2 \cdot \left(\cos^2 a + \sin^2 a\right) = \left(\frac{\mu - 1}{\mu + 1}\right)^2,
\]

which agrees with the expression deduced by Dr. Young and M. Poisson, (Art. 592,) for the intensity of the reflected ray in the case of unpolarized light. And if we regard the unpolarized ray as composed of two rays, each of the same intensity, \( = \frac{1}{2} \) polarized in opposite planes, the reason of the coincidence will be evident. 3d. When \( a = 0 \), or the plane of polarization coincides with the plane of incidence, we have, in general,

\[
I = \frac{\sin^2(i - i')}{\sin^2(i + i')},
\]

4th. When \( a = 90^\circ \), or when the plane of polarization is at right angles to the plane of incidence,

\[
I = \frac{\tan^2(i - i')}{\tan^2(i + i')}.
\]

5th. When \( a = 45^\circ \),

\[
I = \frac{1}{2} \left(\frac{\sin^2(i - i') + \tan^2(i - i')}{\sin^2(i + i') + \tan^2(i + i')}\right).
\]

This last is the same result with that which would result from the supposition of two equal rays polarized, the one in, the other perpendicularly to, the plane of incidence, and each of half the intensity with the incident beam. It is therefore the general expression for the intensity of a ray of natural or unpolarized light reflected at an incidence \( = i \) from the surface. The expressions in Art. 592 apply only to perpendicular incidences. We are thus furnished very unexpectedly with a solution of one of the most difficult and delicate problems of experimental Optics. Bouguer is the only one who has made any extensive series of photometrical experiments on the intensity of light reflected from polished surfaces at various angles, but his results are declared by M. Arago to be very erroneous, which is not surprising, as the polarization of light was unknown to him, and its laws might affect the circumstances of his experiments in a variety of ways.

One only need be mentioned, as every optical experimentalist ought to be aware of, and on his guard against it, it is that the light of clear, blue sky, is always partially polarized, in a plane passing through the sun, and the part from which the light is received. The polarization is most complete in a small circle, having the sun for its pole, and its radius about 78°, (according to an experiment not very carefully made.) Now the semi-supplement of this (which is the polarizing angle) is 51°, which coincides nearly with the polarizing angle of water, (52° 45') Thus strongly corroborating Newton's theory of the blue colour of the sky, which he conceives to be the blue of the first order, reflected from particles of water suspended in the air. Dr. Brewster is the first, we believe, who noticed this curious fact. But to return to our subject.

When the incident ray is only partially polarized, we may regard it as consisting of two portions: the one, which we shall represent by \( a \), completely polarized in a plane, making the angle \( a \) with that of incidence; the other \( = 1 - a \) in its natural state, or, if we please, composed of two portions \( \frac{1 - a}{2} \) polarized in the plane of incidence, and one at right angles to it. The intensity of the reflected portion of the former is equal to

\[
\frac{\sin^2(i - i') \cdot \cos^2 a + a \cdot \tan^2(i - i') \cdot \sin^2 a}{\sin^2(i + i')},
\]

and that of the latter will be represented by

\[
\frac{1 - a}{2} \left\{ \frac{\sin^2(i - i') + \tan^2(i - i')}{\sin^2(i + i') + \tan^2(i + i')} \right\}
\]

therefore, their sum, or the total reflected light, will be

\[
\sin^2(i - i') \cdot \frac{1 + a \cdot \cos 2a}{2} + \frac{\tan^2(i - i') - 1 - a \cdot \cos 2a}{2}.
\]

The above formulae, it must be observed, apply only to the case of reflection from the surfaces of uncrystallized media. The consideration of those where crystallized surfaces are concerned, cannot be introduced in this part of the subject.
When the plane of reflection coincides with that of the primitive polarization of the ray, the polarization is not changed by reflection. Hence, at a perpendicular incidence it is unchanged. But in other relative situations of the two planes above-mentioned, the case is different, and it becomes necessary to inquire what change reflection produces in the state and plane of polarization of the ray. Now it is found, as we have already seen, that when the reflection takes place in the plane of primitive polarization, if the incident ray be only partially polarized, the reflected one will be more so, in that plane. But if the incident ray be completely polarized, it retains this character after reflection, (except in one remarkable case,) and only the plane of polarization is changed. Now, according to M. Fresnel, the new plane of polarization will make an angle with the plane of reflection, represented by $\beta$, such that

$$\tan \beta = \frac{\cos (i + \delta)}{\cos (i - \delta)} \cdot \tan \alpha.$$ 

According to this formula, the plane of polarization coincides with the plane of incidence when $i + \delta = 90^\circ$. Now this is precisely the case when the ray falls at the polarizing angle on the reflecting surface. If $\alpha = 90^\circ$, or the ray before incidence be polarized in a plane perpendicular to the plane of incidence, it will continue to be so after reflection, since in that case we have $\tan \beta = \infty$, or $\beta = 90^\circ$.

The formula has been compared by M. Arago with experiment only in one intermediate case, viz. when $\alpha = 45^\circ$, and the coincidence of the results with experiment at a great variety of incidences, and over a range of values of $\beta$ from $+38^\circ$ to $-44^\circ$, both in the case of glass and water, is as satisfactory as can be desired. The particulars of this interesting comparison will be found in Annales de Chimie, xvii., p. 314. It may be observed also, that these results of M. Fresnel support one another, the latter being concluded from the former by considerations purely theoretical, so that every verification of the one is also a verification of the other.

When the polarized ray is reflected from a crystallized surface, the intensity of the reflected portion is no longer the same, but depends on the laws of double refraction, in a manner of which more hereafter. Whether or how far, the laws above stated hold good for metallic surfaces, remains open to inquiry.

§ V. Of the Polarization of Light by ordinary Refraction, and of the Laws of the Refraction of Polarized Light.

When a ray of natural or unpolarized light is transmitted through a plate of glass at a perpendicular incidence, it exhibits at its emergence no signs of polarization; but if the plate be inclined to the incident ray, the transmitted ray is found to be partially polarized in a plane at right angles to the plane of refraction, and therefore at right angles to the plane of polarization of the portion of the reflected ray which has undergone that modification. The connection between the polarized portions of the reflected and refracted pencils is, however, still more intimate, since M. Arago has shown by a very elegant and ingenious experiment that these portions are always of equal intensity. This law may be stated thus: When an unpolarized ray is partly reflected at, and partly transmitted through, a transparent surface, the reflected and transmitted pencils contain equal quantities of polarized light, and their planes of polarization are at right angles to each other.

Hence it appears, that the transmitted ray contains a maximum of polarized light, when the light is incident at the polarizing angle of the medium, and this maximum is equal to the quantity of light the surface is capable of completely polarizing by reflection. Now in all media known, this is much less than half the incident light, consequently the transmitted portion can never be wholly polarized by a single transmission.

When a ray is totally reflected at the inner surface of a medium, there is no transmitted portion, and it is a remarkable coincidence with the above law, that in this case the reflected beam contains no polarized portion whatever.

With regard to the portion of light which has passed through the surface, and has not acquired polarization, M. Arago maintains that it remains in the state of natural or totally unpolarized light. Dr. Brewster, on the other hand, concludes from his experiments, that, although not polarized, it has undergone a physical change, rendering it more largely susceptible of polarization by subsequent transmission at the same angle. The question, in a theoretical point of view, is a material one, and apparently very easily decided. The facility, however, is only apparent, and as we have no title to decide it on the grounds of our own experience, we shall content ourselves with reasoning on the conclusions to which the two doctrines lead. Let $I$ be the light incident on the first surface of a glass plate at the polarizing angle, and, after transmission through both surfaces, let $a + b$ be the intensity of the transmitted beam, (and of course $1 - a - b$ that of the reflected,) and let $a$ be the polarized portion and $b$ the unpolarized. When $a + b$ falls on another plate at the same angle, the portion $a$ being polarized in a plane perpendicular to that of incidence, and incident at the polarizing angle, will be totally transmitted, and its plane of polarization (as may be proved by direct experiment) in this case undergoes no change. Hence the portion $a$ will be transmitted (supposing no absorption) undiminished through any number of subsequent plates. With regard to the portion $b$, if this be to all intents and purposes similar to natural light, it will be divided by reflection at the second plate into two portions, the first of which $= b \cdot (1 - a - b)$ being reflected wholly polarized, and the other $= b (a + b)$ will be transmitted. Of this, the portion $b a$ will be polarized in a plane at right angles to that of refraction, and will therefore be afterwards transmitted undiminished through all the subsequent plates. But the portion $b b$ will be unpolarized light, and will be again divided by the third plate, and so on. Thus, there will be ultimately transmitted a pencil, consisting of a polarized portion.
If a pile of parallel glass plates be exposed to a polarized ray, so that the angle of incidence be equal to the polarizing angle, and then turned round the ray as an axis preserving the same inclination, the following phenomena take place:

1. When the plane of incidence is at right angles to that of the ray's polarization, the whole of the incident light is transmitted, (except what is destroyed by absorption within the substance of the glass, or lost by irregular reflection from the inequalities in the surface arising from defective polish,) and this holds good whatever be the number of the plates. The polarization of the transmitted ray is unaltered.

2. As the pile revolves round the incident ray as an axis, a portion of the light is reflected, and this increases till the plane of incidence is coincident with the plane of primitive polarization, when the reflected light is a maximum. Now, M. Arago assures us, that the quantity of polarized light reflected from each plate is greater in proportion to the intensity of the incident beam than if natural light had been employed; and the same proportion holding good at each plate, the transmitted ray, however intense it may have been at first, will be weakened in geometrical progression with the number of plates, and at length will become insensible; so that in this situation the pile will present the phenomenon of an opaque body. In this reasoning, the light reflected backwards and forwards between the plates is neglected; but as it is all polarized in the same plane, and as in this situation the reflections, however frequent, produce no change in its plane of polarization, all the reflected rays are in the same predicament; and, supposing the number of plates very great, the total extinction of the transmitted light will ultimately (though less rapidly) take place.

Hence, a pile of a great number of glass plates inclined at an angle equal to the complement of the polarizing angle (35° ±) to a polarized ray ought to present the same phenomena with a plate of tourmaline cut parallel to the axis of its primitive rhomboid, alternately transmitting and extinguishing the whole of the light in the successive quadrants of its rotation, and being thus either opaque or transparent, according to its position. The analogy, however, cannot fairly be pushed further, so as to deduce from this principle an explanation of the phenomena of the tourmaline; for, although it be true that a plate of tourmaline so cut, is composed of laminae inclined to its surface, these laminae are in optical contact; and, moreover, their position with respect to the surface is not the same in plates cut in all directions about the axis, because although an infinite number of plates may be cut containing the axis of a rhomboid in their planes, only three can have the same relation to its several faces, parallel to which the component laminae must be supposed to lie. Moreover, the phenomena are not produced, unless the tourmaline be coloured. The analogy between piles of glass plates and laminae of agate (of which more presently) is also, we are inclined to think, more apparent than real.

A pile of plates such as described above presents, moreover, the same difference of phenomena when exposed to polarized and unpolarized light, that a plate of tourmaline does; since in the latter case, supposing the pile sufficiently numerous, one half the incident light is transmitted, completely polarized in a plane perpendicular to that of incidence.

The laws which regulate the polarization of a pencil transmitted by a transparent surface, inclined at any proposed angle to the incident ray, and in any plane to that of its primitive polarization (supposing it polarized) remain open to experimental investigation.
§ VI. Of the Polarization of Light by Double Refraction.

When a ray of natural light is divided into two by double refraction, in such a manner that the two pencils at their final emergence remain distinct and susceptible of separate examination, they are both found completely polarized, in different planes, exactly, or nearly, at right angles to each other. To show this, take a pretty thick rhomboïd of Iceland spar, and, covering one side of it with a blackened card, or other opaque substance, having a small pinhole through it, hold it against the direct light of a window or a candle, with the plane parallel to the principal section of the surface of incidence, by the extraordinary. These images will appear, to the naked eye, of equal brightness; but, if we interpose a plate of tourmaline, (as already described,) and turn the latter about in its own plane, they will be rendered unequal, and will appear and vanish alternately at every quarter revolution of the tourmaline; the ordinary image being always at its maximum of brightness, and the extraordinary one extinct, when the axis of the tourmaline plate is perpendicular to the principal section of the surface of incidence, and vice versa when parallel to it.

The same thing happens, when, instead of examining the two images through a tourmaline plate, we receive their light on a glass plate inclined at the polarizing angle to it, and turn this plate round the ordinary ray Experiment as an axis. The images will appear and disappear alternately, as the reflector performs successive quadrants of its revolution.

Hence, we see that the two pencils are completely and oppositely polarized; the ordinary pencil in a plane passing through the axis of the rhomboïd; the extraordinary one in a plane at right angles to it.

The same phenomenon is much better seen by using a prism of any double refracting crystal, having such a refracting angle as to give two distinctly separated images of a distant object, (as a candle.) These appear and disappear alternately at quarter revolutions of a tourmaline plate or glass reflector, and are of equal brightness at the intermediate half-quarters.

Double refraction, then, polarizes the two refracted pencils oppositely, into which an unpolarized incident ray is separated. Let us now see what happens to a polarized ray. For this purpose let a plate of glass be laid Transversely before an open window, so as to polarize the reflected light, and hold the rhomboïd of Iceland spar, (covered as before) with the covered side from the eye, not (as in the former experiment) against the direct light, but inclined downwards, against the reflected light from the glass. Then, generally speaking, two images of the pinhole will be seen, but of unequal intensities; and, if we turn round the rhomboïd, in the plane of the covered side, these images will be seen to vary perpetually in their relative brightness, the one increasing to a maximum, while the other vanishes entirely, and so on reciprocally. When the principal section of the rhomboïd is in the plane of reflexion (i.e. of polarization) of the incident ray, the ordinary image is a maximum; the extraordinary is extinct, and vice versa when these two planes make a right angle. The experiment may be advantageously varied by using a doubly refracting prism; and, while looking through it at the polarized image of a candle, turning it round slowly in the plane bisecting its refracting angle.

This experiment leads us to the following remarkable law, viz. that if a ray, at its incidence on a doubly refracting surface, be polarized in the plane parallel to the principal section, it will suffer bifurcation, but unequal division of the light between the two refracted pencils, in every case except when the plane of primitive polarization makes an angle of 45° with the refracted principal section. In general, if α be the angle last mentioned, and A the incident light, (supposing none lost by reflexion,) A cos^2 α will be the intensity of the ordinary, and A sin^2 α of the extraordinary pencil, their sum being A.

All these changes and combinations are exhibited in the following remarkable experiment of Huygens, which, reasoned on by himself and Newton, first gave rise to the conception of a polarity, or distinction of sides, in the rays of light when modified by certain processes. Take two pretty thick rhomboïds of Iceland spar, (which should be very transparent, as they are easily procured,) and lay them down one upon the other, so as to have their homologous sides parallel, or so that the molecules of each shall have the same relations of situation as if the two rhomboïds were contiguous parts of one larger crystal. They should be laid on a sheet of white paper, having a small, very distinct, and well-defined black spot on it. This spot then will be seen double through the combined crystals, as if they were one, (α, fig. 173,) and the line joining the images will be parallel to the Fig. 137. principal section of either. Now, let the upper crystal be turned slowly round in a horizontal plane on the lower, and two new images will make their appearance between the two first seen, which, at first, are very faint, as at b, fig. 173, and form a very elongated rhombus with the two former. They increase, however, in intensity, while the other pair diminishes, till the angle of rotation of the upper crystal is 45°, where the appearance of the images is as at c. Continuing the rotation, the rhomb approaches to a square, as at d, and the two original images have become extremely faint; and when the rotation is just 90°, they will have disappeared altogether, leaving the others diagonally placed, as at e. As the rotation still proceeds, they reappear and increase in brightness, till the angle of revolution = 90° + 45° = 135°, when the images are all equal, as at f after which the original images still increasing, and the others diminishing, the appearance g is produced, which, on the completion of a precise half revolution, passes into h by the union of both the original images into one, and the total evanes-
Light.

The property of a double refraction, in virtue of which a polarized ray is unequally divided between the two images, furnishes us with a most convenient and useful instrument for the detection of polarization in a beam of light, and for a variety of optical experiments. It is nothing more than a prism of a doubly refracting medium rendered achromatic by one of glass, or still better, by another prism of the same medium properly disposed, so as to increase the separation of the two pencils. The former method is simple; and, when large refracting angles are not wanted, the uncorrected color in one of the images is so small as not to be troublesome. It is most convenient to make the refracting angle such as to produce an angular separation of about 2° between the images. Thus, in fig. 174, let ABCG be a prism of Iceland spar, cut in such a manner (we will at present suppose) that the refracting edge CG shall contain the axis of the crystal; and let it be achromatized as much as possible by a prism of glass CDEF. Then, if Q be a small, colourless, luminous circle, Fig. 174.

First achromatized by glass.

Let ABCG be a prism of Iceland spar, cut in such a manner (we will at present suppose) that the refracting edge CG shall contain the axis of the crystal; and let it be achromatized as much as possible by a prism of glass CDEF. Then, if Q be a small, colourless, luminous circle, Fig. 174.

First achromatized by glass.

Let ABCD be a prism of Iceland spar. Then, if A be the intensity of the incident light, supposing none lost by reflexion or absorption,

\[ O = \frac{1}{2} A \cos^2 a = E \sin^2 a = F \]

and the sum of all the four images = A.

881. Use of an achromatic double refracting prism.

882. Dr. Wollaston's mode of doubling the separation of images.

883. Crystals which have no double refraction may be regarded as limits of those which have, or as crystals in which the two rays are propagated with equal velocity, and therefore undergo no bifurcation; or, in other words, in which the images formed coincide. In this case we should expect to find no polarization of the emergent light, because the two pencils, being polarized at right angles to each other, form together a single ray having the characters of unpolarized light. This is verified by experiment. The light transmitted by fluorspar, for...
§ VII. Of the Colours exhibited by Crystallized Plates when exposed to Polarized Light, and of the Polarized Rings which surround their Optic Axes.

This splendid department of Optics is entirely of modern and, indeed, of recent origin. The first account of the colours of crystallized plates was communicated by M. Arago to the French Institute in 1811, since which period, by the researches of himself, Dr. Brewster, M. Biot, M. Fresnel, and, latterly, also of M. Mitscherlich, and others, it has acquired a development placing it among the most important as well as the most complete and systematic branches of optical knowledge. As might be expected, under such circumstances, as well as from the state of political relations, and the consequent limited intercourse between Britain and the Continent at the period mentioned, an immense variety of results could not but be obtained independently, and simultaneously, or nearly simultaneously, on both sides of the channel. To the lover of knowledge, for its own sake,—the philosopher, in the strict original sense of the word,—this ought to be matter of pure congratulation; but to such as are fond of discussing rival claims, and settling points of scientific precedence, such a rapid succession of interesting discoveries must, of course, afford a welcome and ample supply of critical points, the seeds of an abundant harvest of dispute and recrimination. Regarding, as we do, all such discussions, when carried on in a spirit of rivalry or nationality, as utterly derogatory to the interests and dignity of science, and as little short, indeed, of sacrilegious profanation of regions which we have always been accustomed to regard only as a delightful and honourable refuge from the miserable turmoil and contentions of interested life, we shall avoid taking any part in them; and, taking up the subject (to the best of our abilities and knowledge) as it is, and avoiding, as far as possible, all reference to misconceived facts and over-hasty generalizations, which is as in all other departments of science, have not failed (like mists at daybreak) to spread a temporary obscurity over a subject imperfectly understood, shall make it our aim to state, in as condensed a form as is consistent with distinctness, such general facts and laws as seem well enough established to run no hazard of being overset by further inquiry, however they may merge hereafter in others yet more general;—a consumption devoutly to be wished.

The general phenomenon of the coloured appearances to which this section is devoted, may be most readily and familiarly shown as follows. Place a polished surface of considerable extent (such as a smooth mahogany table, or, what is much better, a pile of ten or a dozen large panes of glass laid horizontally) close to a large open window, from which a full and uninterrupted view of the sky is obtained; and having procured a plate of mica, of moderate thickness, (about a thirtieth of an inch, such as may easily be obtained, being sold of crystal in considerable quantity for the manufacture of lanterns,) hold it between the eye and the table, or pile, so as to receive and transmit the light reflected from the latter as nearly as may be judged at the polarizing angle. In this situation of things, nothing remarkable will be perceived, however the plate of mica be inclined; but if instead of the naked eye we look through a tourmaline plate, having its axis vertical, the case will be very different. When the mica plate is away, the reflected beam, and the surface of the table or pile, will appear dark and non-reflective; at least in one point, on which we will suppose the eye to be kept steadily fixed. No sooner is the mica interposed, however, than the reflective power of the surface appears to be suddenly restored; and on inclining the mica at various angles, and turning it about in its own plane, positions will readily be found in which it becomes illuminated with the most vivid and magnificent colours, which shift their tints at the least change of position of the mica, passing rapidly from the most gorgeous reds to the richest greens, blues, and purples. If the mica plate be held perpendicular to the reflected beam, and turned about in its own plane, two positions will be found in which all colour and light disappears; and the reflected ray is extinguished, as if no mica was interposed. Now, if we draw on the plate with a steel point two lines corresponding to the intersection of the mica with a vertical plane passing through the eye in either of these two positions, we shall find that they make an exact right angle. For the moment, let us call these lines A and B; and let a plane drawn through the line A, perpendicular to the plate, be called the section A; and one similarly drawn through the line B, the section B. Then we shall observe further, that when we turn the plane from either of these positions, 45° round, in its own plane, so that the sections A and B shall make angles of 45° with the plane of reflection, (i.e. of polarization of the incident ray,) the transmitted light will be a maximum.

If the thickness of the mica do not exceed 1/8th of an inch, it will be coloured in this position; if materially greater, colourless; and if less, more and more vividly coloured, and with tints following closely the succession of the reflected series of the colours of thin plates, and, like them, rising in the scale, or approaching the central tint (black) as the thickness is less. The analogy in this respect, in short, is complete, with the exception of the enormous difference of thickness between the mica plate producing the tints in question, and those required to produce the Newtonian rings. It appears by measures made in the manner hereafter to be described, that the tint exhibited by a plate of mica exposed perpendicularly to the reflected ray, as above described, is the same with that reflected by a plate of air of 1/8th part of the thickness of the mica employed.
If the mica (still exposed perpendicularly to the ray) be turned round in its own plane, the tint does not change, but only diminishes in intensity as its section A or B approaches the plane of polarization of the incident light. When, however, the plate is not exposed perpendicularly, this invariability no longer obtains; and the changes of tint appear in the last degree capricious and irreducible to regular laws. In two situations, however, the phenomena admit a simple view. These are when the sections A and B are both 45° from the plane of polarization, and the mica plate is inclined backwards and forwards in the plane of one of the other of these sections. This condition is easily attained by first holding the plate perpendicularly to the reflected ray; then turning it in its own plane till the lines A, B are each 45° inclined to the vertical plane, then finally causing it to revolve about either of these lines as an axis. It will then be seen that when made to revolve round one of them (as A) or in the plane of the section B, the tint, if white, will continue white at all angles of inclination; but if coloured, will descend in the scale of the coloured rings, growing continually less highly coloured, till it passes, after more or fewer alternations, into white; after which, further inclination of the plate will produce no change. On the other hand, if made to revolve round B, or in the plane of A, the tints will rise in the scale of the rings; and when the mica plate is inclined either way, so as to make the angle of incidence about 35° 3', will have attained its maximum, corresponding to the black spot in the centre of Newton's rings. In this position of the plate, the reflected beam is totally extinguished by the tourmaline, as if the sections A or B had been vertical. But if the angle of incidence be still further increased, the colours reappear, and descend again in the scale of the rings, passing through their whole series to final whiteness. We take no notice here of a slight deviation from the strict succession of the Newtonian colours, which is observed in the higher orders of the tints, as we shall have more to say respecting it hereafter.

We see, then, that the sections A and B, though agreeing in their characters in the case of a perpendicular exposure of the mica, yet differ entirely in the phenomena they exhibit at oblique incidences. If the incidence take place in the plane of the section B, the tint descends, on both sides of the perpendicular, ad infinitum. While, if the incidence be in the section A, it rises to the central black, which it attains at equal incidences on either side of the perpendicular (35° 3'), and then descends again ad infinitum, or to the composite white at the other extreme of the scale.

The section A, then, (which, for this reason, we will call the principal section of the mica plate,) is characterized by containing two remarkable lines inclined at equal angles to the surface of the plate, along either of which, if a polarized ray be incident, its polarization will not be disturbed by the action of the plate. To satisfy ourselves of this, we have only to take the mica and a tube, so as to bear the axis of the tube inclined at an angle of 35° 3' to the perpendicular (or 54° 57' to the plate) in the plane of the section A; then directing the axis of the tube to the centre of the dark spot, or the reflecting surface, it will be seen to continue dark, and remain so while the tube makes a complete revolution on its axis. Now, this could not be if the mica exercised any disturbing power on the plane of polarization. Hence, we conclude, that the two lines in question possess this remarkable property, viz. that whatever be the plane of polarization of a ray incident along either of them, it remains unaltered after transmission. For, although in the experiment above described, the plane of polarization remained fixed, and that of incidence was made to revolve, it is obvious that the reverse process would come to the very same thing.

Now, this character belongs to no other lines, however chosen, with respect to the plate. If we fix the plate on the end of the tube at any other angle, or in any other plane with respect to the axis of the latter, although two positions in the rotation of the tube will always be found where the disappearance of the transmitted ray takes place, in no other case but that of the two lines in question will this disappearance be total, or nearly so, in all points of its revolution.

The refracting index of mica being 1.500, an angle of incidence of 35° 3' corresponds to one of refraction $= 22° 31'$. Hence, the position of the lines within the mica corresponding to these external lines is $22° 31'$ inclined to the perpendicular, and the angle included between them $45°$. These, then, are axes within the crystal, bearing a determinate relation to its molecules. Dr. Brewster has termed them axes of no polarization, a long name. M. Fresnel, and others, have used the phrase optic axes, to which we shall adhere. As this term has been before applied to the "axes of no double refraction," we must anticipate so far as to advert the reader that these, and the "axes of no polarization," are in all cases identical.

Having, by the criteria above described, determined the principal section, and ascertained the situation of the optic axes of the mica plate under examination, let the plate be inclined to the polarized beam, so that the latter shall be transmitted along the optic axes, the principal section A making an angle of $45°$ with the plane of polarization; and let the eye (still armed with the tourmaline plate, with its axis vertical) be applied close to the mica. A splendid phenomenon will then be seen. The black point corresponding to the direction of the optic axis will be seen to be surrounded with a set of broad, vivid, coloured rings, of an elliptic, or, at least, oval form, divided into two unequal portions by a black band somewhat curved, as represented in fig. 176. This band passes through the pole, or angular situation of the optic axis, about which the rings are formed as a centre. Its convexity is turned towards the direction of the other axis, and on that side the rings are also broader. If, now, the other axis be brought into a similar position, a phenomenon exactly similar will be seen surrounding its place, as a pole. If the mica plate be very thick, these two systems of rings appear wholly detached from, and independent of, each other, and the rings themselves are narrow and close; but if thin (as a 30th or 40th of an inch) the individual rings are much broader, and especially so in the interval between the poles, as to unite and run together, losing altogether their elliptic appearance, and diluting towards the middle (or in the direction of a perpendicular to the plate) into a broad coloured space, beyond which the rings are no longer formed about each pole separately, but assume the form of reentering curves, embracing and including both poles. Their nature will presently be stated more at large.
If, preserving the same inclination of the mica plate to the visual ray, it be turned about as an axis, the black band passing through the pole will shift its place, and revolve as it were on the pole as a centre with double the angular velocity, so as to obliterate in succession every part of the rings. When the plate has made 45° of its revolution, so as to bring its principal section into the plane of polarization of the incident beam, this band also coincides in direction with that plane, and is then visibly prolonged, so as to meet that belonging to the set of rings about the other pole; and is crossed at the middle point between the poles by another dark space perpendicular to it, or in the plane of the section B, presenting the appearance in fig. 177.

These phenomena, if a tourmaline be not at hand, may be viewed, (somewhat less commodiously, unless the mica plate be of considerable size,) by using in its place the reflector figured in fig. 170, or by a pile of glass plates interposed obliquely between the eye and the mica. In this manner of observing them, the colours are generally exerting a considerable absorbing energy on these rays in preference to the rest, and thus the contrast of colours is materially impaired. On the other hand, however, from the greater homogeneity of the transmitted light, the rings are more numerous and better defined; and in this respect the phenomenon is greatly improved by the use of homogeneous light.

We have taken mica as being a crystallized body very easily obtained of large size, and presenting its axes readily, and without the necessity of artificial sections. It is thus admirably adapted for obtaining a general rough view of the phenomena, preparatory to a nicer examination. From the wide interval between its axes, however, and the considerable breadth of its rings, it is less adapted, when employed as above stated, to give a clear conception of the complicated changes which the rings undergo, on a variation of circumstances. For this reason we shall now describe another and much more commodious mode of examining the systems of polarized rings presented by crystals in general, which has the advantage of bringing the laws of their phenomena so evidently under our eyes as to make their investigation almost a matter of inspection.

It is evident, that when we apply the eye close to, or very near a plate of mica, or other body, and view, beyond it, a considerable extent of illuminated surface, each point of that surface will be seen by means of a ray which has penetrated the plate in a different direction with respect to the axes of its molecules; so that we may consider the eye as in the centre of a spherical surface from all points of which rays are sent to it, modified according to the state of primitive polarization, and the influence of the peculiar energies of the medium, corresponding to the direction in which they traverse it, and the thickness of the plate in that direction.

Any means, therefore, by which we can admit into the eye through the plate and tourmaline a cone of rays nearly or completely polarized in one general direction, or according to any regular law, will afford a sight of the rings; and therefore exhibit, at a single view, a synopsis, as it were, of the modifications impressed on an infinite number of rays so polarized traversing the plate in all directions. The property of the tourmaline so often referred to puts it in our power to perform this in a very elegant and convenient manner, by the aid of the little apparatus of which fig. 178 is a section. A B C D is a short cylinder of brass tube, the end of which, A C, Fig. 178. is terminated by a brass plate, having an aperture a b, into which is set a tourmaline plate cut parallel to the axis: g h k is another similar brass cylinder, provided with a similar aperture and a similar tourmaline plate G, and fitted into the former so as to allow of the one being freely turned round within the other by the milled edges B D, h k. A lens H of short focus, set in a proper cell, is screwed on in front of the tourmaline G, so as to have its focus a little behind its posterior surface, (that next the eye, O.) Between the two surfaces A C, g i is another short cylinder of thin tube c d, carrying a brass plate with an aperture somewhat narrower than those in which the tourmalines are set, and on which any crystallized plate F to be examined may be cemented with a little wax. This, with the cylinder to which it is fixed, is capable of being turned smoothly round within the cylinder A B C D by means of a small pin e passing through a slit f made in the side, and extended round so as to occupy about 120° of the circumference; by which a rotation to that extent may be communicated to the crystallized plate F in its own plane between the tourmaline plates. The pin e should screw into the ring c d, that it may be easily detached, and admit the ring and plate to be taken out for the convenience of fixing on it other crystals at pleasure.

The use of the lens H is to disperse the incident light, and thus equalize the field of view when illuminated by any source of light, whether natural or artificial, as well as to prevent external objects being distinctly seen through it, which would distract the attention and otherwise interfere with the phenomena. The rays converge by the lens to a focus within the crystallized plate F, afterwards diverge and fall on the eye O, after traversing the plate in all directions within the limit of the field of view. As by this contrivance they pass through a very small portion of the crystal, there is the less chance of accidental irregularities in its structure disturbing the regular formation of the rings, since we have it in our power to select the most uniform portion of a large crystal. The rays, after passing through the lens, are all polarized by the tourmaline G, in planes parallel to its axis; and passing through the eye in this state, if the crystal F be not interposed, the rays will, or will not, penetrate the second tourmaline, according as its axis is parallel or perpendicular to that of the first. In consequence, when the cylinder carrying the former is turned round within that carrying the latter, the field of view is seen alternately bright and dark.

When the crystallized substance F is interposed, provided it be so disposed that one or other of its optic axes is situated anywhere in the cone of rays refracted by the lens, so that one of them shall reach the eye by selection of traversing the axis, the polarized rings are seen. If both the axes of the crystal (supposing it to have more crystals than one) fall within the field, a set of rings will be seen round both, and may be studied at leisure. In order to bring the whole of their phenomena distinctly under view, it is requisite to select such crystals as have their axes not much inclined to each other, so as to allow the rings about both to be seen without the necessity of looking very obliquely into the apparatus. In mica the axes are rather too far removed for this. The best crystal we can select for the purpose is nitre.
Nitres crystallizes in long, six-sided prisms, whose section, perpendicular to their sides, is the regular hexagon. They are generally very much interrupted in their structure; but by turning over a considerable quantity of the ordinary saltpetre of the shops, specimens are readily found which have perfectly transparent portions of some extent. Selecting one of these, cut it with a knife into a plate about a quarter of an inch thick, directly across the axis of the prism, and then grind it down on a broad wet file, till it is reduced about 1/4 or 1/3 inch in thickness; smooth the surfaces on a wet piece of emery glass, and polish them on a piece of silk strained very tight over a strip of plate glass, and rubbed with a mixture of tallow and coloquint of vitriol. This operation requires practice. It cannot be effected unless the nitre be applied wet, and rubbed till quite dry, increasing the rapidity of the friction as the moisture evaporates. It must be performed in gloves, as the vapour from the fingers, as well as the slightest breath, dims the polished surface effectually. With these precautions a perfect vitreous polish is easily obtained. We may here remark, that hardly any two salts can be polished by the same process. Thus, Rochelle salt must be finished wet on the silk, and instantly transferred to soft bibulous linen, and rapidly rubbed dry. Experience alone can teach these peculiarities, and the contrivances (sometimes very strange ones) it is necessary to ressort to for the purpose of obtaining good polished editions of soft crystals, especially of those easily soluble in water.

The nitre thus polished on both its surfaces (which should be brought as near as possible to exact parallelism) is to be placed on the plate at \( F \); and the tourmaline plates being then brought to have their axes at right angles to each other (which position should be marked by an index line on the cylinders) the eye applied at \( O \), and the whole held up to a clear light, a double system of interrupted rings of the utmost neatness and beauty will be seen, as represented in fig. 179. If the crystallized plate be made to revolve in its own plane between the tourmelines (which both remain unmoved) the phenomena pass through a certain series of changes periodically, returning, at every 90° of rotation, to their original state. Fig. 180 represents their appearance when the rotation is just commenced; fig. 181, when the angle of rotation is 22\( \frac{1}{2} \)°, or 67\( \frac{1}{2} \)°; and fig. 182, when it equals 45°. When the tourmelines are also made to revolve on each other, other more complicated appearances are produced, of which more presently. We shall now, however, suppose them retained in the situation above mentioned, i.e. with their axes crossed at right angles, and proceed to study the following particulars:

1. The form and situation of the rings.
2. Their magnitudes in the same and different plates.
3. Their colours.
4. The intensity of the illumination in different parts of their periphery.

The situation of the rings is determined by the position of the principal section of the crystal, or by that of the optic axes within its substance. These in nitre lie in a plane parallel to the axis of the prisms, and perpendicular to one or other of its sides. It is no unusual thing to find crystals of this salt whose transverse section consists of distinct portions, in which the principal sections make angles of 60° with each other; indicating a composite or mackled structure in the crystal itself. These portions are divided from each other by thin films, which exhibit the most singular phenomena by internal reflexion, on which this is not the place to enlarge. In an uninterrupted portion, however, the forms of the rings are as represented in the figures above referred to, their poles subtending at the eye an angle of about 8°. Now, it is to be remarked, that as the plate is turned round between the tourmelines, although the black hyperbolic curves passing through the poles shift their places upon the coloured lines, and in succession obliterate every part of them; forming, first, the black cross in fig. 179, by their union; then breaking up and separating laterally, as in fig. 180, and so on. Yet the rings themselves retain the same form and disposition about their poles, and, except in point of intensity, remain perfectly unalter'd; their whole system turning uniformly round as the crystallized plate revolves, so as to preserve the same relations to the axes of its molecules. Hence we conclude, that the coloured rings are related to the optic axes of the crystal, according to laws dependent only on the nature of the crystal, and not at all on external circumstances, such as the plane of polarization of the incident light, &c.

The general form of the rings, abstraction made of the black cross, is as represented in fig. 183. If we regard them all as varieties of one and the same geometrical curve, arising from the variation of a parameter in its equation, it will be evident that this equation must, in its most general form, represent a re-entering symmetrical oval, which at first is uniformly concave, and surrounds both poles, as \( A \); then flattens at the sides, and acquires points of contrary flexure, as \( B \); then acquires a multiple point, as \( C \); after which it breaks into two conjugate ovals \( D \), each surrounding one pole. This variation of form, as well as the general figure of the curves, bears a perfect resemblance to what obtains in the curve well known to geometers under the name of the lemniscate, whose general equation is

\[
(a^2 + b^2 + c^2) = a^2 \left( b^2 + 4 c^2 \right),
\]

when the parameter \( b \) gradually diminishes from infinity to zero; \( 2 a \) representing the constant distance between the poles.

The apparatus just described affords a ready and very accurate method of comparing the real form of the rings with this or any other proposed hypothesis. If fixed against an opening in the shutter of a darkened room, with the lens \( H \) outwards, and a beam of solar light be thrown on the latter, parallel to the axis of the apparatus, the whole system of rings will be seen finely projected against a screen held at a moderate distance from \( E \). Now, if this screen be of good smooth paper tightly stretched on a frame, the outlines of the several rings may easily be traced with a pencil on it, and the holes being in like manner marked, we have a faithful representation of the rings, which may be compared at leisure with a system of lemniscates, or any other curve graphically constructed, so as to pass through points in them chosen where the tint is most decided. This has...
accordingly been done, and it has been found that lemniscates so constructed coincide throughout their whole extent, to minute precision, with the outlines of the rings so traced, the points graphically laid down falling on the pencilled outlines. The graphical construction of these curves is rendered easy by the well-known property of the lemniscate, in which the rectangle under two lines P A × P ' A drawn from the poles to any point A in the periphery is invariably throughout the whole curve. This is easily shown from the above equation, and the value of this constant rectangle in any one curve is represented by a × b.

When we shift from one ring to another, a remains the same, because the poles are the same for all. To determine the variation of b, let the rings be illuminated with homogeneous light, (or viewed through a red glass,) and outlined by projection, as above. Then, if we determine the actual value of a b by measuring the length of two lines P A, P ' A drawn from P, P ' to any point of each curve; and, calculating their product, (to which a b is equal,) it will be found that this product, and therefore the parameter b, increases in the arithmetical progression 0, 1, 2, 3, 4, &c. for the several dark intervals of the rings beginning at the pole, and in the progression 3, 3, 3, &c. for the brightest intermediate spaces. To ensure accuracy, the mean of a number of values of P A × P ' A, at different points of the periphery, may be taken to obviate the effect of any imperfection in the crystal.

This, then, is the law of the magnitudes of the successive rings formed by one and the same plate. But if we determine the value of the same product for plates of nitre similarly cut, but of different thicknesses, or of the same reduced in thickness by grinding, it will be found to vary inversely as the thickness of the plate, ceteris paribus.

The colours of the polarized rings bear a great analogy to those reflected by thin plates of air, and in most crystals would be precisely similar to them but for a cause presently to be noticed. In the situation of the tourmaline plates here supposed (crossed at right angles) they are those of the reflected rings, beginning with a black centre, at the pole. If examined in the situation of fig. 179, and traced in a line from either pole cutting across the whole system, at right angles to the line joining the poles, they will almost precisely follow the Newtonian scale of tints. For the present we will suppose that they do so in all directions. It is evident, then, that each particular tint (as the bright green of the third order, for instance) will be disposed in the form of a lemniscate, and will have its own particular value of the product a b. The tint, then, may be said to be corresponding to,—dependent on,—or, if we will, measured by a b. In conformity with this language the coloured curves have been termed, and not inaptly, isochromatic lines. Now, in the colours of thin plates, we have seen that these tints arise from a law of periodicity to which each homogeneous ray is subject; and that (without entering at this moment into the cause of such periods) the successive maxima and minima of each particular coloured ray passed through, in the scale of tints, correspond to successive multiples by $\frac{1}{3}$, $\frac{1}{3}$, $\frac{1}{3}$, &c. of the period peculiar to that colour. In the colours of thin plates, the quantity which determines the number of periods is the thickness of the plate of air, or other medium traversed; and the number of times a certain standard thickness peculiar to each ray is contained therein, determines the number of periods, or parts of a period, passed through. In the colours, and in the case now under consideration, the number of periods is proportional to the product ($\theta \times \theta'$) of the distances from either pole, for one and the same thickness of plate,—and for different plates to $t$ the thickness,—and, therefore, generally, to $\theta \times \theta' \times t$, provided we neglect the effect of the inclination of the ray in increasing the length of the path of the rays within the crystal, or regard the whole system of rings as confined within very narrow limits of incidence.

This condition obtains in the case here considered, because of the proximity of the axes in nitre to each other and to the perpendiculars to the surfaces of the plate. But in crystals such as mica, or others where they are still wider asunder, it is not so; and the projection of the isochromatic curves on a plane surface will deviate materially from their true form, which ought to be regarded as delineated on a sphere having the eye, or rather a point within the crystal, for a centre. In such a case, it might be expected that the usual transition from the arc to its sine should take place; and that, instead of supposing the tint, or value of a b, to be proportional simply to $\theta \times \theta'$, we ought to have it proportional to $\sin \theta \times \sin \theta' \times t$, the sine of the angle of refraction, and $t$ the thickness of the plate. We have then, if we put $n$ for the number of periods corresponding to the tint a b for the ray in question, and suppose $h = \frac{a b}{n}$, or the unit whose multiples determine the order of the rings, we shall have

$$n \cdot a b = \frac{t}{h},$$

$$\sin \theta \times \sin \theta' \times \sec \rho,$$

and

$$h = \frac{t}{\sec \rho \times \cos \rho},$$

$$\sin \theta \times \sin \theta'.$$

If, then, the suppositions made be correct, we ought to have the function on the right hand side of this last equation express a uniform transition for the whole system of rings, if viewed through a plate of mica, having its principal section $45^\circ$ inclined to the plane of primitive polarization, and the mica plate made to revolve in the plane of its principal section about an axis at right angles thereto, (or about the axis B.) In this state of things, if viewed through a tourmaline as above described, or by other more refined means, it has been found that lemniscates so constructed coincide throughout their whole extent, to minute precision, with the outlines of the rings so traced, the points graphically laid down falling on the pencilled outlines. The graphical construction of these curves is rendered easy by the well-known property of the lemniscate, in which the rectangle under two lines P A × P ' A drawn from the poles to any point A in the periphery is invariably throughout the whole curve. This is easily shown from the above equation, and the value of this constant rectangle in any one curve is represented by a × b.

When we shift from one ring to another, a remains the same, because the poles are the same for all. To determine the variation of b, let the rings be illuminated with homogeneous light, (or viewed through a red glass,) and outlined by projection, as above. Then, if we determine the actual value of a b by measuring the length of two lines P A, P ' A drawn from P, P ' to any point of each curve; and, calculating their product, (to which a b is equal,) it will be found that this product, and therefore the parameter b, increases in the arithmetical progression 0, 1, 2, 3, 4, &c. for the several dark intervals of the rings beginning at the pole, and in the progression 3, 3, 3, &c. for the brightest intermediate spaces. To ensure accuracy, the mean of a number of values of P A × P ' A, at different points of the periphery, may be taken to obviate the effect of any imperfection in the crystal.

This, then, is the law of the magnitudes of the successive rings formed by one and the same plate. But if we determine the value of the same product for plates of nitre similarly cut, but of different thicknesses, or of the same reduced in thickness by grinding, it will be found to vary inversely as the thickness of the plate, ceteris paribus.

The colours of the polarized rings bear a great analogy to those reflected by thin plates of air, and in most crystals would be precisely similar to them but for a cause presently to be noticed. In the situation of the tourmaline plates here supposed (crossed at right angles) they are those of the reflected rings, beginning with a black centre, at the pole. If examined in the situation of fig. 179, and traced in a line from either pole cutting across the whole system, at right angles to the line joining the poles, they will almost precisely follow the Newtonian scale of tints. For the present we will suppose that they do so in all directions. It is evident, then, that each particular tint (as the bright green of the third order, for instance) will be disposed in the form of a lemniscate, and will have its own particular value of the product a b. The tint, then, may be said to be corresponding to,—dependent on,—or, if we will, measured by a b. In conformity with this language the coloured curves have been termed, and not inaptly, isochromatic lines. Now, in the colours of thin plates, we have seen that these tints arise from a law of periodicity to which each homogeneous ray is subject; and that (without entering at this moment into the cause of such periods) the successive maxima and minima of each particular coloured ray passed through, in the scale of tints, correspond to successive multiples by $\frac{1}{3}$, $\frac{1}{3}$, $\frac{1}{3}$, &c. of the period peculiar to that colour. In the colours of thin plates, the quantity which determines the number of periods is the thickness of the plate of air, or other medium traversed; and the number of times a certain standard thickness peculiar to each ray is contained therein, determines the number of periods, or parts of a period, passed through. In the colours, and in the case now under consideration, the number of periods is proportional to the product ($\theta \times \theta'$) of the distances from either pole, for one and the same thickness of plate,—and for different plates to $t$ the thickness,—and, therefore, generally, to $\theta \times \theta' \times t$, provided we neglect the effect of the inclination of the ray in increasing the length of the path of the rays within the crystal, or regard the whole system of rings as confined within very narrow limits of incidence.

This condition obtains in the case here considered, because of the proximity of the axes in nitre to each other and to the perpendiculars to the surfaces of the plate. But in crystals such as mica, or others where they are still wider asunder, it is not so; and the projection of the isochromatic curves on a plane surface will deviate materially from their true form, which ought to be regarded as delineated on a sphere having the eye, or rather a point within the crystal, for a centre. In such a case, it might be expected that the usual transition from the arc to its sine should take place; and that, instead of supposing the tint, or value of a b, to be proportional simply to $\theta \times \theta'$, we ought to have it proportional to $\sin \theta \times \sin \theta' \times t$, the sine of the angle of refraction, and $t$ the thickness of the plate. We have then, if we put $n$ for the number of periods corresponding to the tint a b for the ray in question, and suppose $h = \frac{a b}{n}$, or the unit whose multiples determine the order of the rings, we shall have

$$n \cdot a b = \frac{t}{h},$$

$$\sin \theta \times \sin \theta' \times \sec \rho,$$

and

$$h = \frac{t}{\sec \rho \times \cos \rho},$$

$$\sin \theta \times \sin \theta'.$$
Light means presently to be noticed, the succession of tints exhibited by the mica was that of a section of the rings in fig. 182, made by a line drawn through both the poles. To render the observation definite, a red glass was interposed so as to reduce the rings to a succession of red and black bands, and the angles of incidence corresponding to the maxima and minima of the several rings very accurately measured. These are set down in Col. 2 of the following table. Col. 1 contains the values of \( n \), \( \theta \) corresponding to the pole, \( \frac{1}{2} \) to the first maximum, \( 1 \) to the first minimum, \( \frac{3}{2} \) to the second maximum, and so on. The third column contains the angles of refraction computed for an index 1.500; the fourth and fifth, those of \( \theta \) and \( \theta' \); the sixth, those of \( h \) deduced from the above equation, and which ought to be constant. The excesses above the means are stated in the last column, and show how very closely that equation represents the fact. The thickness of the mica was 0.023078 inches = \( t \).

909. General establishment of the law.

By an equation depending only on the nature of the crystal and the ray, were the crystal of a spherical form, instead of a parallel plate, \( t \cdot \sec \rho \), which represents the path traversed by the ray within it, must be replaced by a constant equal to the diameter of the sphere, and in that case the tint would be simply proportional to the product of the sines of \( \theta \) and \( \theta' \). This elegant law is due to M. Biot, though it is to Dr. Brewster's indefatigable and widely extended research that we owe the general development of the splendid phenomena of the polarized rings in biaxal crystals. It appears, then, from this, that if, on the surface of a sphere formed of any crystal, curves analogous to the lemniscate, or having \( \sin \theta \cdot \sin \theta' \) constant for each curve, and varying in arithmetical progression from curve to curve, be described,—then, if the sphere be turned about its center in a polarized beam, as above described, the tint polarized at every point of each curve will be the same, and in passing from curve to curve will obey the law of periodicity proper to the crystal.

There is hardly any character in which crystals differ more widely than in the angular separation of the optic axes, as the table annexed to the end of this article will show. This, while it affords most valuable criteria to the chemist and mineralogist, in discriminating substances and pointing out differences of structure and composition which would otherwise have passed unnoticed, renders the investigation of their phenomena difficult, since it is frequently impossible, by any contrivance, to bring both the axes under view at once; and necessitates a variety of artifices to obtain a sight of the rings about both. It is often very easy to cut and polish crystallized bodies in some directions, and very difficult in others. However, by immersing plates of them in oil, and turning them round on different axes, or by cementing on their opposite sides prisms of equal refracting angles oppositely placed, as in fig. 184, we may look through them at much greater obliquities than without such aid; and thus, by increasing the range of vision to nearly a hemisphere, avoid in most instances the necessity of cutting them in different directions.

When the two axes coalesce, or the crystal becomes uniaxial, the lemniscates become circles; and the black hyperbolic lines, passing through the poles, resolve themselves into straight lines at right angles to each other, forming a black cross passing through the centre of the rings, as in fig. 185. In this case the tint is represented by \( t \cdot \sin \theta \); and in the case of plates, where \( t \), the thickness, is considerable, or where, from the otherwise peculiar nature of the substance the rings are of small dimensions, \( \theta \) is small, and therefore proportional to its sine; so that in passing from ring to ring \( \theta' \) increases in arithmetical progression. Hence the diameters of the rings are as the square roots of the numbers 0, 1, 2, 3, &c.; and therefore their system is similar, with the exception of the black cross, to the rings seen between object-glasses. Carbonate of lime cut into a plate at right angles to the axis of its primitive rhomboid, exhibits this phenomenon with the utmost beauty. The most familiar instance, however, may be found in a sheet of clear ice about an inch thick frozen in still weather. A pane of window-glass, or a polished table to polarize the light, a sheet of ice freshly taken up in winter.
produce the rings, and a broken fragment of plate glass to place near the eye as a reflector, are all the apparatus required to produce one of the most splendid of optical exhibitions.

If $\theta$ be not very small, the measure of the tint, instead of $t \cdot \sin \theta$, is $t \cdot \sec \rho \cdot \sin \theta$. We have seen that in uniaxial crystals, $\sin \theta$ is proportional to the difference of the squares of the velocities $v$ and $v'$ of the ordinary and extraordinary ray, or to $v^2 - v'^2$. Now, if we denote by $t$ and $v'$ the times taken by these two rays to traverse the plate, we have $v = \frac{t \cdot \sec \rho}{\tau}$ and $v' = \frac{t \cdot \sec \rho}{\tau'}$; therefore $t \cdot \sec \rho \sin \theta$ is proportional to

$$\left(\frac{1}{v^2} - \frac{1}{v'^2}\right) \left(\frac{1}{\tau^2} + \frac{1}{\tau'^2}\right),$$

that is, to

$$\left(\frac{1}{\tau^2} + \frac{1}{\tau'^2}\right)$$

or (which is the same thing) to $(v + v') \cdot v' (\tau - \tau')$. But, neglecting the squares of very small quantities, of the order $v' - v$ and $\tau - \tau'$, for such they are in the immediate neighbourhood of the axis, the factors $v + v'$ and $v' \tau'$ are constant; so that the tint is simply proportional to $\tau - \tau'$, the difference of times occupied by the two rays in traversing the plate; or the interval of retardation of the slower ray on the quicker. This very remarkable analogy between the tints in question and those arising from the law of interferences, was first perceived by Dr. Young; and, assisted by a property of polarized light soon to be mentioned, discovered by Messrs. Arago and Fresnel, leads to a simple and beautiful explanation of all the phenomena which form the subject of this section, and of which more in its proper place.

The forms of the rings are such as we have described, only in regular and perfect crystals; every thing which disturbs this regularity, distorts their form. Some crystals are very liable to such disturbances, either arising from an imperfect state of equilibrium, or a state of strain in which the molecules are retained, or to actual interruptions in their structure. Thus, specimens of quartz and beryl are occasionally met with, in which the single axis usually seen is very distinctly separated into two, the rings instead of circles have oval forms, and the black cross (which in cases of a well developed single axis remains quite unchanged during the rotation of the crystallized plate in its own plane) breaks into curves convex towards each other, but almost in contact at their vertices, at every quarter revolution.

Cases of interruption occur in carbonate of lime very commonly, and in muriacite perpetually; and the effects produced by them on the configurations of the rings rank among the most curious and beautiful of optical phenomena. They have not, however, been anywhere described, and our limits will not allow us to make this article a vehicle for theirdescription.

The form of the rings being, then, considered, let us next inquire more minutely into their colours. These being all composite, and arising from the superposition on each other of systems of rings formed by each homogeneous ray, we can obtain a knowledge of their constitution only by examining the rings in homogeneous light. This is easy, for we have only to illuminate the apparatus described above by homogeneous light of all degrees of refrangibility from red to violet, by passing a prismatic spectrum from one end to the other over the illuminating lens H, the eye being applied as usual at O, and observe the changes which take place in the rings, in passing from one coloured illumination to another; and, if necessary, measure their dimensions. This is readily done, either by projecting them on a screen in a darkened room, as described in Art. 903, or by detaching the lens H, fig. 178, and simply looking through the apparatus at a sheet of white paper strongly illuminated by the rays of a prismatic spectrum, where the rings will appear as if depicted on the paper, and their outlines easily marked, or their diameters measured. The following are the general facts which may thus be readily verified:

First, in the case of crystals with a single axis, the rings remain circular, and their centres are coincident for all the coloured rays, but their dimensions vary. In the generality of such crystals, their diameters for different refrangibilities follow nearly the law of the Newtonian rings, when viewed in similar illuminations; their squares (or rather the squares of their sines) being proportional, or nearly so, to the lengths of the fits, or of the undulations of the rays forming them. This law, however, is very far from universal; and in certain crystals is altogether subverted. Thus, in the most common variety of apophyllite, (from Cipit, in the Tyrol, —not from Fassa, as is commonly stated,) the diameters of the rings are nearly alike for all colours, those of the green rings being a little less; those formed by rays at the confines of the blue and indigo exactly equal, and those of violet rays a little greater than the red rings. It is obvious, that were the rings of all colours exactly equal, the system resulting from their superposition would be simple alternations of perfect black and white, continued ad infinitum. In the case in question, so near an approach to equality subsists, that the rings in a tourmaline apparatus appear merely black and white, and are extremely numerous, no less than thirty-five having been counted, and many of those too close for counting being visible in a thick specimen.

When examined more delicately, colours are, however, distinguished, and are in perfect conformity with the law stated, being for the first four orders as follow:

First order. Black, greenish white, bright white, purplish white, sombre violet blue.
Second order. Violet almost black, pale yellow green, greenish white, white, purplish white, obscure indigo inclining to purple.
Third order. Sombre violet, tolerable yellow green, yellowish white, white, pale purple, sombre indigo.
Fourth order. Sombre violet, livid grey, yellow green, pale yellowish white, white, purple, very sombre indigo, &c.

Carbonate of lime, beryl, ice, and tourmaline (when limpid) are instances of uniaxial crystals, in whose rings the Newtonian scale of tints is almost exactly imitated; and, consequently, the intervals of retardation of the ordinary and extraordinary rays of any colour on one another, are proportional to the lengths of their undulations.

On the other hand, in the hyposulphate of lime, we are furnished with an instance of more rapid
The degradation of tints, and therefore of a more rapid variation of the interval just mentioned. The following was the scale of colour of the rings observed in this remarkable crystal:

First order. Black, very faint sky blue, pretty strong sky blue, very light bluish white, white, yellowish white, bright straw colour, yellow, orange yellow, fine pink, sombre pink.

Second order. Purple, blue, bright greenish blue, splendid green, light green, greenish white, ruddy white, pink, fine rose red.

Third order. Dull purple, pale blue, green blue, white, pink.

Fourth order. Very pale purple, very light blue, white, almost imperceptible pink.

After which the succession of colours was no longer distinguishable.

A degradation still more rapid has been observed in certain rare varieties of uniaxal apophyllite, accompanied with remarkable and instructive phenomena. In these, the diameters of the rings (instead of diminishing as the refrangibility of the light of which they are formed increases) increase with great rapidity, and actually become infinite for rays of intermediate refrangibility; after which they again become finite, and continue to contract up to the violet end of the spectrum, where, however, they are still considerably larger than in the red rays. In consequence of this singularity, their colours when illuminated with white light furnish examples of a complete inversion of Newton's scale of tints. The following were the tints exhibited by two varieties of the mineral in question, in one of which the critical point where the rings become infinite took place in the indigo, and in the other in the yellow rays. In the former they were

First order. Black, sombre red, orange, yellow, green, greenish blue, sombre and dirty blue.

Second order. Dull purple, pink, ruddy pink, pink yellow, pale yellow (almost white,) bluish green, dull pale blue.

Third order. Very dilute purple, pale pink, white, very pale blue.

In the latter variety, the tints were

First and only order. Black, sombre indigo, indigo inclining to purple, pale lilac purple, very pale reddish purple, pale rose red, white, white with a hardly perceptible tinge of green.

The doubly refracting energy of a crystal may be not improperly measured by the difference of the squares of the velocities of an ordinary and extraordinary ray similarly situated with respect to the axes; but as this difference, for rays variously situated in one and the same crystal, is proportional to \( \sin \theta^f \) or in biaxal crystals to \( \sin \theta^f \cdot \sin \theta^f' \), the intrinsic double refractive energy of any crystal may be represented by

\[
\epsilon = \frac{v^f - v'^f}{\sin \theta^f \cdot \sin \theta^f'};
\]

regarding this henceforth as the definition of this energy, we have, in uniaxal crystals, \( \epsilon = \frac{v^2 - v'^2}{\sin \theta^2} \), and this will evidently measure the actual amount of separation of two such rays when emergent from the crystal.

If in this we put for \( v \) and \( v' \) their equals \( \frac{1}{\sec \rho} \) and \( \frac{1}{\sec \rho'} \), we shall have, after reduction,

\[
v^2 - v'^2 = v \cdot v' \cdot (v + v') \cdot \frac{\tau' - \tau}{\tau \cdot \sec \rho}.
\]

In a parallel plate, perpendicular to the axis and in the immediate vicinity of the axis, \( \tau' \) and \( \sec \rho \) may be regarded as constant, and \( v^2 - v'^2 \) is proportional to \( \tau' - \tau \), the interval of retardation of one ray on the other, to which the tint in white light and the number of periods and parts of a period in homogeneous light (to which, for brevity, we will continue to extend the term tint) are proportional. We see, then, that in such cases the intrinsic double refractive energy is directly as the tint polarized, and inversely as \( \sin \theta^f \), and therefore also inversely as the squares of the diameters of the rings. As the rings increase in magnitude, then, \( \epsilon \) and the double refractive energy diminishes; and hence a very curious consequence follows, viz. that in the two cases last mentioned it vanishes altogether for those colours where the rings are infinite; in other words, that although the crystal be doubly refractive for all the other coloured rays, there is one particular ray in the spectrum (viz. the indigo in the former, and the yellow in the latter case) with respect to which its refraction is single. In the passage through infinity, there is generally a change of sign. In the instances in question this change takes place in the value of \( \epsilon \) or \( v^2 - v'^2 \), which passes from negative to positive. And the spheroid of double refraction changes its character accordingly from oblate to prolate, passing through the sphere as its intermediate state. The manner in which this may be recognised, without actually measuring, or even perceiving its double refraction, will be explained further on.

For crystals with two axes we have only, at present, the ground of analogy to go upon in applying the above formula and phraseology to their phenomena. The general fact of an intimate connection of the double refracting energy with the dimensions of the rings, is indeed easily made out; for it is a fact easily verified by experiment, that all crystals, whether with one or two axes, in which the rings or lemniscates formed are of small magnitude in respect of the thickness of the plate producing them, are powerfully doubly refractive, and vice versa; and that, generally speaking, the separation of the ordinary and extraordinary pencils is, \( \epsilon \) et cetera paribus, greater in proportion as the rings are more close and crowded round their poles. In uniaxal crystals, in which the laws of double refraction are comparatively simple, there is little difficulty in submitting the point to the test of direct experiment and exact measurement, and it is found to be completely verified. In biaxal, however, such precise and direct comparison is more difficult, and calls for a knowledge of the general laws of double refraction. The analogy, however, supported by the general coincidence above mentioned, is too strong to be refused; and, as we advance, will be found to gain strength with every step.
Light. In biaxal crystals, similar deviations from exact proportionality between the lengths of the periods of the several coloured rays and those of their undulations, or fits, exist; but their effect in disturbing the colours of the rings is much modified, and frequently masked by another cause, which has no existence in uniaxial crystals, viz. that the optic axes differ in situation, within one and the same crystal for the differently refrangible homogeneous rays; and, therefore, that the elementary lemniscates, whose superposition forms the composite fringes seen in a white illumination, differ not only in magnitude but in the places of their poles and the intervals between them. To make this evident to ocular inspection, take a crystal of Rochelle salt, (tartrate of soda and potash,) and having cut it into a plate perpendicular to one of its optic axes, or nearly so, and placed it in a tourmaline apparatus, let the lens H be illuminated with the rays of a prismatic spectrum, in succession, beginning with the red and passing gradually to the violet. The eye being all the time fixed on the rings, they will appear for each colour of perfect regularity of form, remarkably well defined, and contracting rapidly in size as the illumination is made with more refrangible light; but in addition to this, it will be observed, that the whole system appears to shift its place bodily, and advance regularly in one direction as the illumination changes; and if it be alternately altered from red to violet, and back again, the pole, with the rings about it, will also move backwards and forwards, vibrating, as it were, over a considerable space. If homogeneous rays of two colours be thrown at once on the lens, two sets of rings will be seen, having their centres more or less distant, and their magnitudes more or less different, according to the difference of refrangibility of the two species of light employed.

Since the plate in this experiment is supposed to have its surfaces perpendicular to the mean position of the optic axis, the cause of these appearances cannot be found in a mere apparent displacement of the rings by refraction at the surface, existing to a greater extent for the violet than the red rays, add to which, that the angle which their poles describe, is neither the same in magnitude nor direction for different crystals. In some, the optic axes approach each other in violet light, and recede in red; while in others the reverse is the case. In all, however, so far as we are aware, the optic axes for all the coloured rays lie in one plane, viz. the principal section of the crystal. This is rendered matter of inspection by cutting any crystal so that both axes shall be visible in the same plate, and placing it with its principal section in the plane of primitive polarization. In this state of things, the first ring about each pole, as in fig. 179, is seen divided into two halves, and puts on, if the plate be pretty thick, the appearance of two semi-elliptic spots, one on each side of the principal section. These spots are observed to be differently coloured at their two extremities: in some crystals the ends of the spots, as well as the segments of the rings adjacent to them, which are turned towards each other, being coloured red, and the other, or more distant ends, with blue; and in others, the reverse. In some crystals this coloration is slight, and in a very few, imperceptible; but in others it is so great, that the spots are drawn out into long spectra, or tails of red, green, and violet light; and the ends of the rings are in like manner distorted and highly coloured, presenting the appearance in fig. 186. This is the case with Rochelle salt, Fig. 186. above mentioned. If these spectra be examined with coloured glasses, or with homogeneous light, they will be seen to be composed as in fig. 187, by the superposition of well defined spots of the several simple colours arranged in lines on each side of the principal section. In the case of Rochelle salt, the angular extent of these spectra, within the medium, which measures the interval between the optic axes for violet and red rays, amounts to no less than 10°.

Dr. Brewster has given the following list of crystals presenting these phenomena, which he has divided into two classes, according to his peculiar and ingenious views.

Class I.

| Nitre. | Chromate of lead. |
| Sulphate of baryta. | Muriate of mercury. |
| Sulphate of strontia. | Muriate of copper. |
| Phosphate of soda. | Oxynitrate of silver. |
| Tartrate of potash and soda. | Sugar. |
| Supertartrate of potash and soda. | Crystallized Cheltenham salts. |
| Carbonate of lead. (?) | Nitrate of zinc. |
| Sulphato-carbonate of lead. | Nitrate of lime. |

Class II.

| Topaz. | Superoxalate of potash. |
| Mica. | Oxalic acid. |
| Anhydrite. | Sulphate of iron. |
| Native borax. | Carbonate of lead. (?) |
| Sulphate of magnesia. | Cyanophane. |

To which list a great many more might be added. Bicarbonate of ammonia, indeed, is the only biaxial crystal we have examined in which the optic axes for all colours appear to be strictly coincident.

This separation of the axes of different colours explains a remarkable appearance presented by the rings of all biaxial crystals, when placed with their principal section 45° inclined to the plane of polarization of the incident of the violet-light. It is universally observed that, in traversing the whole system of rings in the plane of the principal poles explained.

Part IV.

Separation of the optic axes of differently refrangible rays in biaxal crystals.

Dr. Brewster's list of crystals exhibiting deviations of tint from this cause.

| Native borax. |
| Sulphate of baryta. |
| Muriate of mercury. |
| Muriate of copper. |
| Oxynitrate of silver. |
| Sugar. |
| Crystallized Cheltenham salts. |
| Nitrate of mercury. |
| Nitrate of zinc. |
| Nitrate of lime. |
| Superoxalate of potash. |
| Oxalic acid. |
| Sulphate of iron. |
| Carbonate of lead. (?) |
| Cyanophane. |
| Felspar |
| Benzoic acid. |
| Chromic acid. |
| Nadelstein (Faröe.) |
section, the nearest approximation to Newton's scale of colours is obtained by assuming, for the origin of the scale, not the poles themselves, but other points (which have been called virtual poles, though improperly) lying either between or beyond them, according to the crystal examined, and at a distance from them, inva-

riable for each species of crystal, whatever be the thickness of the plate. In consequence, the poles themselves are not absolutely black, but tinged with colour; and their tint descends in the scale as the thickness of the plate increases, and as, in consequence, one, two, or more orders of rings intervene between them and the points from which the scale originates. These points are observed to lie between the poles in all crystals which have the blue axes nearer than the red, such as Rochelle salt, borax, mica, sulphate of magnesia, topaz; and beyond them for those in which the red axes include a less angle than the blue, as sulphate of baryta, nitre, aragonite, sugar, hyposulphite of strontia; and this fact, as well as the constancy of their distance from the poles when the thickness of the plate is varied, renders their origin evident. In fact, since the violet rings are smaller than the red, if the centre about which the former are described, instead of being coincident with that of the latter, be shifted in either direction, carrying its rings with it, some one of the violet rings will necessarily be brought up to, and fall upon a red ring of the same order; and the same holding good with the intermediate rings, provided the law which determines the separation of the different coloured axes be not very different from that which regulates the dimensions of the rings of corresponding colours, the point of coincidence of a red and violet ring of the same order will be nearly that of a red and green, or any intermediate colour. The tint, then, at this point will be either absolutely black, (if they be dark rings which are thus brought to coincidence,) or white, if bright; and from this point the tints will reck on either way with more or less exactness, according to the same scale which would have held good had the points of coincidence been the poles themselves. Should, however, the two laws above mentioned differ very widely, an uncorrected colour will be left at the point of nearest compensation, just as happens when two prisms whose scales of dispersion are dissimilar are employed to a chromatic effect.

To what an extent the disturbance of the Newtonian scale of tints may be carried by this and the other causes already explained, the reader may see by turning to the table of tints exhibited by Rochelle salt in Phil. Trans. 1820, part 1.

We come next to consider the law of the intensity of the illumination of the rings in different parts of their periphery; but this part of their theory will require us to enter more fundamentally into the mode in which their form is effected, and to examine what modifications the polarized ray incident on the crystallized plate undergoes in its passage through it, so as to present phenomena so totally different from those which it would have offered without such intervention. It is evident then, first, that since the ray, if not acted on by the plate, would have been entirely stopped by the second tourmaline, but, when so acted on, is partially transmitted so as to exhibit coloured appearances of certain regular forms; that the crystallized plate must have either destroyed altogether the polarization of that part of the light which is thereby enabled to penetrate the second tourmaline, or, if not, must have altered its plane of polarization, so as to allow of a partial transmission. Between these two suppositions it is not difficult to decide. Were the portion of light which passes through the second tourmaline and forms the rings wholly depolarized, that is, restored to its original state of natural light, since the remainder, its complement to unity, which continues to be stopped by the tourmaline, retains its state of polarization unaltered, it is evident, that each ray at leaving the crystallizing plate would be composed of two portions, one unpolarized (== A), the other (== 1 – A) polarized. Of these, the half only of the first (== A) would be transmitted by the second tourmaline. Now, suppose this to be turned round in its own plane through any angle (= a) from its original position, then the unpolarized portion will continue to be half transmitted; and the polarized, being now partially also transmitted, (in the ratio of sin^2 a : 1,) will mix with it, so that the compound beam will be represented by

\[ \frac{1}{2} A + (1 - A) \cdot \sin^2 a = \sin^2 a \cdot \frac{1}{2} + \frac{1}{2} A, \cos 2 a. \]

Now, if we suppose a to pass in succession through the values 0, 45°, 90°, 135°, 180°, &c., this will become respectively \( \frac{1}{2} A, \frac{1}{2}, - \frac{1}{2} A, \frac{1}{2}, \frac{1}{2} A, &c. \). Hence, at every quarter revolution the tints ought to change from those of the reflected rings to those of the transmitted, the complements of the former to white light; and at every half quarter revolution no rings at all should be seen, but merely an uniformly bright field illuminated with half the intensity of light which would be seen were the second tourmaline altogether removed.

The phenomena which actually take place are very different. At the alternate quadrants, it is true, the complementary rings are produced, and the appearance is as represented in fig. 188. The black cross is seen changed into a white one; the dark parts of the rings become the bright ones; the green is changed into red, and the red into green, &c.; so that if we were to examine no farther, the fact would appear to agree with the hypothesis. But in the intermediate half quadrants, this agreement no longer subsists. Instead of a uniformly illuminated field, a compound set of rings, consisting of eight compartments, alternately occupied by the primary and complementary set, is seen, presenting the appearance of fig. 191, and which is further described in Art. 935.

The phenomena then are incompatible with the idea of depolarization. It remains to examine what account can be given of them on the supposition of a change of polarization operated by the plate; and here we must remark in limine, that this cause is what in Newton's language would be termed a vera causa, a cause actually in existence; for we have already seen that every ray, whether polarized or not, traversing a double refracting medium in any direction, except precisely along its axis, is resolved into two, polarized in opposite planes. When the incident ray is polarized, these portions (generally speaking) differ in intensity, and though, owing to the parallelism of the plate they emerge superposed, their polarization is not the less real, and either of them may be suppressed, and the other suffered to pass, by receiving them on a tourmaline properly situated. This is so far
agreeable to the observed fact, when the tourmaline plate next the eye is removed, the rays of which the two sets of rings consist, coexist in the transmitted cone of rays whose apex is the eye, but, being complementary to each other, produce whiteness. This may be made matter of ocular demonstration, by employing, instead of a tourmaline, which absorbs one image, a doubly refracting achromatic prism, of sufficiently large refracting angle, to separate the two pencils by an angle greater than the apparent diameter of the system of rings, when the primary set will appear in one image, and its complementary set in the other; meanwhile, to refresh our tourmalines, since the two sets of rings seen in the two positions of the posterior tourmaline are complementary, it follows, that all the rays suppressed in one position are transmitted in that at right angles to it, and vice versa; and, as a necessary consequence, that every pair of corresponding rays in the primary and complementary set are polarized in opposite planes.

The only thing, then, which appears mysterious in the phenomena thus conceived, is the production of colour. A doubly refracting crystal, which receives a polarized ray of whatever colour, divides it between its two pencils, according to a ratio dependent only on the situation of the planes of polarization and of incidence, and of the axes of the crystal, and not at all on its refrangibility. How then happens it, that at certain angles of incidence the red rays pass wholly into one image, and the green or violet into the other, while at other incidences the reverse takes place: whence, in short, arises the law of periodicity observed. To answer this question, M. Biot imagined his theory of alternate, or as he terms it movable polarization, according to which, as soon as a polarized ray enters into a thin crystallized lamina, its plane of polarization commences a series of oscillations, or rather alternate assumptions per saltum of two different positions, one in its original plane, the other in a plane making with that plane double the angle which the principal section of the crystal makes with it. These alterations suppose to be more frequent for the more refrangible rays, and to recur periodically, like Newton’s fits of easy reflection and transmission, at equal intervals all the time the ray is traversing the crystal, which intervals are shorter the more inclined its path is to the axis or axes. This theory is remarkably ingenious in its details; and in its application to the phenomena of the rings, though open (as stated by its author) to certain obvious criticisms, is yet, we conceive, capable of being regarded as a faithful representation of most of their leading features. There is, however, one objection against it of too formidable a nature to allow of its being received unless explained away, if any other can be devised not open to the same or greater. It is, that it requires us to consider the action of a thin crystal on light as totally different, not merely in degree, but in kind, from that of a thick one, while yet it marks no limit by which we are to determine where its action as a thin crystal ceases, and that proper to a thick one commences, nor establishes any gradations by which one mode of action passes into the other. A thick crystal, as we know, polarizes the rays ultimately emergent from it in two planes, dependent only on the position of the crystal and that of the ray, while M. Biot’s theory makes the position of the plane of polarization of the incident ray an element in determining their ultimate polarization by a thin one. Nor are we in this theory to regard as thin crystals only films or delicate laminae. A plate of a tenth of an inch thick or more may be a thin plate in some cases of feebly polarizing bodies, such as apophyllite, &c.

As the apparatus employed by M. Biot for studying the phenomena of the colours of thin crystallized plates offers great conveniences for the measurement of the angles at which different tints are produced, and for their exhibition in their state of greatest purity and contrast, we shall here describe it, and state some of the chief results which he has arrived. A (fig. 189) is a plane glass blackened at the posterior surface, or a plate of obsidian inclined at the polarizing angle to the axis of a tube A B, so as to reflect along it a polarized ray; if greater intensity be required, we may use a pile of glass plates, taking care that they be of truly parallel surfaces, and passed exactly parallel to each other. B C is a tube of stiffly movable round A B as an axis, having a graduated ring at B, read off by a vernier attached to the tube A B, and carrying two arms, G and H, through which the axis of a swing frame E passes, which can thus be inclined at any angle to the common axis of the tubes, its inclination, or the angle of incidence of the ray reflected along the axis on the plane of the frame being read off on an index on the divided lateral circle D. In this frame is an aperture F, in which turns a circular plate of brass having a hole in its centre, over which is fastened with wax the crystallized plate to be examined, and which can thus be turned round in its own plane, independently of any motion of the rest of the apparatus, so as to place its principal section in any azimuth with respect to the plane of incidence. We have found it convenient to have this part of the apparatus constructed as in fig. 190, where a is the square plate of the frame; b a divided circle movable in it and read off by an index; c, d is a circular plate movable within the divided circle to admit of adjustment, after which it is fastened in its place by a little clamp, so as to turn with the circle; this carries in its centre another swinging circle e, moving stiffly on its axis, and having in the middle an aperture over which the crystal is inserted, thus giving room for an adjustment of the plane of the surface of incidence, in case it be not exactly at right angles to the principal section of the crystal, an adjustment very useful when artificial surfaces are under examination, which it is hardly possible to cut and polish with perfect precision. It is also convenient for some experiments to have a second frame similar to the first, placed on the prolongation of the arms G, H. M is a doubly refracting prism, rendered achromatic either by a prism of flint glass, or, still better, by another prism of the same doubly refracting medium. Two prisms of quartz, arranged as in Art. 892, are very convenient. Their angles should be such, that when placed at M the two images of a small aperture P, in a diaphragm near the end of the tube, should appear almost in contact. The prisms so adjusted are mounted on a stand N, independent of the other apparatus, and capable of being turned round by an arm K, carrying a vernier, by whose aid the angle of rotation, or position of the plane in which the double refraction takes place, can be read off on a divided circle L. The prism should be so adjusted in its cell, that when the vernier reads off zero, the extraordinary image should be extinguished; and when 90°, the ordinary. Occasionally a tourmaline plate or a glass reflector may be substituted for the prism.

To use this apparatus, the crystallized lamina (which we will at present suppose to be a parallel plate of any
Light.

Use of this apparatus.

The office of the doubly refracting prism is merely to analyze the emergent pencil, and separate the phenomena of movable polarization, and that we are even necessitated to admit it, provided we take it for granted, that the axis is the only line to which this property belongs, or to which all the rings are symmetrical. It is then evident, that, however the parts of the apparatus be disposed, 1st, the reading off of the vernier D will give the angle of incidence on the plate; 2d, that of the vernier B, the angle made by the plane of incidence with the plane of primitive polarization; 3d, that of the vernier C will indicate the angle included by any assumed section of the crystallized plate perpendicular to its plane with the plane of incidence; and, lastly, that the reading of the vernier K will give the angle between the plane of primitive polarization and the principal section of the doubly refracting prism.

931. Suppose now we adjust the vernier B to zero, it will then be found, that however the plate E be situated, or whatever be the incidence of the ray, only the ordinary image will be seen (being white,) the extraordinary being extinguished (or black.) In this case we traverse the system of rings in the direction of the vertical arm of the black cross, fig. 185, of the primary, and the white one of the complementary set, see fig. 188. The phenomena are the same if we set the vernier B to 90°, and then turn the frame E on its axis, thus varying the incidence in a plane at right angles to that of primitive polarization, or, which comes to the same thing, traversing the rings along the horizontal arm of the black and white crosses. In intermediate positions of the vernier B, we traverse the rings along a diameter, making an angle with vertical equal to the reading of the vernier. In this case the two images of P are both visible, and finely coloured; the extraordinary image presenting the tint of the primary rings due to the particular angle of incidence indicated by the vernier D; the ordinary, that of the complementary system corresponding to the same angle. The colours of the two images are thus seen in circumstances the most favourable, being finely contrasted and brought side by side, so as to be capable of the nicest comparison. It is when the vernier D reads 45°, or the plane of incidence is 45°, inclined to that of primitive polarization, that the contrast of the two images is at its maximum, the tints in the extraordinary image being then most vivid, and those in the ordinary free from any mixture of white light. In general, if A represent the light of the extraordinary image in the position above mentioned, and a the angle read off on the vernier B, in any other position of the plane of incidence, the two images in this new position (for the same angle of incidence) will be represented respectively by

\[ A \cdot (\sin 2 \alpha)^2, \quad 1 - A \cdot (\sin 2 \alpha)^2 \]

that is, by

\[ A \cdot (\sin 2 \alpha)^2, \quad 1 - A \cdot (\sin 2 \alpha)^2 + (1 - A) \cdot (\cos 2 \alpha)^2. \]

The former of these expressions indicates a ray whose tint is represented by A, and its intensity by (\sin 2 \alpha)^2; the latter, a complementary tint 1 - A of the same intensity, diluted with a quantity of white light, whose intensity is represented by (\cos 2 \alpha)^2.

These expressions represent with great fidelity the tints of both images, the intensity of the extraordinary, and the apparent degree of dilution of the ordinary one; and since a ray A polarized in a plane making an angle 2 \alpha with the principal section of the doubly refracting prism, would be divided between the extraordinary and ordinary image in the ratio of (\sin 2 \alpha)^2 : (\cos 2 \alpha)^2, it follows, that if we regard the pencil at its emergence from the crystallized plate as composed of two portions, one (= A) polarized in the above named plane, the other (= 1 - A) preserving its primitive polarization, the two pencils formed by the doubly refracting prism will be composed as follows:

<table>

Office of the doubly refracting prism or tourmaline.

which are identical with those above. Thus we see, that the facts are so far perfectly conformable to M. Biot's hypothesis of movable polarization, and that we are even necessitated to admit it, provided we take it for granted, that the rings exist actually formed and superposed in the pencil emergent from the crystallized lamina, and that the office of the doubly refracting prism is merely to analyze the emergent pencil, and separate the two sets from each other. But if the objection mentioned above against that doctrine be really well founded, this assumption cannot be correct, and we are then driven to conclude, that the doubly refracting prism, or tourmaline, or glass reflector, interposed between the eye and the crystallized plate, performs a more important office than merely to separate the tints already formed; and that, in fact, they are actually produced by its action,—the crystallized plate only preparing the rays for the process they are here finally to undergo.

933. To explain how this may be conceived to happen will form the object of another Section. Meanwhile we will here only add, that the transition from uniaxal to biaxial crystals is readily made. We have only to consider, that by varying the angle of incidence, (the line bisecting the angle between the optic axes being supposed perpendicular to the plane of the plate,) we cross the rings in a line passing through their centre of symmetry O, fig. 188, and making an angle with their principal diameter PP' equal to the angle read off on the vernier B, and that by turning the plate in its own plane, or varying the angle read off by the vernier C, we in effect make the system traversed pass through the successive states represented in fig. 179, 180, 181, 182, changing, not the tint, but the intensity of the extraordinary image.
When the doubly refracting prism is turned in its cell, the tints grow more dilute, and when placed in an azimuth $a$, that is, when its principal section is placed in the plane of incidence, both images are colourless, but of unequal brightness. This accords with M. Biot's doctrine of movable polarization; for if we grant that the pencil $A$ is polarized in a plane making an angle $2a$ with that of primitive polarization, it will make, now, an angle $a$ with that of the principal section of the prism, and $A$. $(\sin a)^2$ will be that part of the extraordinary image arising from the pencil $A$; on the other hand, the pencil $1-A$ retaining its original polarization, $(1-A) \sin a$ will be the portion of the extraordinary image produced by it in the new position of the prism, and the sum, or the whole image, will be simply $1 \times \sin a^2$, which being independent of $A$, or of the tint, indicates that the image is colourless. In the same manner it may be shown, that the ordinary image will equal $1 \times \cos a^2$, and their intensities will, therefore, be to each other as $\sin a^2$ to $\cos a^2$, and will be equal at $45^\circ$ of azimuth; all which is conformable to fact.

The motion of the prism in its cell corresponds to a rotation of the posterior tourmaline in its own plane in the tourmaline apparatus. The general appearance presented by the rings of a single axis, when this rotation is not a precise quadrant, is represented in fig. 191, and the succession of changes being as follows: At the first commencement of the rotation the arms of the black cross appear to dilate; they grow at the same time fainter, and segments of the complementary rings appear in them, whose bright intervals correspond to the dark ones of the primary set, their red to the green portions of that set, and vice versa. The junction of the two sets is marked by a faint white or undecided tint. As the rotation proceeds, the primary segments contract in extent, and become more dilute with white, while the secondary extend, and grow more decided; at the same time the centre of the system grows gradually bright, and when the rotation has attained $90^\circ$, the whole has assumed the appearance in fig. 188. The phenomena are precisely analogous in the rings of biaxial crystals. The least deviation from exact rectangularity in the tourmalines gives rise to complementary segments in the dark hyperbolic curves answering to the arms of the black cross, and to a corresponding contraction of the primary segments, which at last disappear altogether in the undistinguishable whiteness of a pair of white hyperbolas precisely similar to the black ones of the primary rings in their perfect state.

Hitherto we have considered the rings as so narrowed by the thickness of the plate, as to be all contracted within a compass round the poles which the eye can take in at once; but if the thickness be greatly diminished, this will no longer be the case; and, instead of rings of a distinguishable form, we shall see only broad bands of colour extending to great distances from the poles, and even visible when the axes themselves are so much inclined to the surfaces of the plate as to be quite out of sight; or even when the axes actually lie in the plane of the plate. This is the case with the lamina into which sulphate of lime readily splits; the axes lie in their plane, so that to see the rings in them, we must form artificial surfaces perpendicular to the lamina, a difficult and troublesome operation, from the extreme softness and fissile nature of the substance. The phenomena of the colours of this crystal were early studied, and almost of necessity misconceived, till Dr. Brewster, by exhibiting the real axes, showed that they form only a particular case of the general phenomena we have already dwelt on.

Adhering to the denominations employed in Art. 885—888, let us call the plane containing the two axes, the section $A$; that perpendicular to it, and passing through the line which bisects their lesser included angle, the section $B$; and that which similarly passes through the line bisecting their greater included angle, and is perpendicular to both the others, the section $C$. If the crystal have but one axis, the sections $A$ and $B$ pass through it, and $C$ is at right angles to it. Then if the lamina contains both axes, its plane will be that of the section $A$, and the other two sections will intersect it in two lines ($B$ and $C$) at right angles to each other. Conceive, now, a polarized ray to pass through such a lamina at a perpendicular incidence. Then if the plane of polarization coincide with either of the sections $B$ and $C$, its polarization will be undisturbed, and the whole of the transmitted light will pass into the ordinary image. But if the plate be turned round in its own plane, the extraordinary image will reappear and become a maximum at every $45^\circ$ of the plate's rotation; and if it be sufficiently thin, will exhibit some one of the colours of the rings, and the tints will descend regularly in the scale as the thickness is increased, the thickness being a measure of the tint, conformably to the general law in Art. 907, of which this is only a particular case.

When two such plates are laid together, with their sections $B$ and $C$ corresponding, it is evident that they are in the same relation as if they formed part of one and the same crystal; and we might therefore expect to find what really happens, viz. that such a compound plate polarizes the same tint that a single plate equal to the sum of the thicknesses would do. But if they be crossed, i.e. laid so together that the section $B$ of the one shall coincide with the section $C$ of the other, M. Biot has shown that the tint polarized is that due to the difference of their thicknesses. If, therefore, this difference is exactly nothing, the crossed plates will be exactly neutralized, at least at a perpendicular incidence, and that whatever be their thickness. (To procure two plates of exactly the same thickness, we have only to choose a clear and truly parallel plate terminated by fresh surfaces of fissure, and break it across.)

When, however, the incidence is not perpendicular, such a compound plate as described will still exhibit colours which vary in, apparently, a very irregular manner as the incidence changes, and with different degrees of rapidity in different planes. The tourmaline apparatus here renders signal service in rendering the law of these tints, at first sight extremely puzzling, a matter of inspection. When such a crossed plate is placed between the tourmalines, crossed at right angles, it exhibits the singularly beautiful and striking phenomenon represented in fig. 192, in which the tints are those of the reflected scale of Newton, the origin being in the black cross. If the tourmalines be parallel, the complementary colours are produced with equal regularity, as in fig. 198. If the compound crystal be turned round in its own plane, the figures turn with it, but undergo no change other than an alternation of intensity, being at a maximum of brightness when the arms of the cross are parallel and
perpendicular to the plane of original polarization, and vanishing altogether when they make angles of 45° with that plane. If the plates be not crossed exactly at right angles, or be not precisely of equal thickness, other phenomena arise which it is easier for the reader to produce for himself than to read a detailed account of. The same may be said of the very splendid but complicated phenomena produced by crossing two equally thick plates of biaxial crystals, such as mica, topaz, &c. having the section A at right angles to their surfaces.

940. Law of tints formed by the superposition of similar plates.

Regarding, however, at present only the tint produced at a perpendicular incidence, it is found that when any number of plates of one and the same medium, of any thicknesses, are superposed with their homologous sections corresponding, the tint polarized is that due to the sum of their thicknesses; but when any one or more of them have their sections B and C at right angles to the homologous sections of the others, the tint is that due to the sum of the thicknesses of those placed one way, minus the sum of those of the plates placed the other way. In algebraical language, if we call, t, t', t", &c. the thicknesses, and regard as negative those of the plates laid crosswise, the tint T polarized by the system will be that due to the thickness t + t' + t" + &c.

When the ray is made to traverse a plate of quartz, zircon, carbonate of lime, or any other uniaxial crystal cut so as to contain the axis of double refraction, the same law of the tints holds good, the tint T being proportional to the thickness t of the plate, and for any given plate we have $T = kt$, k being a constant depending on the nature of the plate. Now, if several plates of different uniaxal crystals be superposed, of which t, t', &c. are the thicknesses, and if a negative value of t is supposed to denote a transverse position of the axis of the plate, the resultant tint will be represented by $T = k (t + t' + t" + &c.)$.

942. Opposite action of plates of positive and negative crystals.

In this equation, if the plates be all of one substance, k, k', &c. are all alike; but if they be different, k is to be regarded as a negative quantity for all such crystals as belong to M. Biot's repulsive class, (Art. 803,) such as carbonate of lime; and positive for all such (quartz, for instance) which belong to his positive class. Thus, each term in the above equation may change its sign from two causes, either from a change in the nature of the crystal, or from a change of 90° in its azimuth. The above is only a particular case of a more general law which may be thus announced,—The tint ultimately produced is proportional to the interval of acceleration or retardation of the ordinary ray on the extraordinary, after traversing the whole system; the partial acceleration or retardation in each plate being proportional to the length of the path described within the plate, multiplied by the square of the sine of the angle which the transmitted ray makes, internally, with the optic axis of the plate, if it have but one axis, or to the product of the sines of its inclination to either, if it have two; and this law holds good for all positions of the plates, and all arrangements of them one among the other. Thus (to instance its application) in the case of two similar and equal plates crossed at right angles; by the laws of polarization, the ray which, after its transmission through the first plate is ordinary, is refracted extraordinarily by the second, and vice versa; but the two rays, on entering the second plate exchange velocities; and, therefore, when finally emergent, since the thickness of the second is equal to that of the first, the one ray will have lost ground on the other in its second transmission just as much as it gained it in its first; and thus the interval of retardation and the tint will be reduced to nothing.

943. General law.

From this it appears, that if two uniaxal plates cut at right angles to the axis be superposed, and adjusted so as to have their axes precisely coincident, the system of rings will have their diameters diminished if the plates be both attractive or both repulsive; but enlarged, if their characters be opposite. The experiment is rather delicate; but if made with care, placing the plates on one another with soft wax, and adjusting their surfaces by pressure to the exact position, it succeeded perfectly in the hands of Dr. Brewster.

This affords a means, independent of any measurement of the separation of the ordinary and extraordinary pencils, of ascertaining whether an uniaxial crystal be attractive or repulsive; for if its rings be dilated by combining it with a thin plate of carbonate of lime, cut at right angles to the axis, its character is positive; if contracted, negative.

945. Method of ascertaining whether a crystal be positive or negative.

A simpler and readier method still is to fasten on a plate of the substance under examination, so cut as to show the rings, a plate of sulphate of lime of moderate thickness, and then, interposing it between the tourmalines, to turn it about in its own plane. A position will be found where the rings are unaltered. In this situation the section B or C of the sulphate of lime is in the plane of primitive polarization. If the compound plate be turned 45° from this situation, it will now be observed (if the thicknesses of the two plates be properly proportioned) that the rings in two opposite quadrants are entirely obliterated; and that in the other two they are removed to a much greater distance from the centre, forming segments of larger circles, much closer together; and in which the tints, instead of commencing from the centre, commence from a black interval between two adjacent white rings in the midst of the system, and thence descend in the scale both inwards and outwards. In this state of things, the position of the sulphate of lime, with respect to the tourmalines, must be carefully noted; and the crystallized plate being detached, a plate of carbonate of lime, (perpendicular to its axis,) or of any other known uniaxal crystal, must be substituted for it; and the sulphate of lime replaced in the same position. If, then, it be found, that the same two quadrants of the rings are obliterated in this, as in the former case, and the new set of rings in the other quadrants be also similarly situated,—then the crystal examined is of the same character as the carbonate of lime, or other crystal used as a standard of comparison; but if, on the other hand, the quadrants where the rings were obliterated in the former case be those where the new rings are formed in the latter, then the characters of the two substances are opposite. If the crystallized plate be too thin, or of too feeble polarizing power to exhibit these phenomena with necessary distinctness, we must place it in azimuth 45° on the divided apparatus described in a former article (929;) and, fixing conveniently in the polarized beam a very thin plate of sulphate of lime also in azimuth 45°, ascertain, by making the crystal revolve, whether its tints have been raised or depressed in this plane by the action of the sulphate; then, removing the crystal, replace it with a standard one, and repeat the observation without touching
§ VIII. On the Interferences of Polarized Rays.

In repeating the experiments of Dr. Young on the law of interference it occurred to M. Arago, that it would be worth while to examine whether the state of polarization of the interfering rays would cause any modification in the phenomena. The experiment was easy in the case where both rays had the same polarization, being, in fact, the ordinary case; but when the interfering rays were required to have a different state of polarization, it will easily be conceived that it must be a matter of great delicacy and difficulty to superadd this condition to the others called for by the nature of the case, which requires that the interfering rays should emanate at the same instant from a common origin, and should have executed the same precise number of undulations or periods (within a very few units) between their origin and the point where their interference is observed. For it is not possible to change the state of polarization of a ray without either altering its course, or transmitting it through some medium in which more or fewer undulations are executed in the same space. The joint ingenuity of himself and M. Fresnel, who was associated with him in this interesting inquiry, however, soon found means of obviating the difficulties and delicacies of the subject, and the results of their experiments have been embodied by them in the following laws:

1. That two rays polarized in one and the same plane act on or interfere with each other just as natural rays, so that the phenomena of interference in the two species of light are absolutely the same.

2. That two rays polarized in opposite planes (i.e. at right angles to each other) have no appreciable action on each other, in the very same circumstances where rays of natural light would interfere so as to destroy each other.

3. That two rays primitively polarized in opposite planes may be afterwards reduced to the same plane of polarization, without acquiring thereby the power of interfering with each other.

4. That two rays polarized in opposite planes, and then reduced to similar states of polarization, interfere like natural rays, provided they belong to a pencil the whole of which was primitively polarized in one and the same plane.

5. In the phenomena of interference produced by rays which have undergone double refraction, the place of the coloured fringes is not alone determined by the difference of routes or velocities, but that in certain circumstances a difference of half an undulation must be allowed for.

Such are the laws of interference of polarized pencils, as stated by Messrs. Arago and Fresnel. We use in their enunciation, and indeed throughout the sequel of this part of the doctrine of Light, the language of the undulatory system, as really the most natural, and adapting itself with the least violence and obscurity to the facts. The reader may, if he please, substitute that of the corpuscular hypothesis and the Newtonian fits, superadding that of a rotation of the luminous molecules about their axes, with M. Biot; or simply content himself with a bare enunciation of facts, and with general terms expressive of the existing conditions of periodicity, without much trouble, and only a little circumlocution, but with a great sacrifice of clearness of conception. With respect to the laws themselves, the first is easily verified; we have only to repeat any of the experiments on the interference of rays emanating from a common origin, described in our section on that subject, substituting polarized instead of natural light, and the results will be precisely similar, and that in whatever plane the light be polarized. Rays, then, polarized in the same plane, interfere as natural rays under similar circumstances.

The verification of the second law is more difficult and delicate. The conditions of the production of colours by interference require that the interfering rays should emanate simultaneously from a common origin, or form parts of one and the same wave proceeding therefrom as a centre; and should have performed, at the point where their interference is examined, the same number of undulations in their respective routes, within a very few units. Now at their leaving their origin they could not be otherwise than in the same state of polarization; and as they are required to arrive at the point of interference in opposite states, a change of polarization must be operated on one or both rays, either by reflection, transmission, or double refraction, after leaving their origin, and that without altering, more than by a few undulations, the difference of their routes. Now, when we consider how minute a quantity an undulation is, it is easy to conceive the delicacy required in adjusting the parts of any apparatus constructed for this purpose, or the peculiar contrivances which must be resorted to to render such extreme and almost impracticable nicety unnecessary.

Several ingenious and elegant methods of making the experiment have been devised by the authors last named, of which we shall content ourselves with stating one or two of the easiest and most satisfactory. And, first, the origin of the interfering rays being the image of the sun at the focus of a small lens, we shall suppose it throughout this section, (unless the contrary be expressly said,) it is evident that if we intercept between the eye and this image a rhomboid of Iceland spar, there will be formed two images separated from each other by a space which will be greater the thicker is the rhomboid; but which will always (unless extremely thick rhomboids be used) be very small; so that the single luminous point will now be resolved into two, very near each other, and which, by the laws of polarization, send to the eye rays polarized in opposite planes. But in this disposition of things, the condition of near equality of routes is subverted; for the ordinary and extraordinary pencils pursue different paths within the crystal, and with very different velocities; so that a difference will thus arise in the total number of undulations executed by each, sufficient to destroy all evidence.
of interference by the production of coloured fringes. To obviate this difficulty, M. Fresnel sawed in half a rhomboid of Iceland spar, the two halves of which must of necessity have, at their line of separation and its immediate confines, precisely equal thicknesses. These halves he placed one on the other, only turning one 90° round in azimuth, so as to have their principal sections at right angles. In this state, a pencil entering them nearly at the intersection of the planes of separation would at its final emergence be divided, not into four, but into two only, (see Art. 879,) the ray ordinarily refracted in the first half having undergone extraordinary refraction in the second, and vice versa. The two rays, therefore, have exchanged velocities and directions, in the second transmission; and, therefore, when emergent, will have described exactly equal paths with equal velocities in each respectively, and will differ only in their states of polarization, which will be at right angles to each other. We have here, then, a case in which pencils diverge from two points side by side, and in a state in all other respects proper for interfering; nevertheless, when we look for the fringes which ought to be formed under such circumstances, (and which with natural light would be seen, see Art. 735 and 736,) none are visible. Their absence, then, must be owing to the opposite state of polarization of the interfering rays.

M. Arago, to make the same experiment, employed a process independent of double refraction. Two fine slits were made in a thin plate of copper, through which rays from the common origin were transmitted, and formed fringes (in their natural state) when viewed by an eye lens in the manner described, (Art. 709.) He now prepared two piles of pieces of very thin mica, or films of blown glass laid one on the other, fifteen in number, and then divided this compound plate in half by a sharp instrument, so that the halves, in the immediate neighbourhood of the line of division, could not be otherwise than of almost exactly equal thickness. These piles, when exposed at an incidence of 30° to a ray, were found to polarize the portion transmitted almost completely. They were then placed before the slits so as to receive and transmit the rays from the luminous point at precisely that incidence, and through spots which were very near each other in the undivided state of the pile. They were, moreover, so arranged, (being set on revolving frames,) that the plane of incidence could be varied (and therefore that of polarization) by turning either round in azimuth without altering its inclination to the ray, or varying the spot through which the ray passed. And it was then found, that when both piles were placed so as to polarize the rays in parallel planes, as, for instance, when both were inclined directly downwards, or one directly down and the other directly up—the fringes were formed as if the piles were away; but where one of the piles was turned round the incident ray as an axis through 90°, and so placed as to polarize the rays transmitted by it at right angles to the other, the fringes totally disappeared, nor could they be restored by inclining either pile a little more or less to the incident ray in the plane of incidence, the effect of which would be to alter gradually the length of the ray's path within the pile without changing its polarization, and thus, to compensate any slight inequality which might still subsist in their thicknesses. In intermediate positions the fringes appeared, but always the more vividly the nearer the planes of polarization approached to exact parallelism, thus attaining their maximum, and undergoing total obliteration at each quadrant of the rotation of either pile, (the other being at rest.)

A plate of tourmaline carefully worked to exact parallelism, and bisected, would answer equally well with the transparent piles to polarize the rays; but the tourmaline should be selected of very homogeneous texture, such as are not easy to meet with, though they may be found; and in this manner the experiment is perfectly easy and satisfactory. One half the tourmaline is fixed over one aperture, the other movable in a cell in its own plane over the other. The same phenomena will then be observed by turning round the movable tourmaline as with the oblique pile in the last experiment.

An experiment still more simple, and equally conclusive, is the following, of M. Fresnel. He placed before the sheet of copper (having, as before, two narrow slits in it very near each other) a single thin parallel lamina of sulphate of lime. Now, as this body possesses double refraction, each pencil would be divided into two—an ordinary and an extraordinary one—which, according as they emanate from the right or left hand slit, we will term R o, R e, and L o, L e. If natural light be used to illuminate the slits, these pencils will be of equal intensity, but those marked e will be polarized oppositely from those marked o. We may then form four combinations: 1. R o may interfere with L o; 2. R e may interfere with L e; 3. R o with L e; 4. R e with L o. Now of these, R o and R e are similarly polarized, and they have described equal paths with equal velocities; therefore, supposing them capable of interference, they will give rise to a set of fringes corresponding exactly to the middle of the line joining the two spots of, or, as we may express it, in the axis of the apparatus. The same may be said of R e and L e. These two sets of fringes will therefore be superposed, and appear as one of double intensity. Again, R o may be combined with L e; but as these two rays have traversed the sulphate in different directions and with different velocities, those rays of each pencil which meet in the axis will differ by too many undulations to produce colour; and if the pencils interfere, the place of the fringes will, instead of the axis, be shifted towards the side where the pencil has the greatest velocity, (Art. 737,) and that the more, the thicker the lamina of sulphate, so that if taken of a proper thickness, this set of fringes may be removed entirely out of the reach of the middle set, and should be seen independent of it. In like manner, the pencil R e may interfere with L o, and give rise to another set of lateral fringes; but as the ray which in the former combination was the swifter, in this is the slower, this set will lie on the opposite side of the middle set, supposing it produced at all; and thus there should be seen three sets of fringes, one bright, in the middle, and two fainter on either side. But, in fact, only one set is seen, viz. the middle set. Therefore the combination of the rays R o and L e, L o and R e, which are polarized oppositely, produce no fringes, i.e. they do not interfere.

But if we cut the lamina in half, and turn one half a quadrant round in its own plane, these rays are then reduced to the same polarization; and the rays R o and L o, R e and L e, which in the former case gave rise to
Light, the central fringes, are now placed in opposite states of polarization; and it is accordingly found that the central fringes have disappeared entirely, and that two lateral sets formed respectively by \( R_o \) and \( L_o \), \( R_e \) and \( L_e \), have started into existence. If we turn the lamina slowly round, these will gradually fade away, and the central fringes reappear and become brighter, and so on alternately; thus affording a convincing proof of the truth of the second of the laws above enunciated.

The experiment related by Messrs. Arago and Fresnel in support of their third law is as follows: Resuming the arrangement of Art. 955 or 956, and placing the piles or tourmalines so as to polarize the two pencils oppositely, let a doubly refracting crystal be placed between the eye and the sheet of copper, with its principal section \( 45^\circ \) inclined to either of the planes of polarization of the interfering rays. Each pencil will then divide itself by double refraction into two of equal intensity, and polarized in two planes at right angles, one of which is the principal section itself. We ought, therefore, to expect to see two systems of fringes, one produced by the interference of the ordinary ray from the right hand aperture (\( R_o \)) with that of the left (\( L_o \),) and the other by that of \( R_e \) with \( L_e \); yet no fringes are seen. The experiment may be varied by substituting for the doubly refracting prism a tourmaline, or pile, with its principal section in azimuth \( 45^\circ \). This must reduce to a common polarization all the rays which traverse it, viz. the half of each pencil, yet no fringes are seen, and therefore no interference takes place.

The following experiment is adduced in the Memoir cited in support of the fourth and fifth of the above laws. A lamina of sulphate of lime is perpendicularly exposed to a polarized pencil diverging from a minute point, and immediately behind it is placed a plate of brass pierced with two very small holes near together. The principal section of the lamina is to be placed at an angle of \( 45^\circ \) with the plane of primitive polarization. In consequence, from each of the holes (right, \( R \), and left, \( L \)) will emerge a ray composed of two equal rays, \( R_o \) and \( R_e \) and \( L_o \) \( L_e \) oppositely polarized, viz. at angles \( + 45^\circ \) and \( - 45^\circ \) with the plane of primitive polarization, which we will suppose vertical. In this situation of things a rhomboid of Iceland spar is placed between the two holes, and the focus of the eye lens employed to view the fringes, with its principal section vertical. i.e., making again with that of the lamina angles of \( 45^\circ \) either way. Each of the four rays then above mentioned will be divided into two equal rays, an ordinary and an extraordinary, thus giving rise in all to the eight rays

\[
\begin{align*}
R_{o0}, & R_{eo}, L_{oo}, L_{eo}, R_{oe}, R_{ee}, L_{oe}, L_{ee}.
\end{align*}
\]

These rays are received on the eye lens, and conveyed into the eye. Let us now examine their respective routes and states of polarization.

First, then, the rays \( R_o \) and \( R_e \), after quitting the lamina, are parallel; and by reason of the very small thickness of it, may be regarded as superposed, being undistinguishable from each other; but they have described within the lamina different paths by different velocities, so that on emerging they will differ in phase, by an interval of retardation proportioned to the thickness of the lamina, and which we will call \( \delta \). The very same may be said of \( L_o \) and \( L_e \). Moreover, the two rays of either of these pairs respectively are oppositely polarized, viz. in planes \( + 45^\circ \) and \( - 45^\circ \) from the vertical. This we may represent at once thus:

\[
\begin{array}{c|c|c}
\text{Ray.} & \text{Phase.} & \text{Plane of Polarization.} \\
R_o & x & + 45^\circ \\
R_e & x + \delta & - 45^\circ \\
L_o & x & + 45^\circ \\
L_e & x + \delta & - 45^\circ \\
\end{array}
\]

Next, the portions into which either of these rays is subdivided, in traversing the rhomboid, follow in their passage through it different paths, and have different velocities; but all which are refracted ordinary have one common direction and velocity; and so of those refracted extraordinarily; hence, between the ordinary and extraordinary rays here produced, will arise a difference of phase which we shall call \( \delta \), so that if \( x \) be the phase of any ordinary ray, \( x + \delta \) will be that of the corresponding extraordinary one, and their planes of polarization will be opposed, and will form angles respectively \( = 0 \) and \( 90^\circ \) with the vertical. Thus the circumstances will stand thus:

\[
\begin{array}{c|c|c}
\text{Ray.} & \text{Phase.} & \text{Plane of Polarization.} \\
R_{o0} & x & 0^\circ \\
R_{eo} & x + \delta & 0^\circ \\
L_{oo} & x & 0^\circ \\
L_{eo} & x + \delta & 0^\circ \\
\end{array}
\]

These eight pencils are all equal in intensity, and all those contained in the first set (marked A) will meet in one part of the field of view, while those marked B (on account of the thickness of the rhomboid, which we here suppose considerable, so as to produce a sensible, and even a large separation of the ordinary and extraordinary pencils) will meet in another, distant from the point of concourse of (A) by an interval proportional to the thickness of the rhomboid, and which we will here suppose so large as to throw the fringes (if any) there produced, entirely out of the way of mixing with those produced at the concourse of A. Let us then consider separately, the pencils of rays of the parcel A, and see what interferences can take place. And first, \( R_{o0} \) may...
Next, \( R^o o \) may interfere with \( L^o o \); but there being a constant difference of phases \( d \) in favour of the latter, the fringes produced by their concourse will lie to the left of the axis, by an interval proportional to the thickness of the lamina of sulphate, and will be seen separately. Similarly, the concourse of the pencils \( R^o o \) and \( L^o o \) will determine the production of another set of lateral fringes; but the difference of phases \( d \) being in this case in favour of the right hand pencil, this system will be situated as much to the right of the axis as the other was to the left.

Thus in the ordinary image three sets of fringes ought to be seen, and in the extraordinary, by a similar reasoning, as many. Now, in fact, this is the case, and the phenomena are seen on making the experiment precisely as here described. But it is evident that the rays which form the lateral fringes, by their interferences, are precisely those which, at their leaving the sulphate, had opposite polarizations, but have been afterwards reduced to similar polarization by the action of the rhomboid.

If instead of a rhomboid of sensible double refraction we substitute a plate of sulphate of lime, or of rock crystal, so thin as to produce no visible separation of the pencils, the fringes produced by the pencils \( B \) will be superposed on those arising from the interference of the pencils \( A \), and we should expect therefore, instead of six, to see three sets of fringes, the middle one being still the brightest. But, in fact, we see but one set, and the lateral fringes vanish altogether. This remarkable result proves that the colours resulting from the concourse of the rays ordinarily refracted by the rhomboid, are complementary to those resulting from that of the extraordinary rays; and therefore that we must allow half an undulation to be gained or lost when we would pass from one set to the other, precisely as in the phenomena of the reflected and transmitted colours of thin plates.

One of the most important consequences of these laws, is that they supply the defective link in the chain which connects the doctrine of undulations with the colours of crystallized laminae as described in the last section. It had been already remarked (as we have seen) by Dr. Young, that the passage of the ordinary and extraordinary rays with different velocities through the crystallized plate, would give rise to that difference of physical condition of the rays at their emergence which would lead to the production of colours; but the difficulty remained to explain, not why colours were produced in certain circumstances, but why they were not produced in all, in short, what share the polarization of the incident, and the analysis of the emergent rays, had in the production of the phenomena.

To see the nature of this difficulty more clearly, imagine a wave proceeding from a distant radiant point to be incident on a very thin crystallized lamina. It will be subdivided into two, each traversing the plate in a different direction and with its own proper velocity, and each of them emerging parallel to its original direction. The incident wave will, therefore, after emergence be resolved into two parallel to each other, but separated by a small interval equal to the interval of retardation. Now the hindmost of these ought, according to the law of interferences, to interfere with a subsequent wave of the system to which the foremost belongs, and thus periodical colours should arise on merely looking against the sky through such a lamina without any other apparatus. Why then are none seen? To this the law of Messrs. Arago and Fresnel afford a satisfactory answer. The two systems of waves into which the incident system is resolved are oppositely polarized, and therefore, though all other conditions be satisfied, incapable of interfering.

To understand how the colours of the polarized rings must be conceived to be produced by interference, let us take the simplest case when a polarized ray, \( A B \), fig. 194, is incident on any thin crystallized plate \( B \), whose principal section is \( 45^\circ \) inclined to the plane of primitive polarization. Let \( A \) be the system of waves which constitutes the incident ray; then in its passage through the crystallized lamina it will be divided into systems \( O \) and \( E \) of equal intensities, polarized in planes \( +45^\circ \) and \( -45^\circ \) inclined to that of primitive polarization, and the one lagging a few undulations behind the other, so as to interfere, as represented in the figure, and constituting the parallel rays \( C F \) and \( D G \). Let these now be received on, and transmitted through, a doubly refracting prism \( F G H L \) placed with its principal section in the plane of primitive polarization, or \( 45^\circ \) inclined to that of the crystallized lamina. Then will each of the incident rays be again subdivided, \( C F \) into \( H M \) and \( I P \), and \( D G \) into \( K N \) and \( L Q \), all of equal intensity. Of these, \( H M \) and \( K N \) emerge parallel, as also \( K N \) and \( L Q \) respectively. Now the systems of waves \( O \) and \( E \) which follow each other at a certain interval \( d \) will continue to do so in both the refracted rays, as if they formed one compound system; so that each of the pencils \( H M \) and \( K N \) and \( I P \) and \( L Q \) will consist of a double system of waves \( O e \) and \( E o \) respectively. The former pair following each other at the interval \( d \), and the latter at the interval \( d + \frac{\lambda}{2} \), undulation, (by reason of the demonstrated fact, that in passing from the ordinary to the extraordinary system half an undulation must be allowed. See Art. 966.) Now as each ray of these pairs respectively have similar polarizations, viz., those of the pair ordinarily refracted \((O o \text{ and } E o)\) in the plane of the principal section of the prism, and those of the extraordinary pair \( O e \text{ and } E e \) in a plane at right angles to it, there is no reason why interference should not take place, and the consequence must be, the production of complementary colours in the two pencils finally emergent corresponding to the intervals of retardation \( d \) and \( d + \frac{\lambda}{2} \), which is just what really happens.

Conceive now another ray incident on \( B \) in the direction \( A B \), but polarized in a plane at right angles to that of the ray considered in the last paragraph. Then this will undergo precisely the same series of divisions as subdivisions as the former. But the intervals of retardation will be different; for its plane of polarization when incident on \( B \) being now related to the plane of ordinary refraction, as that of the other ray at its incidence was
Light. to the extraordinary, and vice versa, a difference of half an undulation must (as already explained) be admitted in the relative position of the two systems of waves O, E, at their emergence, from this cause, independent of the interval of retardation within the plate; so that if \( d \) were the interval in the former case, \( d - \frac{1}{2} \lambda \) will be the difference now, and, after passing through the prism, we shall have for the intervals of retardation in the two binary pencils, instead of \( d \) and \( d + \frac{1}{2} \lambda \) which they were before, \( d - \frac{1}{2} \lambda \) and \( d \). Hence the two pencils will exchange colours when the polarization of the incident light is varied by a quadrant, and this is also conformable to fact. If this reasoning be not thought conclusive, the reader is referred forwards to Art. 983 and 984.

Next, let the incident ray be unpolarized. This case, as we have seen Art. 851, is the same with that of a ray consisting of two equal rays oppositely polarized, and therefore in each pencil will coexist, superposed on each other, the primary and complementary colour arising from either portion, which being of equal intensity will neutralize each other's colours and the emergent pencils will be white, and each of half the intensity of the incident beams. This then is the reason (on this doctrine) why we see no colours when the light originally incident on the crystallized plate is unpolarized.

Thus, the theory of interferences, modified by the principles above stated, affords, as we see, an explanation of the colours of crystallized plates totally distinct from that of movable polarization. The only delicacy in its application to all cases, lies in the determination which of the emergent pencils must be regarded as having its interval of retardation increased by half an undulation. M. Fresnel gives the following rule for this essential point. (Note on M. Arago's Report to the Institute on a Memoir of M. Fresnel relative to the colours of doubly refracting laminae. Annales de Chimie, vol. xvi. p. 80.*) The image whose tinl corresponds precisely to the difference of routes, is that in which the planes of polarization of its constituent pencils after having been separated from each other, are brought together by a contrary motion, while, on the other hand, the pencils whose planes of polarization are brought to coincidence by a continuance of the same motion by which they were separated, produce by their reunion the complementary image. To understand this better, let \( P \) be the plane of primitive polarization projected on that of the paper, to which let us suppose the ray perpendicular, \( C \) O that of the principal section of the crystallized lamina, and \( C \) S that of the principal section of the doubly refracting prism; then the incident pencil polarized in the plane \( P \) will after penetrating the lamina be divided into two, one \( O \) polarized in the plane \( C \) O, the other \( E \) in the plane \( C \) E perpendicular to it. Now, \( C \) O may always be so taken as to make an angle not greater than a right angle with \( C \) P, and \( C \) E so as to have \( C \) P between \( C \) E and \( C \) O; so that the plane \( C \) P may be conceived to open or unfold itself like the covers of a book, into \( C \) O and \( C \) E, one on either side. Again, \( C \) S may always be regarded as making an angle not greater than a right angle with \( C \) O, and when the ray \( O \) resolves itself into two \( O \) o and \( O \) e by refraction at the prism, its plane of polarization \( C \) O may be conceived to open out into the two \( C \) S and \( C \) T at right angles to each other, including \( C \) T between them; and in like manner the ray \( E \) will resolve itself into two \( E \) o and \( E \) e, and its plane of polarization \( C \) E will open out into the two \( C \) S and \( C \) T', having \( C \) E between them in the case of fig. 195 (a), and into \( C \) S' and \( C \) E in that of fig. 195 (b); in the former case \( C \) T' is a prolongation of \( C \) T, in the latter \( C \) S' is a prolongation of \( C \) S. The rays \( O \) o and \( E \) o then which make up the ordinary pencil, have, in the case of fig. (a), been each brought to a coincident plane of polarization \( C \) S by two motions in contrary directions, as represented by the arrows, and the extraordinary ones \( O \) e and \( E \) e have been separated and brought back to a coincident plane by motions continued in the same direction for each respectively. The reverse is the case in fig. (b). In the case then of fig. a the colours of the ordinary pencil \( O \) o + \( E \) o will be those which correspond precisely to the difference of routes, and those of the extraordinary one \( O \) e + \( E \) e will correspond to that difference plus half an undulation, while in that of fig. b the reverse happens. This rule is empirical, i.e., is merely a result of observation. It is clear that the principle of the conservation of the \( vis \ vita \) in this, as in the colours of uncrystallized plates, requires that the two images should be complementary to each other, and therefore half an undulation must be gained or lost by one or the other pencil, but which of the two is to be so modified we have no means of knowing a priori.

This once determined, however, we have no difficulty in deducing the formule of intensity and other circumstances of the phenomena when the azimuth of the crystallized plate is arbitrary, instead of being, as we have hitherto supposed, limited to 45°. The analytical expressions of the intensity of the pencils we must reserve for our next section.

§ IX. Of the application of the Undulatory Doctrine to the explanation of the phenomena of Polarized Light and of Double Refraction.

The phenomena of double refraction and polarization, as exhibited in the experiments of Huygens on Iceland spar, were regarded by Newton and his followers as insuperable objections to the undulatory doctrine, inasmuch as it appeared to them impossible, by reason of the \textit{quaquiduorum} pressure of an elastic fluid, to conceive an undulation as having a different relation to different regions of space, or as possessing sides. "Are not," says Newton, "all hypotheses erroneous in which light is supposed to consist in pressure or motion propagated..."
Examined

contiguous particles are related to each other and affect each other's motion, yet it is certain that the mode and form of medium, must be on all sides alike, whereas it appears that the rays of light have different properties in their different sides. To me, this seems inexplicable, if light be nothing else than pressure or motion propagated through ether. Opticks, book iii, quest. 28. And, again, quest. 29; "Are not rays of light very small bodies emitted from shining substances?" The unusual refraction of Iceland crystal looks very much as if it were performed by some kind of attractive virtue lodged in certain sides both of the rays and of the particles of the crystal. "I do not say this virtue is magnetic.—It seems to be of another kind. I only say, that, whatever it be, it is difficult to conceive how the rays of light, unless they be bodies, can have a permanent virtue in two of their sides which is not in their other sides, and this, without any regard to their position as to the space or medium through which they pass."

Although we have no knowledge of the intimate constitution of elastic media, or the manner in which their contiguous particles are related to each other and affect each other's motion, yet it is certain that the mode and laws of the propagation of motion through them by undulation cannot but depend very materially on this connection. The only analogies we have to guide us into any inquiry into these laws, are those of the propagation of sound in air or water, and of tremors through elastic solids, and along tended chords and surfaces; and such is the extreme difficulty of the subject when taken up in a purely mathematical point of view, that we are forced to have recourse to these analogies, and, dismissing in the present state of science the whole subject in analytical formulae, suffer ourselves to be instructed by experience, as to what modifications the peculiar constitution of vibrating media may produce in the propagation of motion through them. Now, if sound is propagated through air or water, in which the molecules are at least supposed to have no mutual connection but to be capable of moving with equal facility, and to be restored to their places with equal elastic forces, in whatever direction they are displaced, and in which, moreover, it is (at least theoretically) taken for granted, that the motion of any molecule has an equal tendency to set in motion those adjacent to it, in whatever direction these may be situated with respect to it; it is difficult to conceive that the motion of a molecule in the surface of a wave, at some distance from the centre whence the sound emanates, can be performed otherwise than in the direction of the radius, or at right angles to the surface of the wave; so that in this case the motion of the vibrating molecules must coincide with the direction of the rays of sound, and there appears, therefore, no reason why such rays should bear different relations to the different regions of space surrounding them, whether right or left, above or below; for the ray being regarded as an axis, all parts of the sphere round it are similarly related to it.

If we conceive a connection of any kind, such as may possibly be established by repulsive and attractive forces, or magnetic or other polarities subsisting between the molecules of the vibrating medium, the case is altered. It will no longer then follow of necessity, that the individual motion of each molecule is performed in the direction in which the general wave advances, but it may be conceived to form any angle with that direction, even a right angle. A familiar instance of such a mode of propagation may be seen in the wave which runs along a long stretched cord, struck, shaken, or otherwise disturbed at one end. The direction of the wave is the length of the cord, and that of the motion of each molecule lies in a plane perpendicular to it. Now this is precisely the kind of propagation which M. Fresnel conceives to obtain in the case of light. He supposes the eye to be affected only by such vibrating motions of the ethereal molecules as are performed in planes perpendicular to the directions of the rays. According to this doctrine, a polarized ray is one in which the vibration is constantly performed in one plane, owing either to a regular motion originally impressed on the luminous molecule, or to some subsequent cause acting on the waves themselves, which disposes the planes of vibration of their molecules all one way. An unpolarized ray may be regarded as one in which the plane of vibration is perpetually varying, or in which the vibrating molecules of the luminary are perpetually shifting their planes of motion, and in which no cause has subsequently acted to bring the vibrations thus excited in the ether to coincident planes.

The analogy of the tended cord (which appears to have suggested itself to Dr. Young on considering the optical properties of biaxal crystals in 1818) will help our conception greatly. Suppose such a cord of indefinite length, stretched horizontally, and one end of it being held in the hand, let it be agitated to and fro with a motion perpendicular to the length of the cord. Then will a wave or succession of waves be propagated along it, and every molecule of the cord will, after the lapse of a time proportional to its distance from the hand, begin to describe a line or curve similar and similarly situated to that described by the extremity at which the agitation originates. If the original agitation be regularly repeated and constantly confined to one plane, the same will be true of the motion of each molecule, and the whole extent of the cord will be thrown into the form of an undulating curve lying in one plane, so far as the motion has reached. In this case it will represent a polarized ray or system of waves. If, after a few vibrations in one plane, the extremity be made to execute a few in another, and then again in another, and so on, so that the plane of vibration shall assume in rapid succession all possible situations, since each molecule obeys exactly the same law of motion with the extremity, the curve will consist of portions lying in all possible planes, and since by reason of the propagation of the undulation along it, every point of it is in succession agitated by the motion of every other, all these varied vibrations will run through any given point of it, and were a sentient organ like the human retina stationed there, the impression it would receive would be analogous to that excited in the eye by an unpolarized ray of light.

It may be objected to this mode of conceiving the luminous undulations, that the molecules of the ether, if it be a fluid, such as we have hitherto all along regarded it, cannot be supposed connected in strings, or chains like those of a tended cord, but must exist separate and independent of each other. But it is sufficient for our purpose to admit such a degree of lateral adhesion (we hesitate to term it viscosity) as may enable each molecule in its motion not merely to push before it those which lie directly in the line of its motion, but to drag along

Part 17.

L I G. H. T.
with those which lie on either side, in the same direction with itself. Or, acknowledging at once the
difficulty, since light is a real phenomenon, we are not to expect it to be produced without a mechanism
adequate to so wonderful an effect. We do not hesitate to attribute to the fluids which are imagined to account
for the phenomena of heat, electricity, magnetism, &c. properties altogether repugnant to our ordinary notions
of fluids, and why should we deny ourselves the same latitude when light is to be accounted for. It is true
the properties we must attribute to the ether appear characteristic of a solid than of a fluid, and may be
regarded as reviving the antiquated doctrine of a plenum. But if the phenomena can be thereby accounted
for, i.e. reduced to uniform and general principles, we see no reason why that, or any still wilder doctrine,
should not be admitted, not indeed to all the privileges of a demonstrated fact, but to those of its representa-
tive, or locum tenens, till the real truth shall be discovered. Assuming it, then, with M. Fresnel, as a post-
tulatum, that the vibrations of the ethereal molecules which constitute light are performed in planes at right
angles to the direction of the ray’s progress, let us see what account can be given of the phenomena of
polarized light.

And first, then, of the interference of two polarized rays, whether polarized in the same, or different planes.
The plane of polarization in this doctrine may be assumed to be either that in which the vibrations are executed,
(i.e. a plane passing through the direction of the ray and the line described by each of the vibrating molecules
in its excursion,) or one perpendicular to it, which we please. Reasons, presently to be stated, render the latter
preferable, but at present it is a matter of indifference which we assume. Now, in § 8, Part III. we have
investigated at length, with a view to the present inquiry, the modes of vibration which result from the combi-
nation of any assigned vibrations, whether executed in the same or different planes; and it follows from the
purely mechanical principles there laid down, 1st, That the combination of two vibrations executed in the same
plane, produces a resultant vibration in the same plane, which may be of any degree of intensity from the sum
of the intensities of its component vibrations, according to the difference of their phases. Now,
each of these systems of vibration represents a polarized ray; so that rays polarized in the same plane ought
on these principles, to be capable of destroying or reinforcing each other by interference, as we see they do.
But the case is otherwise when the component vibrations are executed in different planes, for in that case it is
obvious that they never can destroy each other completely so as to produce rest. The general case of non-
coincident planes of vibration is analyzed in Art. 618; and in Art. 621 we see, that even when each of the
component vibrations is rectilinear, the resultant is elliptic; so that each molecule of the ether performs
continual gyrations in one direction, and never can be totally quiescent.

Thus we see that the interference of rays similarly polarized, and the non-interference of those dissimilarly,
is a necessary consequence of the hypothesis we are considering; and indeed was the phenomenon which first
suggested it. It may be familiarly explained by the analogy of our tended cord. Conceive such a cord to
have its extremity agitated at equal regular intervals with a vibratory motion performed in one plane, then it
will be thrown, as we have seen, into an undulatory curve, all lying in the same plane. Now, if we superadd
to this motion another, similar and equal, but commencing exactly half an undulation later, it is evident that the
direct motion every molecule would assume, in consequence of the first system, will at every instant be exactly
neutralized by the retrograde motion it would take in virtue of the other; and, therefore, each molecule will
remain at rest, and the cord itself be quiescent. But if the second system of motions be performed in a plane
at right angles to the first, the effect will evidently only be to distort the figure of the cord into a curve of double
curvature, which, in the general case, will be an elliptic helix, and pass into the ordinary circular one when
the two component vibrations differ in phase by a quarter of an undulation, or 90°. (See Art. 627. Corol.)

In this case the extremity of the cord describes a circle with a continuous motion, and this motion is imi-
tated by each molecule along its whole length. It is easy to make this a matter of experiment; we have only
to hold in our hands the end of a long stretched cord, or grasp it firmly in any part of its extent, and work the
part held round and round, with a regular circular motion, and we shall see the cord thrown into a helicoidal
curve, each portion of which circulates in imitation of the original source of the motion.

But experience shows, not merely that two equal rays polarized at right angles do not destroy each other for
any assignable difference of origins, but that, whatever be this difference, the intensity of the resultant ray remains
absolutely the same. Now this is also a necessary consequence of the theory of transverse vibrations. To show
this, we need only refer to the expressions for A, B, C in equation (7,) Art. 619, resuming at the same time the
notation and reasoning of that article. The intensity of the impression made on the eye by any ray being
proportional to the vis viva, is represented by the sum of the several visus visus in the three rectangular
directions, or by $A^2 + B^3 + C^4$, that is, by

$$a^2 + b^2 + c^2 + a^2 + b^2 + c^2 + 2 a' \cdot \cos (p - p') + 2 b' \cdot \cos (q - q') + 2 c' \cdot \cos (r - r')$$

Now if we assume the directions of the coordinates $x$ and $y$ to be those transverse to that of the ray, and the
one in the plane of polarization of one ray, the other in that of the other, at right angles to it, and that of $z$
in the direction of the ray itself, we have

$$a' = 0, \quad b = 0, \quad c = 0, \quad c' = 0;$$

and therefore the above expression for the intensity becomes

$$A^2 = B^2 + C^3 = a^2 + b^3,$$

which is independent of $p - p', q - q', r - r'$, the difference of phases, and is equal to the sum of the inten-

Part IV.

L I G H T. 535
sities of the separate rays. And we may remark, by the way, that no other supposable mode of vibration but that in question, in which \( e \) and \( e' \), the amplitudes of vibration in the direction of the ray vanish, could produce the same result. (Fresnel's Considerations Théoriques sur la Polarisation de la Lumière. Bulletin de la Société Mathématique, October, 1824.)

Let us now consider what will happen when a ray polarized in any plane is resolved into two polarized in any other two planes at right angles to each other, and these again reduced to two others also at right angles to each other, by a second resolution. Suppose \( C \), (fig. 195, a) to be the course of a ray projected on a plane perpendicular to its direction, (that of the paper,) and in which, consequently, the vibrations of the molecule \( C \) are performed. Let \( PCP' \) be the line of vibration of this molecule, and therefore (according to the hypothesis assumed) at right angles to the plane of primitive polarization. When this ray is divided into two others oppositely polarized, the vibrations are of course resolved into two others performed in planes at right angles to each other. Let \( CO \) and \( CE \) be the projections of these planes, which are therefore perpendicular to the planes of polarization of the two new rays respectively. Suppose that at any instant the molecule \( C \) of the primitive ray is moving from \( C \) in the direction \( CP \); then this motion, if resolved into two, will give rise to two motions, one in the direction from \( C \) towards \( O \), the other from \( C \) towards \( E \). If each of these motions be again resolved into two, in planes whose projections are \( SC \) \( S' \) and \( TCT' \), at right angles to each other, that in the direction \( CO \) will produce two motions, one in the direction \( CS \), and the other in the direction \( CT \); and on the other hand the motion in the direction \( CE \) will produce one in the direction \( CS \), and the other (in the case of fig. 195, a) in the direction \( CT \) opposite to \( CT \). Thus the two resolved motions in the plane \( SS' \) will conspire, but those in the plane \( TT' \) will oppose, each other. In the case of fig. 195, b, the reverse will happen; the motions in the plane \( T \), \( T' \) conspiring, and those in the plane \( SS' \) opposing, each other. For simplicity of conception, however, we will confine ourselves to the former case. If, now, we pass from the consideration of the vibrations to that of the rays, it will appear that we have, in fact, resolved the original ray polarized in the plane \( PP' \) into two, polarized in planes perpendicular respectively to \( CO \) and \( CE \); and these again, finally, each into two, viz. one polarized in the perpendicular to \( SS' \), and one perpendicular to \( TT' \). The two portions polarized perpendicular to \( SS' \) form one ray, and those perpendicular to \( TT' \) another; but in the former, the component portions tend to strengthen,—in the latter, to destroy each other. Hence, if we consider the two former portions as having a common origin, we must regard the latter as differing by half an undulation.

Hitherto we have supposed the second resolution of the rays to take place at the same point \( C \) in the course of the ray as the first, but this may not be the case, and several cases may be imagined; first, we may suppose the two portions into which the ray is first resolved to run on in the same line with equal velocities; and after describing any given space, to be then resolved, at another point \( C' \) (whose projection in the figure will coincide with \( C \)) into the final rays \( SS' \) and \( TT' \). It is evident that this will make no difference in the result, for the phases in which each ray arrives at \( C' \) will be alike; and after the second resolution the conspiring vibrations in the direction \( SS' \) will still be in the same phase, and the opposing ones in the plane \( TT' \) must still be regarded as in opposite phases, i. e. as differing by half an undulation. Or, secondly, we may suppose, that, owing to any cause, the two resolved rays do not travel with equal velocity, (as in the case where the resolution is performed by double refraction.) In this case, if \( i \) be the interval of retardation of the one ray on the other when they arrive at \( C' \), \( i \) will represent the difference of phases of the two rays at the instant of their second resolution. Consequently, when resolved, the final ray, whose vibrations are performed in \( SS' \), will be the \( \text{sum} \); and that whose vibrations are performed in \( TT' \), the difference of two rays, one in a certain phase \( \theta \), the other in the phase \( \theta + i \); the latter, \( \text{sum} \) of two components in the phases \( \theta \) and \( \theta + i \); the latter, \( \text{sum} \) of two in the phases \( \theta \) and \( \theta + i + 180^\circ \), so that still the difference of half an undulation is to be applied. In the case of fig. 195, b, if we pursue the same reasoning, it will appear that this difference still subsists, but must be applied conversely, viz. to the compound ray whose vibrations are performed in \( CS \).

We have here, then, the theoretical origin of the allowance of half an undulation, in those cases where it is required to account for the polarized tints, Art. 966, and of the rule laid down in Art. 972 for its correct application. However arbitrary the assumption may have appeared as there presented, and however singular it may have seemed to make the affections of a ray at one point of its course dependent on those which it had at a former instant, we now see that the whole is a direct and very simple consequence of the ordinary elementary rules for the composition and resolution of motions. It is worthy of notice, that the fact was ascertained before the theory of transverse vibrations was devised, so that this theory has the merit of affording an a priori explanation of what had previously all the appearance of a mere gratuitous hypothesis.

In conceiving the resolution of a ray into two others polarized in different planes, we may be aided by the analogy of the tending cord, which we have before had occasion to refer to. In fig. 196 let \( AB \) be a stretched cord, branching at \( B \) into the two \( BC \) and \( BD \), making a small angle with each other at \( B \), and having either equal or unequal tensions. Suppose the plane in which the two branches lie to be (for illustration's sake) horizontal, and let the extremity \( A \) of the single cord be made to vibrate regularly in a vertical plane; or, at least, let the vibrations of the cord, before arriving at \( B \), be reduced to a vertical plane by means of a small polished vertical guide \( IK \), against which the cord shall press lightly, and on which it may slide freely without friction. Beyond the point of bifurcation \( B \), and at such a distance that the excursions of the molecule \( B \) shall subtend no sensible angle from them, let two other such polished guiding planes be placed, inclined at different angles to the horizon, and making a right angle with each other. Suppose now \( B \) to make any excursion from its point of rest, then were the plane \( EF \) parallel to \( IK \), the molecule of the branch \( BC \) contiguous to \( EF \) would slide on \( EF \) through a space equal to the whole excursion of \( B \); but since it is inclined to \( IK \) at an angle...
Light.

\[ \text{\(\approx \theta\)} \text{ a part only of the motion of } B \text{ will be employed in causing this molecule to glide on } EF, \text{ and the remainder will cause the cord to bend over and press on the obstacle; but by reason of the minuteness of the excursions of } B, \text{ this bending and the resistance of the obstacle and consequent loss of force will be very minute and may be neglected. Now, since the pressure of the obstacle removes the cord from the position it would have taken if no obstacle existed, in a direction perpendicular to its surface, it is easy to see that the amplitude of excusion of the contiguous molecule on the plane } EF \text{ must be to that of } B \text{ as } \cos \theta \text{ to radius; and, therefore, calling } a \text{ the amplitude of } B \text{ 's excursions, } a \cdot \cos \theta \text{ will be that of the molecule contiguous to } EF, \text{ and of course that of every subsequent molecule of the branch } BC. \text{ Here the part of } B \text{ 's motion, which is perpendicular to } EF, \text{ is not expended or destroyed in bending the cord } BC \text{ over the obstacle, but remains in activity, and exerts itself on the branch } BD, \text{ causing it to glide on the plane } GH; \text{ and the amplitude of the excursions of the molecule in contact with this plane will in like manner be represented by } a \cdot \cos (\text{inclination of } GH \text{ to } IK), \text{ that is, by } a \cdot \cos (90 - \theta), \text{ or by } a \cdot \sin \theta. \text{ The vis viva, then, in each of these respective planes is represented by } a^2 \cdot \cos \theta \text{ and } a^2 \cdot \sin \theta, \text{ whose sum is equal to } a^2, \text{ the initial vis viva.}

If we decompose, in like manner, the maximum velocity } a \text{ of the ethereal molecule } C \text{ (fig. 195) in the direction } CP \text{ into two in the respective directions } CO \text{ and } CE, \text{ we get } a \cdot \cos \theta \text{ and } a \cdot \sin \theta \text{ for the elementary velocities; and since the amplitudes, } \cos \text{ paribus, are as the velocities, (Art. 610,) the amplitudes of the component rays will be respectively } a \cdot \cos \theta \text{ and } a \cdot \sin \theta; \text{ and their intensities, which are as the squares of the amplitudes, (Art. 605,) will be } a^2 \cdot \cos \theta \text{ and } a^2 \cdot \sin \theta. \text{ Now this is the very law propounded by Malus for the intensities of the two portions into which a polarized ray is divided by double refraction, and of which the theory of transverse vibrations gives, as we see, a simple and rational } \text{ a priori account, thus raising it from a mere empirical law to the rank of a legitimate theoretical deduction.}

We have not done with the analogy of the tended cord. What we have shown in Art. 986 is independent of the tensions of the branches into which the cord is divided, and relates only to the amplitudes of their excursions from rest when thrown into vibration. But the velocity with which the waves, once produced, will be propagated along either branch depends solely on its tension. Nothing, however, prevents the tensions of the two branches from being very different; for, whatever be the ratio of two forces applied in the directions } BC \text{ and } BD, \text{ they may be balanced at } B \text{ by a proper force applied along any other line as } BA. \text{ Hence the waves will run along } BC \text{ and } BD \text{ with different velocities. Similarly, if we conceive, that owing to the peculiar constitution of crystallized bodies, and the relation of their particles to the ether which pervades them, their molecules are more easily displaced, or yield to a less force in certain planes than in others; or, in other words, that it possesses different elasticities in different directions; then will the planes of polarization assumed by the resolved portions of the rays determine the elasticities brought into action, and, consequently, the velocities of their propagation. Now we have, in a former section, shown that the bending of a ray at the confines of a medium depends essentially on its velocity within as compared with that without, by the analytical relations deduced from the "principle of swiftest propagation." A difference of velocity, therefore, draws with it, as a necessary consequence, a diversity of path; and thus the bifurcation, or double refraction of a ray incident on a crystallized surface, presents no longer any difficulty in theory, provided we can find an adequate reason for the resolution of its vibrations into two determinate planes at the moment of its entering the crystal.

Let us take (with M. Fresnel, } Annales de Chimie, \text{ xvii. p. 179 et seq.) the case of a crystal with one axis. We may regard this, or rather the other within it, modified in its action by the molecular forces of the crystal, as an elastic medium in which the elasticity in a direction perpendicular to the axis is different from that in a direction parallel to it, that is, in which the molecules are more easily compressible in the one than in the other direction; but, equally so in all directions perpendicular to the axis, on whatever side the pressure be applied. To aid our conceptions in imagining such a property, we may assimilate an uniformly elastic medium to an assemblage of thin, elastic, hollow, spherical shells in contact; and such a medium as we are considering, to a similar assemblage of oblate or prololate hollow ellipsoids, arranged with all their axes parallel to one common direction, which is that of the axis of the crystal. \* \text{ It is evident that the resistance of the spherical assemblage to pressure must be the same in all directions, but that of the spheroidal must differ according as the pressure is applied perpendicularly or parallel to the axis. Thus, it is easy to crush an egg by a force applied in the direction of its shorter diameter, which will yet sustain a violent pressure applied at the extremities of its longer. It is, moreover, evident, if any molecule of such an assemblage were disturbed, so as to throw it into vibration, that, provided always the amplitude of its excursions were extremely small compared to the diameter of each ellipsoid, the immediate tendency of the vibration will be to communicate motion to two strata only of molecules, viz. that in which the axis and equator of the disturbed molecule lie respectively, since it is only at the poles and equator that they touch, and therefore only through these points that motion that can be communicated from one to the other. Consequently, any motion communicated to a molecule of such a mass could only be propagated by vibrations performed in planes parallel and perpendicular to the axis. Hence, if a vibratory motion in any plane be propagated into such an assemblage of particles from without, it will immediately, on its reaching it,}

\* \text{ The idea of spheroidal molecules in Iceland spar suggested itself to Huygens (rather fancifully, perhaps) as a means by which spheroidal undulations might be propagated through it, (Op. Opus. tom. I. Trocades de Lumine, p. 78, cited by Wollaston, } Phil. Trans. cit. p. 56;) \text{ and the last-named eminent Philosopher, in the Balian Lecture for 1812, has most ingeniously shown how such molecules may be supposed to build up crystals, having the primitive forms and cleavages of acute and obtuse rhomboids. It is true, that in all this there is much hypothesis; and it should be observed, too, that the crystallographic structure would require oblate spheroids, where in the text we have employed prolates, and vice versa. But we intend there only an analogy, not a theory. It would be easy to devise hypothetical indices of action where these forms might be reversed if needful.}

\text{VOL. IV.}
be resolved into two, in the planes above named; and these, by reason of the different elasticities, will be propagated with different velocities.

The reader must not suppose that this is intended for an account of the real mechanism of crystallized bodies. It is merely intended to show that it is not absurd, or contradictory to sound mechanical principles, to assume that such may be their constitution, that vibrations can only be propagated through them by molecular excursions executed in planes parallel and perpendicular to their axes. Assuming, then, that such is the case, the vibrations of a ray incident on such a crystal will be resolved into two, performed in these respective planes, and their velocities of propagation being different, the rays so arising will follow different courses when bent by refraction. Let us first consider that whose vibrations are executed in planes perpendicular to the axis. Since the crystal is symmetrical with respect to its axis, and equally elastic in all directions perpendicular to it, the velocity of propagation of this portion will be the same in all directions. Its index of refraction, therefore, will be constant, and the refraction of this portion will follow the ordinary law. Moreover, its plane of polarization being that perpendicular to which the vibrations are performed, will necessarily pass through the axis, in which respect it also agrees with the ordinary ray, as actually observed.

The extraordinary ray arises from the other resolved portion of the original vibration, which is performed in a plane parallel to the axis. By the principle of transverse vibrations, it is also performed in a plane perpendicular to the ray. If, then, we suppose a plane to pass through the extraordinary ray and the axis, it will cut a plane perpendicular to the ray in a straight line, which will be the direction of the vibratory motion. This direction, then, is inclined to the axis in an angle equal to the complement of that made by the extraordinary ray with the latter line, and therefore, when the extraordinary ray is parallel to the axis, the line of vibration is perpendicular to it, and vice versa. In the former case, the elastic force resisting the displacement of the molecules is the same as in the case of the ordinary ray, and therefore the velocities of both rays are equal, and their directions coincide, and thus along the axis there is no separation of the rays. In the latter, the elasticity is that parallel to the axis, and therefore differing from the former by the greatest possible quantity. Here, then, the difference of velocities, and therefore of directions is at its maximum. In intermediate situations of the extraordinary ray, the elasticity developed is intermediate, and therefore also the velocity and double refraction. Thus we see, that according to this doctrine the difference of velocities, and consequent separation of the pencils should be nothing in the axis, and go on increasing till the extraordinary ray is at right angles to it, which is conformable to fact. Lastly, the plane of polarization of the extraordinary ray being at right angles to the plane of vibration, must also be at right angles to a plane passing through the ray and the axis, which is also conformable to fact.

The theory of M. Fresnel gives then, as we see, at least a plausible account of the phenomena of double refraction in the case of uniaxal crystals: and when we consider the profound mystery which, on every other hypothesis, was admitted to hang over this part of the subject, we must allow that this is a great and important step. But the same principles are equally applicable to biaxal crystals with proper modifications, and (which is a strong argument for their reality) lead, when so applied, to conclusions which, though totally at variance with all that had been taken for granted before, on the grounds of imperfect analogy and insufficient experiment, have been since verified by accurate and careful experiments, and have thus opened a new and curious field of optical inquiry. Nothing stronger can be said in favour of an hypothesis, than that it enables us to anticipate the results of experiment, and to predict facts opposed to received notions, and mistaken or imperfect experience.

But before we enter on this, it may be right to show how the phenomenon on which the theory of movable polarization is founded, is accounted for by the doctrine of transverse vibrations. According to this theory, as soon as a polarized ray enters a crystal, it commences a series of alternate assumptions of one or other of two planes of polarization, in the azimuth $\theta^\circ$ and $2 \theta$, $i$ being the inclination of the principal section to the plane of primitive polarization: the plane assumed being in azimuth $\theta^\circ$, when the thickness traversed is such as to render the interval of retardation of the ordinary ray on the extraordinary ray $0$, or any whole number of undulations, and in azimuth $2 \theta$ when it is any whole odd number of semi-undulations. Suppose a ray polarized in the azimuth $0$ to be incident perpendicularly on a crystallized lamina, having its principal section in the azimuth $i$, then it will be resolved into two, the vibrations of which are respectively performed in the principal section, and perpendicular to it. Consequently, if we represent by unity the amplitude of the original vibrations, those of the two resolved vibrations will be equal respectively to $\sin i$ and $\cos i$. Now, the thickness of the plate being first supposed such as to render the interval of retardation an exact number of undulations, these rays will emerge from the lamina in exact accordance, and being parallel, the systems of waves of which they consist will run on together. Being polarized, however, in opposite planes they will neither destroy each other, nor produce a compound ray equal to their sum, but their resultant must be determined as in Art. 623. For we have here the case of rectilinear vibrations, in complete accordance, of given amplitudes, and making a given angle (90°) so that the result there obtained is immediately applicable to this case, and the resultant vibration will be, first, rectilinear, so that the compound ray will appear wholly polarized in one plane: and, secondly, its amplitude will be, both in quantity and direction, the diagonal of a parallelogram whose sides are the amplitudes of the component vibrations. Consequently, it will be identical with that by whose resolution these were produced, and therefore the resultant, or emergent compound ray will be, in respect both of its polarization and intensity, precisely similar to the original incident one.

When the difference of paths within the crystal is an exact odd multiple of half an undulation, the waves at their egress from the posterior surface will be in complete discordance. But their resultant may still be determined by the same rule, regarding either of the rays as negative, i.e. as having its vibrations executed in the opposite direction. For suppose the molecule $C$ moving in the direction $CP$, with the velocity $CP$...
When the difference of routes is neither an exact number of whole, or half undulations, the vibrations of the resultant ray (by Art. 621) will no longer be rectilinear, but elliptic; and in the particular case when the interval of retardation is a quarter or an odd number of quarter undulations, it will be circular. In this case, the emergent ray, varying its plane of vibration every instant, will appear wholly depolarized, so as to give two equal images by double refraction in all positions of the analyzing prism.

These several consequences may be rendered strikingly evident by a delicate and curious experiment related by M. Arago. Let a polarized pencil, emitting from a single radiant point, be incident on a double rhomboid of Iceland spar, composed of two halves of one and the same rhomboid, superposed so as to have their principal sections at right angles to each other. Then the emergent rays will emanate as if from two points (see Art. 879) near each other, and polarized in opposite planes. Let these two cones of rays be received on an emeried glass, or in the focus of an eye-lens, so that the glass or field of view shall be illuminated at once by the light of both, which being oppositely polarized will exhibit no fringes or coloured phenomena, but merely a uniform illumination; but let all the light but that which falls on a single very small point of the field of view be stopped by a plate of metal, with a small hole in it, so as to allow of examining the state of polarization of the compound ray illuminating this point, separately from the rest. Then it will be seen, on analysing its light by a tourmaline or double refracting prism, that, when the spot examined is distant from both radiants by the same number of undulations, although in fact composed of two rays oppositely polarized, (as may be proved by stopping one of them, and examining the other singularly,) yet it presents the phenomenon of a ray completely polarized in one plane, which is neither that of the one or the other of its component rays, but the original plane of polarization of the incident light. Suppose now, by a fine screw we shift gradually the place of the metal plate so as to bring the hole a little to one or the other side of its former place. The ray which illuminates it will appear to lose its polarized character as the motion of the plate proceeds, and at length will offer no trace of polarization; continuing the motion, and bringing in succession other points of the field of view under examination, the light which passes through the hole will again appear polarized, at first partially, and at length totally; not, however, as before, in the plane of primitive polarization, but in a plane making with it twice the angle included between it and the principal section of the first rhomboid, and so on alternately.

Thus we are presented with the singular phenomenon of two rays polarized in planes at right angles, which produce by their concourse a ray either wholly polarized in one or the other of two planes, or not polarized at all, according to the difference of routes of the rays before their union.

In 1821, M. Fresnel presented to the Academy of Sciences of Paris a Memoir, containing the general application of the principle of transverse vibrations to the phenomena of double refraction and polarization as exhibited in biaxal crystals, which was read in November of that year. A brief report on the experimental parts of this Memoir by the Committee of the Academy appointed to examine it, about half a dozen pages, was published in the Annales de Chimie, vol. xx. p. 337, recommending it to be printed as speedily as possible in the collection of the Memoires des Savans Etrangers. We are sorry to observe, that this recommendation has not yet been acted upon, and that this important Memoir, to the regret and disappointment of men of science throughout Europe, remains yet unpublished; though we trust (from the activity recently displayed by the Academy in the publication of their Memoirs in arrear) this will not long continue to be the case. An abstract of the author himself, which appeared in the Bulletin de la Societe Philomathique of 1822, and was subsequently reprinted in the Annales de Chimie, 1823, enables us, however, to present a sketch, though an imperfect one, of its contents, supplying to the best of our ability the demonstration of the fundamental propositions, and reaping a melancholy gratification from the inadequate tribute, which, in thus introducing for the first time to the English reader a knowledge of these profound and interesting researches, we are enabled to pay to departed merit. His saltum accumulam donis—et fungar inani munere. For even at the moment when we are recording his discoveries, their author has been snatched from science in the midst of his brilliant career by a premature death, like his hardly less illustrious contemporary, Fraunhofer, the early victim of a weakly constitution and emaciated frame, unfit receptacles for minds so powerful and active.

M. Fresnel assumes, as a postulatum, that the displacement of a molecule of the vibrating medium in a crystallized body (whether that medium be the ether, or the crystal itself, or both together, in virtue of some mutual action exercised by them on each other,) is resisted by different elastic forces, according to the different directions in which the displacement takes place. Now it is easy to conceive, that in general the resultant of
all the molecular forces which act on a displaced molecule, is not necessarily parallel to the direction of its displacements when the partial forces are unsymmetrically related to this direction, but the proposition may be demonstrated a priori, as follows. Suppose three coordinates $x$, $y$, and $z$, to represent the partial displacements of any molecule $M$ in their respective directions, and $r = \sqrt{x^2 + y^2 + z^2}$ the total displacement, making angles $\alpha$, $\beta$, $\gamma$, respectively with the axes of the $x$, $y$, $z$, so that $x = r \cos \alpha$, $y = r \cos \beta$, $z = r \cos \gamma$. Now, since in this theory we assume that the displacements of the molecules are infinitely, or at least extremely small compared with the distances of the molecules inter se, it is evident that whatever be the law of molecular action, the resultant coming from any displacement must (ceteris paribus) be proportional to the linear magnitude of that displacement, and can, therefore, be only of the form $r \phi$, where $\phi$ is some unknown function of the angles $\alpha$, $\beta$, $\gamma$, or their cosines. And, moreover, since such infinitely small displacements, in whatever direction made, neither alter the angular position, nor distance of the displaced molecule among the rest, by any sensible quantity, all their forces will act on it in its displaced position in the same manner as before. Hence the total force developed by the simultaneous displacements $x$, $y$, $z$, or by the single displacement $r$ must be equivalent to (or the statical resultant of) the three which would be developed independently by the several partial displacements $x$, $y$, $z$. Now the force originating in the partial displacement $x$ alone will result from $r \phi$ by making $r = x$ and $\phi$ equal to $a$, where $a$ is the same function of 1, 0, 0, that $\phi$ is of $\cos \alpha$, $\cos \beta$, $\cos \gamma$. $a$ therefore is a constant depending only on the position of the axes of the $x$, $y$, $z$ with respect to the molecules of the crystal. And when this partial force $= ax$ is resolved into the directions of these several axes, since its direction (whatever it be) is determinate, the resolved portions can only be of the form $A x$, $A' x$, $A'' x$, where $A$, $A'$, $A''$ are in like manner only on the position of the coordinates $x$, $y$, $z$ with respect to the molecules, and not at all on $\alpha$, $\beta$, $\gamma$, which are arbitrary, and where $A^2 + A'^2 + A''^2 = \alpha^2$. The same being true of the partial forces brought into play by the displacements $y$ and $z$, it follows that the total force arising from the displacement $r$ must be the resultant of the three forces

$$f = A x + B y + C z, \quad f' = A' x + B' y + C' z, \quad f'' = A'' x + B'' y + C'' z,$$

respectively parallel to the axes of the $x$, $y$, $z$, where the coefficients are independent of $\alpha$, $\beta$, $\gamma$, and where, in like manner, $B^2 + B'^2 + B''^2 = \beta^2$, $C^2 + C'^2 + C''^2 = \gamma^2$. But we have $x = r \cos \alpha$, $y = r \cos \beta$, $z = r \cos \gamma$, so that if we put

$$f = r \{ A \cos \alpha + B \cos \beta + C \cos \gamma \}, \quad f' = r \{ A' \cos \alpha + B' \cos \beta + C' \cos \gamma \}, \quad f'' = r \{ A'' \cos \alpha + B'' \cos \beta + C'' \cos \gamma \},$$

the resultant of $f$, $f'$, $f''$ will be the force urging the displaced molecule.

Now these forces acting in the directions of the coordinates may each be decomposed into two, one in the direction of the displacement $r$, and the other at right angles to it in the planes respectively of $r$ and $x$, $r$ and $y$, $r$ and $z$, and the sum of the former will be

$$F = f \cos \alpha + f' \cos \beta + f'' \cos \gamma,$$

which is the whole force tending to urge the displaced molecule directly to its position of equilibrium. The latter will be respectively equal to $f \sin \alpha$, $f' \sin \beta$, $f'' \sin \gamma$; but as they act, although in one plane, yet not in the same direction, they will not destroy each other, unless they be to each other in the ratio of the sines of the angles they make with each other's direction. But it is evident, that since $\alpha$, $\beta$, $\gamma$ are arbitrary, this condition cannot hold good in general, because it furnishes two equations, which, taken in conjunction with the relation $\cos \alpha^2 + \cos \beta^2 + \cos \gamma^2 = 1$, suffice to determine $\alpha$, $\beta$, $\gamma$. Hence it follows, that the displaced molecule is, except in certain cases, urged by the elastic forces of the medium obliquely to the direction of its displacement.

Mr. Fresnel next goes on to observe, that in general every elastic medium has three rectangular axes, in the direction of which, if a molecule be displaced, the resultant of the molecular forces urging it will act in the direction of its displacement. These are the excepted cases just alluded to, and to the axes possessing this property, (which he regards as the true fundamental axes of the crystal,) he gives the name of Axes of Elasticity.

To demonstrate this proposition we must observe, that, by mechanics, in order that the resultant of three rectangular forces $f$, $f'$, $f''$ shall make angles $\alpha$, $\beta$, $\gamma$ with their three directions, and therefore be coincident in direction with $r$, they must be to each other in the ratio of the cosines of these angles, and therefore we must have the following equations expressive of this condition,

$$\frac{f}{f} = \frac{\cos \alpha}{\cos \beta}, \quad \frac{f}{f'} = \frac{\cos \alpha}{\cos \gamma}, \quad \frac{f'}{f''} = \frac{\cos \beta}{\cos \gamma}.$$
Suppose by elimination we have derived from these equations the position of one axis of elasticity, then it will follow of necessity, that two others must exist, at right angles to it and to each other. To prove this, we must consider the connection between the partial forces developed by any displacement of the molecule $M$, and the molecular attractions and repulsions of the medium. Let $\phi$ be the action of any molecule $d m$ on $M$, which we suppose to be exerted in the direction of their line of junction, and to be a function of their mutual distance $\rho$. Then, if we suppose $M$ displaced by any arbitrary quantities $\delta x, \delta y, \delta z$ (infinitely small in comparison with $\rho$) in the direction of the three coordinates, we have

$$\delta \phi = \left(\frac{x}{\rho} \delta x + \frac{y}{\rho} \delta y + \frac{z}{\rho} \delta z\right). \frac{d \phi}{d \rho},$$

and putting

$$\phi' = \frac{d \phi}{d \rho}, \quad \text{and} \quad \frac{x}{\rho} = \cos \lambda, \quad \frac{y}{\rho} = \cos \mu, \quad \frac{z}{\rho} = \cos \nu,$$

we have

$$\delta \phi = \phi'. \left(\delta x \cdot \cos \lambda + \delta y \cdot \cos \mu + \delta z \cdot \cos \nu\right).$$

Consequently, since the force of the molecule $d m$, resolved into the directions of the coordinates, is equal to

$$(\phi + \delta \phi) d m \cdot \frac{x}{\rho}, \quad (\phi + \delta \phi) d m \cdot \frac{y}{\rho}, \quad \text{and} \quad (\phi + \delta \phi) d m \cdot \frac{z}{\rho},$$

the sum of all these throughout the medium will be the total action on $M$; but since in the original position of the molecule $M$ it is in equilibrium, we have

$$\int \phi d m \cdot \frac{x}{\rho} = 0, \quad \int \phi d m \cdot \frac{y}{\rho} = 0, \quad \text{and} \quad \int \phi d m \cdot \frac{z}{\rho} = 0,$$

so that the whole action of the medium on $M$ in its displaced situation will be, in the three directions

$$\int \frac{x}{\rho} d m \cdot \delta \phi, \quad \int \frac{y}{\rho} d m \cdot \delta \phi, \quad \int \frac{z}{\rho} d m \cdot \delta \phi;$$

that is, in the direction of the $x$,

$$\int \phi' d m \cdot \{\cos \lambda \cdot \delta x + \cos \mu \cdot \delta y + \cos \nu \cdot \delta z\};$$

$\delta x, \delta y, \delta z$ are the partial displacements of $M$ in the directions of the coordinates, and are, therefore, the same we denoted in Art. 998 by $x, y, z$. Restoring these denominations, we see that, on this hypothesis, (the most natural which can be formed respecting the mode of molecular action) the coefficients $A, B, C$, can be no other than the following,

$$A = \int \phi' d m \cdot \cos \lambda, \quad B = \int \phi' d m \cdot \cos \lambda \cdot \cos \mu, \quad C = \int \phi' d m \cdot \cos \lambda \cdot \cos \nu;$$

and by similar reasoning we find

$$A' = \int \phi' d m \cdot \cos \lambda \cdot \cos \mu, \quad B' = \int \phi' d m \cdot \cos \mu, \quad C' = \int \phi' d m \cdot \cos \nu;$$

$$A'' = \int \phi' d m \cdot \cos \lambda \cdot \cos \nu, \quad B'' = \int \phi' d m \cdot \cos \mu \cdot \cos \nu, \quad C'' = \int \phi' d m \cdot \cos \nu;$$

and, consequently, the following relations must necessarily subsist between these coefficients

$$B = A', \quad C = A'', \quad C' = B''.$$ 

This premise, suppose we have determined one axis of elasticity of the medium by the foregoing equations. Since the positions of the axes of the coordinates are arbitrary, we are at liberty to suppose that of the $x$, coincident with the axis so determined, which renders $A' = A'' = 0$, and consequently $B = 0$ and $C = 0$, and $B'' = C'$, because the relations above demonstrated are general and independent of any particular situation of the axes. The equations of Art. 1000 then become

$$A u v = (B' v + C' w) u, \quad A u w = (B'' v + C'' w) v,$$

$$(B' v + C' w) w = (C' v + C'' w) v, \quad u^2 + v^2 + w^2 = 1.$$ 

Now if we put $u = 0$, or $a = 90^\circ$, the two former of these are satisfied without any relation supposed between $v$ and $w$, so that if we determine these from the two latter only, the whole system will be satisfied. These (making $u = 0$) give at once by elimination

$$w = \sqrt{\frac{1}{2} \left(1 \pm \frac{1}{\sqrt{4 m^2 + 1}}\right)}; \quad v = - \sqrt{\frac{1}{2} \left(1 \mp \frac{1}{\sqrt{4 m^2 + 1}}\right)}.$$

where $m = \frac{C'}{B' - C''}$. Now since $m^2$ is necessarily positive, $4 m^2 + 1$ is so, and is $> 1$; therefore $\frac{1}{\sqrt{4 m^2 + 1}}$ is real and $< 1$, consequently $w^2$ and $v^2$ are both positive, and therefore $v$ and $w$ both real, and less than unity. Hence it follows, that there are necessarily two axes at right angles to the $x$, which satisfy the conditions of axes of elasticity, and the opposite signs of $v$ and $w$ show that they are at right angles to each other.

For simplicity, therefore, we will in future suppose the directions of the coordinates to be coincident with those of the axes of elasticity, so as to make

$$w = \sqrt{\frac{1}{2} \left(1 \pm \frac{1}{\sqrt{4 m^2 + 1}}\right)}; \quad v = - \sqrt{\frac{1}{2} \left(1 \mp \frac{1}{\sqrt{4 m^2 + 1}}\right)}.$$
542

Light.

\[ A = a, A' = A'' = 0; \quad B' = b, B = B'' = 0; \quad C'' = c, C = C' = 0; \]

then we have by Art. 998 for the partial forces,

\[ f = ax + ar \cdot \cos \alpha, \quad f' = by = br \cdot \cos \beta, \quad f'' = cz = cr \cdot \cos \gamma, \]

and by 999,

\[ F = r \{ a \cdot \cos \alpha + b \cdot \cos \beta + c \cdot \cos \gamma \} \]

for the whole force urging the molecule in the direction of the r, generally assumed, in which it will be observed that

\[ a = \int \phi' \cdot \cos \lambda d m, \quad b = \int \phi' \cdot \cos \mu d m, \quad c = \int \phi' \cdot \cos \nu d m. \]

1004. M. Fresnel next conceives a surface, which he terms the "Surface of Elasticity," constructed according to the following law:—on each of the axes of elasticity, and on every radius r drawn in all directions, take a length proportional to the square root of the elasticity exerted on the displaced molecule by the medium in the direction of the radius, or to \( \sqrt{F} \). Then if we call R this length, or the radius vector of the surface of elasticity, we shall have

\[ R = \{ a \cdot \cos \alpha + b \cdot \cos \beta + c \cdot \cos \gamma \} \times \text{const.} \]

The values of R parallel to the axes are then had by the equation

\[ R^2 = \text{const} \times a r, \quad R^2 = \text{const} \times b \theta, \quad R^2 = \text{const} \times c \phi, \]

which (for brevity, as we shall have no further occasion to recur to our former denominations) we shall express simply by \( a^2, b^2, c^2 \), so that the equation of the surface of elasticity will be of the form

\[ R^2 = a^2 \cdot \cos X + b^2 \cdot \cos Y + c^2 \cdot \cos Z, \]

where X, Y, Z, now stand for \( a, b, c \), the angles made by R with the axes of the coordinates.

1005. Velocity and plane of polarization of an interior wave determined.

Let us now imagine a molecule displaced and allowed to vibrate in the direction of the radius R, and retained in that line, or at least let us neglect all that part of its motion which takes place at right angles to the radius vector. Then the force of elasticity by which its vibrations are governed will be proportional to \( R^2 \), and the velocity of the luminous wave propagated by means of them, in a direction transverse to them (or at right angles to R) will be proportional to R, so that the surface of elasticity being known, the velocity of a wave transmitted through the medium in a given direction, and with a given plane of polarization will be had at once as follows. Parallel to the surface of the wave, and at right angles to its plane of polarization draw a straight line. This will be the direction of the vibrations by which the wave is propagated. Parallel to this line draw a radius vector to the surface of elasticity, and it will represent the wave's velocity.

1006. Equation of the surface of elasticity, if we put for R, cos X, cos Y, cos Z, their values in terms of three coordinates will become

\[ (x^2 + y^2 + z^2)^2 = a^2 x^2 + b^2 y^2 + c^2 z^2. \]

It is, therefore, in general a surface of the fourth order. If we suppose it cut by a plane passing through its centre, whose equation must therefore in general be of the form \( m x + n y + p z = 0 \), the curve of intersection will be a species of oval whose diameters are not necessarily all equal.

Suppose now any molecule set in vibration in this plane, then at any period of its motion it will not be urged directly to its point of rest but obliquely, so that it will not describe a straight line, but will circulate in a curve more or less complicated; its motion in this, however, will always be resolvable into two vibratory rectilinear ones at right angles to each other, one parallel to the greatest, and the other to the least diameter of the section. Each of these vibratory motions will, by the laws of motion, be performed independently of the other, and therefore the motion propagated through the crystal will affect every molecule of it in the same way as if two separate and independent rectilinear vibrations (at right angles as above) were propagated through it, with different velocities. Consequently every system of waves propagated from without into the crystal, will necessarily on entering be resolved into two propagated with different velocities, and polarized in planes at right angles to each other, viz. those parallel respectively to the greatest and least diameter of a section of the surface of elasticity parallel to the plane of either wave. And as every difference in the velocities of two waves propagated parallel to each other through a medium, gives rise to a corresponding difference in their planes at their emergence from it into another, where they assume a common velocity, these waves will at their egress no longer be parallel, and the rays which are perpendicular to them will be inclined to each other, thus producing the phenomena of double refraction; and it is evident that the waves at their egress must retain the planes of polarization they received in the crystal, because any molecule of the exterior medium at the junction of the media will begin to move only in the plane in which it was displaced by the contiguous molecule in the medium.

1007. Resolution of an incident wave into two.

Polarized in opposite planes.

1008. This theory then accounts perfectly both for the bifurcation of the emergent ray, and the opposite polarizations of the two portions into which it is divided. These portions will coincide in direction, and there will be no double refraction when the section of the surface of elasticity above mentioned is (if such can ever be the case) a circle, because all its radii being then equal, the elasticity is the same in all directions, and all vibrations performed in it will have equal periods, so that in this case the resolution of the incident wave into two no longer takes place, nor is its plane of polarization changed. Now the section in question becomes a circle, when \( x^2 + y^2 + z^2 = \text{const} = r^2 \), or when \( a^2 x^2 + b^2 y^2 + c^2 z^2 = r^2 \). Combining these with \( m x + n y + p z = 0 \), we get
and equating these, and considering that the equation hence resulting ought to be verified independently of any particular values of $x, y$, we get

$$r^2 (m^2 + p^2) = a^2 r^2 + m^2 c^2,$$

and

$$m n r^2 = m n c^2,$$

$$r^2 (p^2 + n^2) = b^2 p^2 + n^2 c^2.$$  

These equations cannot be satisfied except by supposing either $m, n,$ or $p$ to vanish, or the section in question to pass through one or other of the axes. If we suppose $m = 0$, we have $r = a$, which shows that

$$\left(\frac{n}{p}\right)^2 = \frac{a^2 - b^2}{c^2 - a^2},$$

and of course $n$ is not real, unless $a$, the semi-axis of the surface through which the section passes, be that intermediate in length between $b$ and $c$, the other two semi-axes.

It appears then, that the surface of elasticity admits of two circular sections and no more, formed by diametral planes passing through the mean axis of the surface, and (since $\frac{n}{p}$ has two values equal but of opposite signs)

that these sections are both equally inclined to each of the other two axes. The normals to these sections are the directions of no double refraction, or the optic axes of the crystal. Of these, then, there will be two and two only, in all crystals which possess three unequal axes of elasticity, and rays propagated along them will suffer neither double refraction, nor change of polarization.

The position of these axes depends wholly on the values of $a, b, c$, the semi-axes of the surface of elasticity. We have, however, no other measure of the elasticity of the medium than the velocity with which the rays are propagated through it; and if, as the phenomena of ordinary dispersion indicate, the rays of different colours be propagated in one and the same medium with velocities somewhat different, (an effect which might result from certain suppositions relative to the extent of the sphere of action of its molecules compared with the lengths of an undulation,) the semi-axes $a, b, c$, which must be taken proportional to the velocities of propagation, must be supposed to vary a little for waves of different lengths. Now this variation may not be in the same ratio for all the three semi-axes, and thus a variation in the values of $\frac{n}{p}$ will arise. But $\frac{n}{p}$ is the tangent of the inclination of the plane of section to the plane of the $x, y$, or of half the angle the two circular sections make with each other, i.e. the cotangent of half the angle between the optic axes, which will thus vary, and give rise to that separation of axes of different colours, and their distribution over a certain angle, in the plane containing any two of the same colour, which observation shows to exist. (Art. 921 and 922.)

The general laws of double refraction flow with great facility from these principles. We have only to resume the construction and reasoning of Art. 806 and 897, et seq., substituting for the ellipsoid of revolution, which the Huygenian theory assumes as the figure of a wave originating in any molecule of the crystal, the surface, whatever it be, which, in the general case, terminates a wave so propagated, and investigating the point of contact $I$ (fig. 170) of this surface with a plane $IKT$ passing through the line $KT$ drawn as there described.

There is this difference, however, in the two cases, or, at least, in the method of treating them, that in the theory there stated the form of the wave is made a matter of arbitrary assumption, in the present case it is to be determined $a priori$. This will render it necessary to depart in some respects from the course before adopted. If we know, $a priori$, the form of the wave, the position of the tangent plane is given; vice versa, if we can determine the position of this plane in all cases, $a priori$, the figure of the wave, which must be such as to touch all such planes, under the conditions of the case, becomes known.

Now, in Art. 807, it is shown that the tangent plane in all cases coincides with the position assumed within the crystal, by the surface of a plane indefinite wave propagated from an infinitely distant luminary, perpendicular to the line of incidence $RC$. It follows, moreover, from Art. 811, that if we know the velocity with which a plane wave advances within the crystal in a direction perpendicular to its surface, we may calculate its inclination to the surface of incidence by the law of ordinary refraction, assuming an index of refraction which is to that of the ambient medium as the velocity of the wave before incidence is to its velocity within the medium perpendicular to its own surface. The reader will here keep in view the distinction noticed in Art. 813 between the velocity of the wave and that of the ray conveyed by it, whose direction, generally speaking, is oblique to its surface. Now the velocity of a wave within the medium in any direction is given by the equation of the surface of elasticity, whose radius vector expresses it in all cases. But it has been shown, that every vibration impressed on the molecules of the crystal is resolved into two rectilinear ones propagated with velocities proportional to the greatest and least diameters of that section of the surface of elasticity which is parallel to the plane in which they are performed. Now it is the same thing, (as far as the law of double refraction is concerned,) whether we regard the bifurcation to take place by the separation of a single exterior ray into two interior ones, or a single interior into two exterior. We will take the latter case, and suppose the
Light.

Ordinary and extraordinary plane waves to be parallel within the medium. Their velocities may then be investigated as follows: the equation of the surface of elasticity being

\[ R^4 = a^2 x^2 + b^3 y^2 + c^4 z^4, \]

if we take, for the equation of the second plane,

\[ z = m x + n y, \]

and put \( V \) for the maximum or minimum radius vector of the surface in the section in question, \( V \) will be the value of \( R \), which makes \( dR = 0 \), and therefore will be given by elimination from the following system of equations

\[
\begin{align*}
V_x &= a^2 x^2 + b^3 y^2 + c^4 z^4, \\
V_y &= (1 + m^2) x^2 + (1 + n^2) y^2 + 2 m n x y, \\
0 &= m n q x^2 - m n r y^2 + k x y,
\end{align*}
\]

where

\[ k = p + n q \cdots m r = (1 + m^2) q - (1 + n^2) r. \]

These, by elimination, give the following, in which

\[
\begin{align*}
M &= k^2 + 4 m^2 n^2 q r; \\
M x^2 &= V_x (V^2 - c^4) \{ (1 + n^2) k + 2 m n r \} - r k V_x, \\
M y^2 &= -V_y (V^2 - c^4) \{ (1 + m^2) k - 2 m n q \} + r q V_y, \\
M x y &= -m n \{ (1 + m^2) q + (1 + n^2) r \} V_x (V^2 - c^4) + 2 m n q r V_y;
\end{align*}
\]

and by equating the square of the last of these to the product of the two first, we find, after all reductions, the following equation for determining \( V \):

\[
(V^2 - a^2) (V^2 - b^2) + m^2 (V^2 - b^2) (V^2 - c^2) + n^2 (V^2 - a^2) (V^2 - c^2) = 0.
\]

The roots of this equation determine the maximum and minimum values of the radius vector in the plane of section, and therefore the velocities of ordinary and extraordinary plane waves moving parallel to each other within the crystal, and these found, the figure of the wave becomes known, from the condition that its surface must always be a tangent to a plane distant by the quantity \( V \) from the secant plane whose equation is \( z = m x + n y \); and that, whatever be the values of \( m \) and \( n \). Its investigation is therefore reduced to a purely geometrical problem. Required the equation of a curve surface, which shall touch every plane parallel to a plane whose equation is \( z = m x + n y \); and distant from it by a quantity \( V \), a function of \( m \) and \( n \) given by the above equation, which, being resolved, will be found to lead to the following equation

\[
(a^2 x^2 + b^3 y^2 + c^4 z^4) (x^2 + y^2 + z^2) - a^2 (b^3 + c^4) x^2 - b^3 (a^2 + c^4) y^2 - c^4 (a^2 + b^3) z^2 = 0.
\]

The surface represented by this equation is, generally speaking, of the fourth order, and consists of two distinct surfaces, or sheets, \( (nappes) \). One of these, by its contact with the plane in question, determines the direction of the ordinary, and the other of the extraordinary ray. Now, it is important to remark, that this equation, so long as particular values are not assigned to \( a, b, c \), is not decomposable into quadratic factors, so that neither of the sheets of which it consists is spherical, or ellipsoidal; and, consequently, neither the ordinary nor the extraordinary ray follows either the Cartesian or Huygenian law of refraction. This is a consequence too remarkable not to have been put to the test of experiment. Two methods have been put in practice by M. Fresnel for this purpose. The first consisted in measuring directly the velocities of the two rays in plates of topaz cut in different directions with respect to their axes by the method explained under the head of interferences, \( (Art. 738 \) and \( 739. \) \) Since a difference of velocity of the interfering rays displaces the diffracted fringes as a difference of thickness would do, it is manifest that if, in two plates differently cut, but of precisely the same thickness, the fringes formed by the ordinary rays are differently displaced when the plates are combined successively with one and the same equivalent plate of glass, or any other standard medium, their velocity cannot be the same in both plates; and if such difference be observed to take place, both in the fringes formed by the interference of the ordinary and of the extraordinary rays severally, with a compensated pencil, it is clear that neither can have a constant velocity. Now the condition of equal thickness is secured by cementing the two plates edge to edge, and grinding and polishing them together, and carefully examining the surfaces after the operation, to be satisfied of their precise continuity, which may be done by the reflected image of a distant object, and yet more delicately by pressing slightly on them a convex lens of long focus, over their line of junction. If the coloured rings formed between the surfaces be uninterrupted, we are sure that this condition
Light. is rigorously satisfied. The experiment so made, M. Fresnel found to confirm the conclusion to which the above theory leads. But in corroboration of this important result, the following method was also used.

In topaz the extraordinary refraction is stronger than the ordinary; so that the ordinary ray, when the two are separated by a prism of that medium, is less deviated. M. Fresnel procured two prisms to be cut from one topaz, in both of which the base was parallel to the cleavage planes, and therefore perpendicular to a line bisecting the angle between the optic axes and to the principal section of the crystal, i.e. to the mean axis of elasticity; but in one the plane of the refracting angle was coincident with, and in the other perpendicular to, that section, these being the planes in which the difference between the velocities of the ordinary ray is the greatest, as is easily seen from what has above been said. These prisms were cemented side by side, so as to have their bases in one plane and their refracting edges in one straight line; and were then very carefully ground and polished to plane surfaces, so that the refracting angles in both could not be otherwise than precisely equal. In this situation the compound prism A B C, fig. 199, 1, (which is seen in perspective in fig. 199, 2,) whose refracting angle A B C was about 92°, was achromatised by two prisms C B A and D C A of crown glass, in which circumstances a slight, uncompensated refraction remained in favour of the topaz prism. Looking now through the side E B, the whole combination was turned round the refracting edge as an axis, till the image of a distant object, a black line on a white ground, appeared stationary; so that the refracted rays, both ordinary and extraordinary, must have traversed the prisms very nearly parallel to the base, or at right angles to the mean axis, but in the different planes above mentioned in each. Now it was observed, that the least refracted image of the black line so seen, that is the ordinary one, was broken at the junction of the two prisms, being more deviated by one than by the other, while the most refracted or extraordinary image formed a continuous line in both. This latter fact (which, at first sight, would lead us to suspect that the extraordinary image had been mistaken for the ordinary) is a consequence of the theory above explained, and is an additional confirmation of it.

When two of the axes of elasticity (as b and c, for instance) are equal, the general equation of the surface of the wave becomes decomposable into two factors, and may be put under the form

\[(a^2 + b^2 + c^2 - b^2) (a^2 c^2 + b^2) - a c b^2 \] = 0,

which is the product of the equation of a sphere with that of an ellipsoid of revolution. In this case the two circular sections coincide with the plane of the y z, and the two optic axes with the axis of the x. We have then here the case of uniaxal crystals, and are thus furnished with an a priori demonstration, both of the Huygenian law of elliptic undulations, in the case of the extraordinary wave in such crystals, and of the constancy of the index of refraction in that of the ordinary. The manner in which this results as a corollary from the general case is at once elegant and satisfactory.

M. Fresnel gives the following simple construction for the curve surface bounding the wave in the case of unequal axes, which establishes an immediate relation between the length and direction of its radii. Conceive an ellipsoid having the same semiaxes a, b, c; and having cut it by any diametral plane, draw perpendiculars to this plane from the centre two lines, one equal to the greatest, and the other to the least, radius vector of the section. The loci of the extremities of these perpendiculars will be the surfaces of the ordinary and extraordinary waves; or, in other words, their lengths will be the lengths of the radii of the waves in those directions, and will therefore measure the velocity of the two rays propagated in those directions, in the same way as the radii of the Huygenian ellipsoid are proportional to the velocities of the extraordinary ray in their direction.

Finally, if we divide unity by the squares of the two semiaxes of a diametrical section of the ellipsoid, the difference of these quotients will be found to be proportional to the product of the sines of the angles which the perpendicular to this section makes with the two normals to the planes of the circular sections of the ellipsoid. Now, in all the crystals hitherto known, these sections differ very little from the circular sections of the surface of elasticity, and may, without sensible error, be supposed to coincide with them; consequently, the two normals in question may be taken for this purpose as the optic axes of the crystal. We have thus the origin of that law, deduced from the phenomena of the coloured lemniscates, which makes the difference of the squares of the reciprocal velocities proportional to the product of the sines made by the ray with the optic axes; and thus the phenomena of the polarized rings are all made to depend on the same general principle on a projective basis.

Such is the beautiful theory of Fresnel and Young, (for we must not in our regard for one great name forget the justice due to the other, and to separate them and assign to each his share would be as impracticable as injurious, so intimately are they blended throughout every part of the system; early, acute, and pregnant suggestion characterising the one,—and maturity of thought, fulness of systematic development, and decisive experimental illustration, equally distinguishing the other. If the deduction in succession of phenomena of the greatest variety and complication from a distinctly stated hypothesis, by strict geometrical reasoning, through a series of intermediate steps, in which the powers of analysis alone are relied on, and whose length and complexity is such as to prevent all possibility of foreseeing the conclusions from the premises, be a characteristic of the truth of the hypothesis,—it cannot be denied that it possesses that character in no ordinary degree; but, however that may be, as a generalization the reader will now be enabled to judge whether the encomium we passed on it in a former Article be merited. We can only regret that the necessary limits of this Essay, which is already extended greatly beyond our original design, forbid our entering farther into its details.

The axes of elasticity are those which M. Fresnel regards as the fundamental axes of a doubly refractive medium. The optic axes can in no view of the subject be regarded as such, for several obvious reasons. First, Dr. Brewster's theory of polarization shows that the axes vary in position according to the colour of the incident light; thirdly, because it is found that for one and the same coloured illumination, and in the same crystal, their situation varies by a variation of temperature.
Postulate 1. A polarizing axis, when single, has the characters of an axis of no double refraction, and is coincident with the axis of the Huygenian spheroid in such crystals as have but one. A positive axis acts as the axis in quartz, &c. may be supposed to do, and a negative, as that of carbonate of lime, &c.

Post. 2. The polarizing force of a single axis in any medium is proportional to, and measured by, the tint pointing a for polarized by their joint action, and C the angle between the planes just described, the tint T will be given by the equation

\[ T = \sqrt{t^2 + t'^2 \cos C + \alpha} \]

Corol. 1. If \( a \) and \( b \) represent the intensities of the tints polarized by either of two axes separately, \( T \) that polarized by their joint action, and \( C \) the angle between the planes just described, the tint \( T \) will be given by the equation

\[ T = \sqrt{a^2 + b^2 - 4ab \cos C} \]

Corol. 2. If \( \gamma \) be the angle contained between the polarizing axes, since \( \alpha, \beta, \gamma \) are the sides of a spherical triangle, and \( C \) the angle included between the sides \( a \) and \( b \), or opposite to \( \gamma \), we have

\[ \cos C = \frac{\cos a \cos b - \cos \gamma}{\sin a \sin b} \]

and if this be written for \( \cos C \) in the latter of the expressions above given for \( T \), we find on reduction

\[ T = \sqrt{a^2 + b^2 - 4ab \cos C} \]

Corol. If the polarizing axes be at right angles to each other, \( \gamma = 90^\circ \) and \( \cos \gamma = 0 \), and the expression for the compound tint becomes

\[ T = a \sin \alpha + b \sin \beta \]

Proposition. Two rectangular polarizing axes, either both positive or both negative, being given, two other axes, or fixed lines, may be found, such that calling \( \theta \) and \( \phi \) the angles made with them respectively by a ray traversing a spherical portion of the medium, the tint polarized shall be proportional to \( \sin \theta \sin \phi \).

Let \( A \) and \( B \) (fig. 199) be the two polarizing axes including a right angle, of which let \( B \) be the more powerful. Let \( O \) be a ray penetrating the crystal in that direction; and in a plane \( PCQ \) perpendicular to \( ACB \), draw any two lines \( PC, QC \), making equal angles with \( B \), each of which will represent by \( x \).

Then if a sphere about \( C \) as a centre be conceived, it will intersect the planes \( ACB \), \( PCQ \), \( AOC \), \( OCB \), \( OCP \), \( OQC \) in lines of great circles \( B, PB, OA, OB, OP, OQ \), and we shall have \( PB = QB = x \), \( OA = a \), \( OB = b \), \( OP = \theta \), \( OQ = \theta' \); and by Spherical Trigonometry, from the triangle \( OBP \), we have

\[ \cos OBP = \frac{\sin OB \sin AOB}{\sin AB} = \frac{\sin a \sin \alpha}{\sin \beta \sin \alpha} \]

* M. Biot appears to have first noticed the fact announced in this proposition, viz. that Dr. Brewster's hypothesis of polarizing axes leads to a result mathematically identical with his own elegant law of the product of the sines. He has, however, suppressed his demonstration. Dr. Brewster's verification of this coincidence of results seems to have been founded on a numerical comparison of Biot's experiments on sulphate of lime with his own theory.
and therefore
\[-\cos \theta = \sin a \cdot \sin \beta \cdot \sin \gamma \cdot \cos \beta \cdot \cos \alpha,
\]
and similarly from the triangle O B Q, since O B Q = 90° + O B A, we obtain a second relation
\[+ \cos \theta' = \sin a \cdot \sin \beta \cdot \sin \alpha \cdot \sin \gamma + \cos \beta \cdot \cos \alpha;
\]
and, adding and subtracting, (putting, for brevity's sake, \(\cos \theta' = p, \cos \theta = q\))
\[p + q = 2 \cdot \cos \beta \cdot \cos \alpha; \quad p - q = 2 \cdot \sin a \cdot \sin \beta \cdot \sin \alpha \cdot \sin \gamma.
\]
These equations express the geometrical relations subsisting between the lines P C, Q C, and the axes A C, B C; and, if combined with the equations of Art. 1028 and 1029, suffice to eliminate \(a, \beta, \) and \(C\), and to express \(T\) in terms of \(\alpha, \theta\), and \(\theta'\) alone. To execute this, we have by the equations just demonstrated
\[
\left(\frac{p + q}{2 \cdot \cos \alpha}\right)^2 = \cos \beta^2; \quad \left(\frac{p - q}{2 \cdot \sin \alpha}\right)^2 = \sin a^2 \cdot \sin \beta^2 \cdot \sin \gamma^2;
\]
and in the latter, putting \(1 - \cos C = \sin C, \) and for \(\cos C\) its value given by Art. 1028, which, since \(\gamma = 90^\circ\), becomes simply
\[\sin a^2 \cdot \sin \beta^2 \cdot \cos C = \cos a \cdot \cos \beta;
\]
we have
\[
\left(\frac{p - q}{2 \cdot \sin \alpha}\right)^2 = \sin a^2 \cdot \sin \beta^2 - \cos a^2 \cdot \cos \beta^2 = \sin a^2 - \cos \beta^2.
\]
Hence we get, for the values of \(\sin a^2\) and \(\sin \beta^2\),
\[
\sin a^2 = \left(\frac{p + q}{2 \cdot \cos \alpha}\right)^2 + \left(\frac{p - q}{2 \cdot \sin \alpha}\right)^2,
\]
\[
\sin \beta^2 = 1 - \left(\frac{p + q}{2 \cdot \cos \alpha}\right)^2;
\]
and, substituting these in the equation of Art. 1029,
\[T = \left\{b + \frac{a - b}{4 \cdot \sin x^2} \cdot (p + q)^2 + \frac{a}{4 \cdot \sin x^2} (p - q)^2 \right\}^2 \frac{a - b}{4 \cdot \cos x^2} (p - q)^2.
\]
Such is the general form of the expression for the tint, when referred to arbitrary axes in the manner here supposed, and it is complicated enough; but if we fix the position of the new axes so as to make \(\sin \beta^2 = \frac{a}{b}\) the complication disappears; we have then \(\frac{a}{4 \cdot \sin x^2} = \frac{b}{4}\), and \(\frac{a - b}{4 \cdot \cos x^2} = \frac{b}{4}\), so that the value of \(T^e\) reduces itself to
\[T^e = b^e \left\{(1 - \left(\frac{p + q}{2}\right)^2 + \left(\frac{p - q}{2}\right)^2\right\} \frac{(p - q)^2}{(p - q)^2},
\]
\[= b^e \left\{(1 - p^2)^2 - (p - q)^2\right\} = b^e \left\{1 - p^2 - q^2 + p^2 q^2\right\},
\]
restoring the values of \(p\) and \(q\), or \(\cos \theta'\) and \(\cos \theta\), consequently
\[T = - b \cdot \sin \theta \cdot \sin \theta'.
\]
The negative sign is prefixed for the reason stated further on in Art. 1034.

Thus we see that the combined action of the two axes in the manner here supposed, on Dr. Brewster's principles, will give rise to a series of isochromatic lines arranged in the form of spheroidal lemniscates about two poles \(P, Q\), determined by the condition
\[
\sin B P = \sin B Q = \sqrt{\frac{\text{intensity of the feeblest axis}}{\text{intensity of the stronger}}};
\]
and the lines \(C P, C Q\) so determined have therefore the character of the optic axes in biaxal crystals, and may be designated with Dr. Brewster by the name of resultant axes. We must be careful, however, not to confound a resultant with a polarizing axis in this theory.

If the polarizing axes be not of the same denomination, as if one be positive and the other negative, the value of \(\sin B P\) becomes imaginary, and the tints cannot be so arranged. But if we suppose the new axes to lie in this case in the same plane with the polarizing ones, as in fig. 200, all other things remaining, we have here
\[\cos O B A = + \cos O B Q, \quad \text{and} \quad \cos O A B = - \cos O B P,
\]
but
\[\cos O B A = - \frac{\cos a}{\sin \beta}, \quad \text{and} \quad \cos O B Q = \frac{\cos \beta \cdot \cos x - \cos \theta'}{\sin \beta \cdot \sin x},
\]
so that we find
\[\cos \theta' = p = \cos \beta \cdot \cos x + \cos a \cdot \sin x; \quad 4 b 2\]
and similarly
\[
\cos \theta = q = \cos \beta \cdot \cos x - \cos \alpha \cdot \sin x,
\]
whence, by adding and subtracting, we get at once
\[
\cos \alpha = \frac{p - q}{2 \cdot \sin x}; \quad \cos \beta = \frac{p + q}{2 \cdot \cos x};
\]
which, substituted in the value of \( T^o \), give
\[
T^o = \left( (a + b) - \left( \frac{a}{\sin x} + \frac{b}{\cos x} \right) \frac{p^q}{4} + \left( \frac{a}{\sin x} - \frac{b}{\cos x} \right) \frac{p^q}{2} \right)
\]
\[-4 \cdot \frac{a}{\sin x} \cdot \frac{b}{\cos x} \cdot (p^q + q) + 2 \cdot \frac{a}{\sin x} \cdot \frac{b}{\cos x} \cdot (p^q - q) \cdot \frac{p^q}{2}.
\]
Now, if in this we suppose \( \frac{a}{\sin x} + \frac{b}{\cos x} = 0 \), or \( \tan x^2 = -\frac{a}{b} \), it will, on substitution and reduction, take the form
\[
T^o = \frac{1}{\cos x^2} \cdot (1 - p^q) \cdot (1 - q^p) \cdot \frac{p^q}{\cos x^4}.
\]
and
\[
T = -\frac{b}{\cos x^2} \cdot \sin \theta \cdot \sin \theta';
\]
that is, restoring the value of \( x \), (since \( \tan x^2 = -\frac{a}{b} \), and therefore \( \cos x^2 = \frac{b}{b - a} \)), finally,
\[
T = -\frac{b}{\cos x^2} \cdot \sin \theta \cdot \sin \theta'.
\]

1033. Thus, in this case also, the isochromatic lines are spheroidal-lemniscates, and the only difference is that their poles lie now in the plane of the polarizing axes, instead of at right angles to it; and whereas in the former case the semi-angle between them \( x \) was given by the equation \( \sin x = \sqrt[3]{\frac{a}{b}} \), that is, \( \cos x = \sqrt[3]{\frac{b}{b - a}} \), in this it is given by the equation \( \cos x = \sqrt[3]{\frac{a}{b}} \).

1034. Case of the resolution of a single axis into two.

Corol. 1. In the case when \( a = b \), or when the two polarizing axes are of the same denomination and of equal intensity, we have \( x = 90^\circ \), so that the angle between the resultant axes being \( 180^\circ \), they form one straight line, the lemniscates become circles, and the single resultant axis has now the characters of a polarizing axis. Hence, vice versa, a single polarizing axis, in any direction, may be resolved into two others equal in intensity, at right angles to it and to each other, and of an opposite denomination to the resolved axis. This follows from the negative sign of \( T \), which is prefixed in extracting the square root in Art. 1030 and 1032; because in the case supposed, when the arc \( A B \) is \( 90^\circ \) the angle \( C \) or \( A O B \) is necessarily greater than \( 90^\circ \), and \( 2 \cdot C \) the angle of the parallelogram of tints \( > 180^\circ \); so that the diagonal will be to be measured backwards through the angle, or must be a negative quantity.

Corol. 2. Since a single axis is equivalent to two equally intense axes of an opposite character at right angles to it and to each other, if we superadd to both another equal axis also of the opposite kind, and in the direction of the first, this will destroy the effect of the first, and therefore the combination of three equal and similar axes arising on the other side at right angles to each other, will be equivalent to none at all. Thus, three equal rectangular axes of the same character destroy each other's effects. This is Dr. Brewster's account of the want of polarization and double refraction in crystals whose primitive form is the cube, regular octahedron, &c., and whose secondary forms indicate a perfect symmetry in their molecules with respect to three rectangular axes.

1036. There is no necessity to pursue further the general subjects of this species of composition of axes and of tints. Indeed, it appears to us that the rule for the parallelogram of tints, as laid down by Dr. Brewster, becomes inapplicable when a third axis is introduced; for this obvious reason, that when we would combine the compound tint arising from two of the axes (A, B) with that arising from the action of the third (C), although the sides of the new parallelogram which must be constructed are given, (viz. the compound tint T, and the simple tint \( t^p \)) yet the wording of the rule leaves us completely at a loss what to consider as its angle, inasmuch as it assigns no single line which can be combined with the axis C in the manner there required, or which \( quod hoc \) is to be taken as a resultant of the axes A, B. For further information therefore on this subject we shall content ourselves with referring the reader to his original Paper in the Transactions of the Royal Society, 1818.

§ X. Of Circular Polarization.

1037. The first phenomena referable to the class of facts to whose consideration this section will be devoted, were noticed by M. Arago in his Memoir published among those of the Institute for 1811 on the colours of crystallized plates. He observed that when a polarized ray was made to traverse at right angles a plate of rock crystal
(quartz) cut perpendicularly to the axis of double refraction, on analyzing the emergent ray by a doubly refracting prism, the two images had complementary colours, and that these colours changed when the doubly refracting prism was made to revolve; so that in the course of a half revolution, the extraordinary image (for example) which at first was red, became in succession orange, yellow, yellow-green, and violet, after which the same series of tints would of course recur. It is evident that this is just what would take place, supposing the several coloured rays at their emergence from the rock crystal to be polarized in different planes; and to this conclusion M. Arago came in a second Paper, subsequently read to the Institute. The subject was resumed by M. Biot, in a Paper published in the Mem. de l'Inst., 1812; and his labours were completed in a second extremely interesting Paper read to that body in September, 1818.

When a polarized ray is made to traverse the axis of Iceland spar, beryl, and other uniaxial crystals, we have seen that it undergoes no change or modification; and that when analyzed at its egress by a doubly refracting prism, having its principal section in the plane of primitive polarization, the ordinary image will contain the whole ray, or the complementary tints will be white and black. Quartz, however, is an exception to this rule. A polarized ray transmitted, however precisely, along its axis, is still coloured and subdivided, and that the more evidently, the thicker is the plate. If we place on a proper apparatus, such as that described in Art. 929 and figured in fig. 189, a very thin plate of this body, and turn round the analyzing prism in its cell, till the extraordinary image is at its minimum of brightness, it will in this position have a sombre violet, or purple tinge, because the yellow or most luminous rays, which are complementary to purple, are now completely extinguished. Let the angle of rotation of the prism in its cell, measured on the divided circle $R$, and which in this case will be small, be noted; and then let the rock crystal plate be detached, and another cut from the same crystal, but of twice the thickness, be substituted. The tint of the extraordinary image will no longer be violet; but if the prism be made to revolve through an additional equal arc in the same direction, the violet or purple tint will be restored, and the minimum of brightness attained; and, in general, if the thickness of the plate (always supposed cut from the same crystal) be greater or less in any ratio, the angle of rotation through which the prism must be moved in the same direction, to produce a minimum of intensity and a purple tint in the extraordinary image, is increased or diminished in the same ratio. In consequence, if the plate be sufficiently thick, one or more circumferences will be required to be traversed; and as only the excesses over whole circumferences can be read off, this may produce some confusion or doubt, unless we take care to use a succession of thicknesses so gradually increasing as not to allow of a saltus of a whole, or a half circumference.

From this experiment we collect, that the plane of polarization of a mean yellow ray which has traversed the axis of a quartz plate, has been turned aside from its original position, through an angle proportional to the thickness of the plate; and, therefore, assumes at its egress a position the same as it would have, had it revolved uniformly in one direction, during every instant of the ray's progress through the plate. The same holds good for all the other homogeneous rays; but to prove it, we must abandon the use of white light, and operate with pure rays of the particular colour we would examine. If we use pure red light, for instance, or defend the eye with a pure red glass, the same will be observed, only that instead of a violet tint and a minimum of light, we shall have a total obliteration of the extraordinary pencil when the prism attains its proper position, thus proving, what in the former mode of observation might have been doubtful, that the polarization of the emergent ray is complete.

In examining in this way the quantity by which one and the same plate of quartz turns aside the planes of polarization of the different homogeneous rays, M. Biot ascertained that the more refrangible rays are more energetically acted on than the less, and have their planes of polarization deviated through a greater arc. According to this eminent philosopher, the constant coefficient, or index, which represents the velocity with which the plane of polarization may be conceived to revolve, is proportional to the square of the length of an undulation of the homogeneous ray under consideration; so that if we call $\lambda$ the length of an undulation, and $t$ the thickness of the plate, the deviation produced will be equal to $k \cdot \frac{\lambda^2}{t}$, $k$ being a certain constant. The value of this constant he assigns at $16^\circ.414$ when $t$ is reckoned in millimetres; and the following is stated by him as the numerical amount of the deviations in degrees (sexagesimal) produced by one millimètre of thickness of rock crystal on the several rays:

In the course of these researches M. Biot was led to the very singular discovery of a constant difference subsisting in different specimens of rock crystal, in the direction in which this rotation or angular shifting of the plane of polarization of a ray traversing them takes place. In some specimens it is observed to be from right to left, in others from left to right. To conceive this distinction, let the reader take a common cork-screw, and, holding it with the head towards him, let him turn it in the usual manner, as if to penetrate a cork. The head will then turn the same way with the plane of polarization of a ray in its progress from the spectator through a right-handed crystal may be conceived to do. If the thread of the cork-screw were reversed, or what is termed a left-handed thread, then the motion of the head as the instrument advanced would represent that of the plane of polarization in a left-handed specimen of rock crystal. It will be observed, that we do not here mean to say that the plane of polarization does so revolve in the interior of a crystal, but that the ray at its egress presents the same phenomena as to polarization as if it had done so. This is necessary, for we shall see presently that a very different view of the subject may be taken.

In crystals which present this remarkable difference, when cut and polished, and when the external indications of crystalline form are obliterated, no other difference can be detected. Their hardness, transparency, refractive and double refractive powers are the same; and, with the exception of the direction in which it takes place, their effects in deviating the planes of polarization of the rays which traverse them are alike. Experiments subsequent to M. Biot’s researches have, however, established, as a result of extensive induction, a very curious connection between this direction and the crystalline forms affected by individual species. In the variety of crystallized quartz, termed by Hauy, Plagiedral, there occur faces which (unlike those in all the more common varieties) are unsymmetrically related to the axes and apices of the primitive form, whether regarded as the rhomboidal or bipyramidal dodecahedron. Fig. 201 represents such a crystal, in which when the apex A is set upwards, the faces C, C, C, are observed to lean all in one direction, viz. to the right, with respect to the axis, as if distorted from a symmetrical position by some cause acting from left to right round the crystal. When the vertex B is set upwards, the same distortion, and in the same direction, is observed in the plagiedral faces D, D, D, and crystals of quartz are excessively rare, if they exist at all, in which two plagiedral faces leaning opposite ways occur. Now it has been ascertained, that in crystals where one or more of these faces, however minute and even of microscopic dimensions, can be seen, we may thence predict with certainty the direction of rotation in a plate cut from it, which is always that in which the plagiedral face appears to lean with respect to an observer regarding it as the reader does the figure, which represents a right-handed crystal. Hence we are entitled to conclude, that whatever be the cause which determines the direction of rotation, the same has acted in determining the direction of the plagiedral faces. Other crystallized minerals, as apatite, &c. also present plagiedral and unsymmetrical faces; but, independent of their extreme rarity, they are not possessed of the property of rotation; so that at present we are unable to say whether this curious law be general, or to conjecture to what principles it will hereafter prove to be referable.

When two plates of rock crystal are superposed, if they be both right-handed or both left, their joint rotatory effect will be the sum of their respective ones, i.e. each ray’s plane of polarization will be shifted through an angle equal to the sum of those through which it would have been shifted by their separate actions. If their characters be opposite, it will be their difference, i.e. the index of rotation in a right-handed crystal being regarded as positive, it will be negative in a left-handed one.

The amethyst (and, possibly, also the agate in some cases) presents the very remarkable and curious phenomenon of these two species of quartz crystallized together in alternate layers of very minute thickness. Accordingly, when a crystal of amethyst is cut at right angles to the axis, and examined by polarized light transmitted exactly along the axis, and analyzed as usual, it offers a striped or fringed appearance, as represented in fig. 202, variegated with different colours, according to the different planes of polarization assumed by the rays emergent at its several points, and presenting, according to the distribution of its elements, the most beautiful combinations and contrasts of coloured fasciae and spaces. For a particular account of these phenomena, the reader is referred to a Paper by Dr. Brewster, (Edinburgh Transactions, vol. xi.) who first observed and publicly described them, though we have reason to believe them to have been known to others by independent observation previous to the publication of his very curious and interesting Memoir. The layers may be distinctly seen cropping out to the surface in a fresh fracture of the mineral, and imparting that peculiar undulated fracture which is the chief mineralogical character of this substance by which it is known from ordinary quartz.

But the phenomena of rotation as above described are not confined to quartz. Many liquids, and even vapours exhibit it, a circumstance which would seem very unexpected, when we consider that in liquids and gases the molecules must be supposed unrelated to each other by any crystalline arrangement, and independent of each other; so that to produce any such phenomena, each individual molecule must be conceived as unsymmetrically constituted, i.e. as having a right and a left side. M. Biot and Dr. Seebeck appear about the same time to have made this singular and interesting discovery; but the former has analyzed the phenomena with particular care, and it is from his Memoir above cited that we extract the following statements. The liquids in which he observed a right-handed rotatory property, according to our sense of the word above explained, in which the observer is supposed to look in the direction of the ray’s motion, are oil of turpentine, oil of Laurel, vapour of turpentine oil, and an alcoholic solution of artificial camphor produced by the action of muriatic acid on oil of turpentine. The left-handed rotation was observed by him in oil of lemons, syrup of cane sugar, and alcoholic solution of natural camphor. In all these, the intensity of the action, or the velocity of rotation, was measured by a circulus of angles, which is used in opticks. The following are their indices of rotation, or the arcs of rotation produced by one millimetre of thickness in the plane of polarization of a certain homogeneous red ray chosen by M. Biot for a standard, as calculated from his data.
It follows further from M. Biot's researches, that when any two or more liquids are mixed together, or combined with plates of rock crystal, the rotation produced by the compound medium will be always the sum of the rotations produced by the several simple ones, in thicknesses equal to their actual thicknesses present in the combination, the thicknesses in mixed liquids being assumed in the ratio of the volumes of each respectively mixed; so that calling $T$ the compound thickness, and $R$ the resulting index of rotation, we shall always have

$$R = T = r + t + r' + t' + r'' + t'' + \ldots$$

where $r$, $r'$, $t$, $t'$, etc. are the indices (with their signs) of the elementary ingredients, and $t$, $t'$, $t''$, etc. their thicknesses.

Thus, when 66 parts by measure of oil of turpentine, having the index +0.258 are made to act against 38 of oil of lemon, we have

$$+ 66 \times 0.258 - 38 \times 0.436 = 0.002,$$

so that these thicknesses ought almost exactly to compensate each other; and such was, in fact, the result of M. Biot's experiment, the whole pencil transmitted being found to retain its primitive polarization without the least trace of an extraordinary image. Again, when into two tubes of the same bore, but of very unequal lengths, equal quantities of oil of turpentine were poured, and the rest of their lengths filled with sulphuric ether, which has no rotatory property, or in which $r = 0$, the two compound thicknesses thus differently constituted gave identically the same tints in all positions of the analyzing prism. Thus we see that dilution or mixture which only separate, without decomposing the molecules, do not alter their rotatory power. Nay, even when reduced to vapour, M. Biot found, that oil of turpentine still preserved its property and peculiar character; and, had not the explosion of his apparatus prevented accurate measures, would probably enough have been found to retain the same index of rotation allowing for the change of density. From these circumstances he concludes that the rotatory power is essentially inherent in the molecules of bodies, and carried with them into all their combinations. But this is too rapid a generalization; for neither sugar nor camphor in the solid state possesses this property, though examined for it in the same circumstances as quartz is, by transmitting the polarized ray along their optic axes; and, on the other hand, quartz held in solution by potash, or (as Dr. Brewster has found) melted by heat, and thus deprived of its crystalline arrangement, manifests no such property. This obscure part of chemical optics well deserves additional attention.

M. Fresnel's researches have been directed to the rotatory phenomena with the same brilliant success which has distinguished his other inquiries into the nature of light; and he has shown that they may be explained by conceiving the molecules of the ether, which propagate rays along the axis of quartz, or rotatory fluids, instead of vibrating in straight lines, to revolve uniformly in circles, in the manner explained in Art. 627, (where we have shown Corol.) that such a mode of vibration may subsist, and must arise from the interference of two rectangular vibrations of equal amplitude, but differing in phase by a quarter undulation,) and by admitting that, in virtue of some peculiar mechanism in the molecules of the media in question, such circular vibrations, when performed from right to left, bring into play an elasticity slightly different from that which propagates them forward when performed in the contrary direction. The colours produced by such media he conceives to originate in the interference of two pencils thus circularly polarized, and lagging the one behind the other by an interval of retardation proportioned to their difference of velocities.

But to make this last hypothesis admissible, it is incumbent on us to show that the phenomenon which necessarily accompanies a difference of velocities, viz. a bifurcation of the pencil in the act of refraction at oblique surfaces, really takes place. This has accordingly been shown by M. Fresnel, by an experiment which, though of great delicacy, is decisive and satisfactory. From a crystal of quartz he procured to be cut a prism having its refracting angle 158°, and its faces equally inclined to the axis; so that a ray traversing it internally parallel to its axis should be incident at equal angles, viz. of 75° on either face. As this is too great to allow of the ray's egress, he cemented on the surfaces the two halves of another precisely similar prism cut from another rock crystal of an opposite rotatory character. Thus in fig. 203, $ABC$ is the first prism, and the side $CB$ of the second prism $CBE$ being cemented on to $CB$, this prism is bisected by the plane $BD$, and the half of it $DBE$ transferred to the other side, and cemented with its side $BC$ in contact with $AC$, thus producing the achromatic parallelepiped $FABD$; so that if a ray be incident on $Q$ in the direction $PQ$ parallel to the base $AB$, i.e. to the axis of the two crystals, it will traverse all three in the direction of the axes of their spheroids of double refraction; and, therefore, so far as the Huygenian law of double refraction is concerned, ought to undergo no division. Now it is evident, that if the ray $PQ$ be at its entry into $AFC$ divided into two circularly polarized in opposite directions, the one ($R$) moving quicker than the other ($L$), then, at quitting the surface $AC$, a bifurcation must take place, the ray $R$ being least, and $L$ most refracted. In this state they are incident on the medium $ACB$, and now the portions $R$ and $L$, by reason of the opposite nature of the media, exchange velocities; so that $R$, which at its emergence from the face $AC$ of $FAC$ was least refracted upwards, will now

</table>
be most refracted downwards; and thus the separation of the images will be doubled, and the same will take place at the common face C B. Thus this combination, both from the doubling of the separation, and the greatness of the angles of incidence, is peculiarly well adapted to render sensible any bifurcation, or difference of velocities, however small, which may exist along the axis. Accordingly, with the compound prism, so constructed, a double refraction is produced; and the two rays are really observed to emerge, making a sensible angle with each other.

But it is, moreover, observed, that though thus separated by a real double refraction, the two pencils have not acquired the characters which double refraction usually impresses on the ordinary and extraordinary rays, at their emergence, but very different ones. In common cases of double refraction the two emergent pencils are each wholly polarized in opposite planes, and either of them when examined with a doubly refracting prism gives two unequal images, one alternately more and less bright than the other, as the prism revolves through successive quadrants. This is not the case with the two pencils produced in the case before us, for First, Either of them, when examined with a doubly refracting prism, gives constantly two images of equal intensity, in whatever plane the principal section of the latter be placed. In this respect, then, they present the characters of unpolarized light, and may be regarded as each consisting of two rays polarized at right angles to each other. But Secondly, They differ from ordinary, or unpolarized light, in a very remarkable property, which was first discovered by Fresnel, and is a chief distinctive character of this kind of polarization. Suppose either of them to be incident at right angles on the surface A B of a parallelepiped of crown glass of the refractive index 1.51, having its angles A B C and A D C each 54°; it will then be totally reflected at the internal surface B C; and (if the parallelepiped be long enough) again in the same plane at the opposite surface A D, and will emerge at length so perpendicularly through the surface B C, that the emergent ray, instead of emerging, as ordinary light, will now be found to be completely polarized in a plane 45° inclined to that in which the reflections were made, whatever may have been the position of that plane. If both the pencils be treated in this manner, it will be found that the one, after its two total reflexions will assume a plane of polarization 45° in azimuth to the right, and the other 45° to the left of the plane of the reflexions.

Thus we see that the effect of double refraction along the axis of quartz is to impress on either of the emergent pencils opposite polarizations, or modifications, of a nature totally distinct from that given to a ray by ordinary reflexion, or by double refraction through Iceland spar, &c.; and, as in the last described experiment, so long as the ray enters perpendicularly into the first surface of the glass parallelepiped, it is indifferent in what plane the two reflexions are operated, and since when presented to a doubly refracting prism in any plane differently it always divides itself into two equal pencils, it is evident that the ray thus modified has no sides, i. e. no particular relations to certain regions of space; and therefore that the epithet circular polarization, apart from all theoretical considerations, may be naturally applied to this peculiar modification. But the characters above described are not the only ones belonging to a ray thus modified, for Thirdly, Such a ray being transmitted through a thin crystallized lamina, and parallel to its axis, is divided by subsequent double refraction into two rays of complementary colours, thus marking a decided difference between it and a ray of common light; while, on the other hand, these colours are not the same with those which would arise from a ray of light polarized in the usual way and similarly analyzed, but differ from them by an exact quarter of a tint, either in excess or defect, as the case may be.

Fourthly, A ray so modified by this peculiar double refraction, when transmitted again along the axis of rock crystal, or through columns of oil of turpentine, of lemons, &c., and then analyzed by a double refracting prism, gives rise to no phenomena of colour, differing in this from polarized, and agreeing with common light.

Another independent mode of impressing on a ray all this assemblage of characters has been discovered by M. Fresnel. It consists in inverting the process described in Art. 1049. Thus, into the side C D of the glass parallelepiped there mentioned, let a common polarized ray be introduced at a perpendicular incidence, the parallelepiped being so placed that the plane of internal reflexion at the side A D shall be 45° inclined to that of its primitive polarization. Then, after undergoing two total internal reflexions at G and F, it will emerge at E deprived of its characters of ordinary polarization and endowed with those of circular, and being in no way distinguishable from one of the pencils produced by double refraction along the axis of rock crystal.

It remains to show, however, that the characters here described, as impressed on a ray by transmission along the axis of rock crystal, are really those which ought to belong to a ray propagated by circular vibrations. And, first, it follows from Art. 627, that this latter ray is the resultant of two rays polarized at right angles, and differing in their phases by a quarter undulation. It must, therefore, of necessity possess the first character, viz. that of division into two equal pencils by double refraction in any plane, for the same reason that unpolarized light is so divided, the difference of phases having nothing to do with this character.

In the next place, a ray propagated by circular vibrations when incident on rock crystal in the direction of the axis, will (by hypothesis) be propagated along it by that elasticity which is due to the direction of its rotation, the wave then will enter the crystal without further subdivision and there will be no difference of paths, or interfering rays at its emergence; and, of course, no colours produced on analyzing by double refraction, which is another of the characters in question.

When a ray propagated by circular vibrations is incident on a crystallized lamina it may be regarded as composed of two, one polarized in the plane of the principal section, the other at right angles to it, of equal intensity, and differing in phase by a quarter undulation. Each of these will be transmitted unaltered, and therefore at their emergence and subsequent analysis will comport themselves in respect of their interferences, just as would do the two portions of a ray primitively polarized in azimuth 45°, and divided into two by the
double refraction of the lamina, provided that a quarter undulation be added to the phase of one of these latter rays. Now such rays will, as we have shown at length in Art. 969, produce by the interference of their doubly refracted portions, the ordinary and extraordinary tints due to the interval of retardation within the crystallized lamina. Hence, in the present case, the tints produced will be those due to that interval, plus or minus the quarter of an undulation added to, or subtracted from, the phase of one of the portions; and, consequently, will differ one-fourth of a tint, or order, from that which would arise from the use of a beam of ordinary polarized light incident in azimuth 45° on the lamina.

There remains but one more character of the rays transmitted along the axis of quartz, which we must show to belong to a ray propagated by circular vibrations, viz. that described in Art. 1049. But in order to this it will be necessary to state the result of M. Fresnel's researches on the modifications which light undergoes by total reflection in the interior of transparent bodies.

When a ray polarized in any azimuth is incident on a reflecting surface which reflects the whole of the incident light, if we decompose it into two, the one having its vibrations performed parallel, and the other perpendicular to the surface, and regard each of these as independent of the other; it is evident that the reflexion of these portions will be performed under very different circumstances, the etheral molecules having in the former case to glide as it were on the surface, and therefore parallel to the strata in which their density is constant, while in the latter each molecule in the act of vibration will pass into strata of variable density. The reflexions therefore will be performed at different depths in the two cases; and from this cause will arise a difference of route, and a consequent difference of phase in the reflected portions, so that the total reflected ray will no longer be capable of being regarded as having a single origin, but as two of unequal intensities, oppositely polarized, and differing in phase by a quantity depending on the angle of incidence and the refractive power of the medium.

From peculiar considerations, of a delicate nature, and depending on a discussion of the imaginary forms assumed by the general expressions for the intensity of a ray reflected at any angle (Art. 852) when applied to the case of total reflexion, M. Fresnel has been led to the following expression for the difference of phases (δ) of the two portions in question.

\[
\cos \delta = \frac{2 \mu^2 \cdot (\sin i)^4 - (\mu^2 + 1) \cdot (\sin i)^4 + 1}{(\mu^2 + 1) \cdot (\sin i)^4 - 1},
\]

where \( \mu \) is the index of refraction, and \( i \) the angle of internal incidence. This formula, it is to be observed, is given by him, not as strictly demonstrated, but merely as highly probable, as an interpretation of the analytical meaning of the imaginary formula alluded to. The mode of its deduction being, however, independent of experiment, and entirely \textit{a priori}, it is clear that if found verified by careful experiment in circumstances properly varied, it may be received as a physical law, like any other result of the same kind. Now we have already seen, that in the case of crown glass, where \( \mu = 1.51 \) and \( i = 54° 37' \), a polarized ray, having its azimuth 45°, reckoned from the plane of total reflexion, has its polarization destroyed, and becomes resolved into a ray having the other characters of a resultant from two differing 45° in phase, by two total reflexions at this angle, (Art. 1056.) But if in the above formula we make \( \mu = 1.51 \), and \( i = 54° 37' \), we shall find \( \delta = 45° \), and \( 2 \delta = 90° \), so that the above equation is verified in this case. M. Fresnel also found that the same effect was produced by three reflexions when the angle of incidence was 69° 12', and by four when 74° 42', both agreeing with the formula which gives in the former case \( \delta = 90° \), and in the latter \( \delta = 90° \), for the difference of phase gained or lost by one portion on the other at each reflexion. Similar verifications were obtained by performing two reflexions at the internal surface of glass, and two at the confines of glass and water at angles of 69° 27'.

It appears, then, that when a ray polarized in azimuth 45° undergoes two total reflexions at the angles, and in the manner described, it becomes circularly polarized; and if vice versa, the two elements of a ray so circularly polarized be made to retrace their course, they will reunite into a ray polarized completely in one plane.

Thus we see, that all the characters of the rays transmitted along the axis of rock crystal agree with those of a ray so compounded, and possessing \textit{circular polarization}. In order, then, to explain the phenomena presented by a polarized ray when incident on a plate of this substance cut at right angles to its axis, we must first regard the ray as resolved into two others (which we will call A and B) of equal intensity; the one A polarized in a plane 45° inclined to the right, the other 45° inclined to the left of the vertical, (which, to fix our ideas, we shall take for the plane of primitive polarization.) Now, since by Art. 615 a ray polarized in any plane may be regarded as equivalent to two rays each of half its intensity, differing in their phases by a quarter undulation, let us conceive the ray A as resolved into two, A a polarized in the plane + 45°, and having its phase advanced + $\frac{1}{4}$ undulation, and another A b also polarized at + 45°, but having its phase retarded, or $-\frac{1}{4}$ undulation. Similarly, let B be regarded as decomposed into B a polarized at $-45^\circ$, and having its phase $+\frac{1}{4}$ undulation, and B b polarized also at $-45^\circ$, but having its phase $-\frac{1}{4}$ undulation different from B. Thus will the original ray be resolved into the four A a, A b, B a, B b. Now, let us combine these two and two in a cross order, then A a combined with B a will be equal rays, polarized in opposite planes, and differing $\frac{1}{4}$ undulation in their phases, and will therefore compose one circularly polarized ray, in which the rotation is from \textit{right to left}. Similarly, the pair A b, B a will compound another equally intense circularly polarized ray having its rotation the contrary way.

Now these will (\textit{ex hypothesi}) be transmitted through the quartz with unequal velocities, and thus an interval of retardation will arise, and if the surface of egress or ingress be \textit{oblique} to the axis, a double refraction will take place; and two circularly polarized rays will emerge in different directions, as experiments show they do. If \textit{perpendicular} they will emerge superposed, and will compound one ray. Let us now examine what will be the character and state of polarization of this compound ray. To this end conceive a molecule of ether C to be at once agitated by two circular motions in opposite directions; one in a circle equal and similar to A P in
the direction A P, the other in a circle equal and similar to B Q, and in the direction B Q, fig 205. Let A, B be two molecules setting out at once from A, B in these circles with equal velocities, then will the motion of C at any instant be equal to that compounded of the motions of A and B at that instant. When A comes to P let B come to Q, then are A P = B Q, and the motions at P and Q will be each resolved into two, those of which parallel to C D (a perpendicular to P Q) conspire, while those, in the directions P D and Q D parallel to P Q oppose, and being equal destroy each other; thus C will move only in virtue of the sum of the two former, and its vibrations will therefore be rectilinear, and in the plane C D perpendicular to P D Q. If the thickness of the plate of quartz were nothing, or such that the interval of retardation were an exact number of undulations, A, B would lie at opposite extremities of a diameter, and C D the new plane of polarization would be perpendicular to A M that diameter, or coincident with the plane of primitive polarization. But if not, the quicker motion will have gained on the other a part of a circumference M B, which is to a whole circumference as the thickness of the plate is to that which would produce a difference of a whole undulation; and at the emergence of the two waves into air, after which they circulate with equal velocity, if we suppose the one molecule to be setting out from A, the other will be setting out, not from M the opposite extremity of the diameter, but from B, and therefore C D the new plane of polarization (which from what has just been shown must always bisect the angle A C B) will no longer be coincident with C N the primitive plane of polarization, at right angles to A M, but will make an angle D C N with it equal to half B C M, and therefore proportional to M B, or to the interval of retardation, i.e. to the thickness of the plate. Thus the system of rays emerging from the rock crystal plate will compound one ray polarized in one plane, and in the position the original plane would have had, had it revolved uniformly round the ray as an axis during its passage through the plate. Thus we have a complete and satisfactory explanation of the apparent rotation of the plane of polarization, as observed by Biot in the case of a homogeneous ray.

It is observed, that the spectra formed by the double refraction of rock crystal along its axis are very highly and unequally coloured. The violet rays are most separated, and therefore the difference of velocities of the two rotating pencils is much greater for violet than for red rays. Consequently, the apparent velocity of rotation of the plane of polarization will also be greater for the violet rays in the same proportion, and thus arise all the phenomena of coloration observed and described by M. Biot. It is scarcely possible to imagine an analysis of a natural phenomenon more complete, satisfactory, and elegant. With regard to the physical reason of the difference of velocity in the two circular polarized pencils within the quartz, it is true we remain in the dark; but the fact of such difference existing is now shown to be no hypothesis, but a fact demonstrated by their observed difference of refraction, and by the observed characters of the two emergent rays.

§ XI. Of the Absorption of Light by Crystallized Media.

Crystallized media, endowed with the property of double refraction, are found to absorb the differently coloured rays differently, according to their planes of polarization, and the manner in which these planes are presented to the axis of the crystal, and also to exert very different absolute absorbing energies on rays of one colour polarized in different planes. A remarkable instance of this has been already often referred to in the case of the brown tourmaline, a plate of which, cut parallel to the axis, absorbs almost entirely all rays polarized in the plane of the principal section, and lets pass only such among oppositely polarized rays as go to constitute a brown colour.

When such a plate, then, is exposed to natural light, since at the entrance of each ray into its substance it is resolved into two, one polarized in the plane of the principal section, and one perpendicular to it, the former is absorbed in its progress by the action of the crystal, while the brown portion of the latter escaping absorption, but retaining at its egress the polarization impressed on it, after traversing the plate, appears with its proper colour, and wholly polarized in a plane at right angles to the axis. Thus the curious phenomenon of the polarization of light by transmission through a plate of tourmaline, or other coloured crystal, is explained, or at least resolved into the more general fact of an absorbing energy varying with the internal position of the plane of polarization. The crystal, in virtue of its double refractive property, divides the ray into two, and polarizes them oppositely; and the unequal absorption of these two portions subsequently causes the total suppression of one, and the partial of the other of the portions so separated. Thus we see that the polarized beam obtained by transmission through a tourmaline must always be of much less than half the intensity of the incident light.

The destruction of the pencil polarized in the principal section is not, however, sudden; for if the plate of tourmaline be very thin, the emerging pencil will only be partially polarized, indicating the existence in it of rays belonging to the other pencil. This is best shown by cutting a tourmaline into a prism having its refracting edge parallel to the axis, and its angle small, so as to produce a wedge whose thickness increases not too rapidly. If we look through this at a distant candle, we shall see only one image, viz. the extraordinary through the back of the wedge, (if thick enough;) but as the eye approaches the edge, the ordinary image appears at first very faint, but increasing in intensity till, at the very edge, it becomes equal to the other. At the same time the colour of the latter, which at first was intense, becomes diluted; and the images approximate not only to equality of light, but to similarity of tint. We see by this, too, that in strictness the ordinary pencil is never completely absorbed by any thickness, however great; but as it diminishes in geometrical progression as the thickness increases in arithmetical, the absorption may for all practical purposes be regarded as total at moderate thicknesses.
The indefatigable scrutiny of Dr. Brewster, to whom we owe nearly all our knowledge on this subject, has shown that the same property is possessed in greater or less perfection by the greater number of coloured doubly refracting media; and the expression of the property may be rendered general by considering all doubly refractive media as possessing two distinct absorbing powers or two separate scales of absorption for the two pencils, or (adopting the language of § III. part 2) as having two distinct types, or curves expressing the law of absorption throughout the spectrum. If these types be both straight lines parallel to the abscissa, the crystal will be colourless. Such are limpid carbonate of lime, quartz, nitre, &c. If they be similar and equal curves, the medium, although coloured, will present the same colour, and the same intensity of tint, in common as in polarized light. If dissimilar, or if, although similar, their ordinates are in a ratio of inequality, the character, in the former case, and the intensity in the latter, will vary on a variation of the plane of polarization of the incident beam, so that if a plate cut from such a crystal be exposed to a beam of polarized white light, and turned round in its own plane, or otherwise inclined to the beam, its colour will change either in hue or depth or both. Dr. Brewster has remarked such change of colour and the phenomena connected with it in a great variety of crystals both with one and two axes, of which he has given a list in a most interesting Paper on the subject in the Philosophical Transactions, 1819, p. 1, which we strongly recommend to the reader's perusal. It may be similarly seen in a prism of smoked quartz of a pretty deep tinge, which held with its axis in the plane of polarization appears of a purple or amethyst colour, while if held in a direction at right angles to this position, its colour is a yellow brown.

But in order to analyze the phenomena more exactly, we must examine the two pencils separately. To this end Dr. Brewster took a rhomboid of yellow carbonate of lime of sufficient thickness to give two distinct images of a small circular aperture placed close before it, and illuminated with white light, when he observed that the image seen by extraordinary refraction appeared of a deeper colour and less luminous than the other, being an orange yellow, while the ordinary image was a yellowish white. He found, moreover, that the difference of colour was greater as the paths of the refracted rays within the crystal were more inclined to the axis, being 0 when the rays passed along the axis, and a maximum when at right angles to it. If we denote by \( Y, \) and \( Y. \) the ordinates of the curves expressing the law of absorption as in Art. 490, for the ordinary and extraordinary pencil respectively, these will both therefore decrease as we proceed from the red to the violet end of the spectrum, corresponding to types of the character of that represented in fig. 114; but \( Y \), being smaller, and decreasing more rapidly than \( Y. \). Moreover, since \( Y = Y. \) in the axis, and since as we recede from the axis \( Y. \) increases (because the colour of the ordinary pencil becomes whiter and more luminous) while \( Y \), diminishes by the same degrees, (the extraordinary becoming deeper and less bright,) we shall represent both these changes satisfactorily by putting

\[
Y = Y (1 + k \cdot \sin \theta) ; \quad Y. = Y (1 - k \cdot \sin \theta) .
\]

These give \( Y + Y. = 2Y = \) constant, or independent of \( \theta \), which agrees with an observation of Dr. Brewster, that in every situation the combined tints of the two images are exactly the same with the natural colour of the mineral, (which, in this instance, appears to have been alike in all directions.)

In this case, then, the colour of a plate of the crystal of given thickness exposed to natural light will be the same, whether the plate be cut parallel or perpendicular to the axis. But Dr. Brewster has observed, that this is not always the case, but that great differences occasionally exist in this respect. Thus he found, that in some specimens of sapphire the colour when viewed along the axis was deep blue, and when across it yellowish green. In tourmaline also are not uncommon in which the tint across the axis is green, while along the axis it is deep red; and, in general, this mineral is always much more opaque in the direction of the axis than in any other; so much so, indeed, that plates of a very moderate thickness cut across the axis are nearly impermeable to light. One of the most remarkable instances of this kind we have met with is a variety of sub-oxysulphate of iron, which crystallizes in regular hexagonal prisms, and which viewed through two opposite sides of the prism is light green, but along the axis, a deep blood red, so intense that a thickness of \( \frac{1}{100} \) inch allows scarcely any light to pass. It is obvious, that to such cases the formulae of the last article do not extend. But a slight modification will enable us to embrace the phenomena in an analytical expression. For if we take

\[
y = X_n + Y_n \cdot \sin \theta ; \quad y = X_n + Y_n \cdot \sin \theta ;
\]

where \( X_n, Y_n, \) &c. as well as \( y, y \), represent functions of \( \lambda \) (the length of an undulation) being the ordinates of so many curves, or types of tints, whose relations are to be determined, we have

\[
y_n + y_n = (X_n + X_n) + (Y_n + Y_n) \cdot \sin \theta .
\]

Now this is the tint which a sphere of the medium of a diameter = 1 will exhibit when viewed by natural light along a diameter inclined \( \theta \) to the axis. If we represent by \( A \) and \( B \) the ordinates of the types of the tints it is observed to exhibit in the directions of the axis, and perpendicular to it, we have, when \( \theta = 0 \),

\[
y + y = A = X_n + X_n ;
\]

and when \( \theta = 90^\circ \),

\[
y + y = B = (X_n + X_n) + (Y_n + Y_n) ;
\]

whence we have

\[
Y_n + Y_n = B - A ;
\]

and the tint exhibited by ordinary light at the inclination \( \theta \) to the axis, will be represented by

\[
y + y = A + (B - A) \cdot \sin \theta , \quad = A \cdot \cos \theta + B \cdot \sin \theta .
\]
Thus in the case of our sub-oxysulphate of iron, A is the ordinate of the type of a deep blood-red tint, and B in like manner represents a bright pale green, so that we shall have at any intermediate inclination

\[
tint = (\text{deep red}) \times \cos \theta + (\text{light green}) \times \sin \theta,
\]

which represents faithfully enough the gradual passage of one hue into the other as the inclination changes.

Suppose now the incident beam polarized in any plane, and let the plane in which the ray and the axis of the sphere lie make an angle = a with that plane. Then would \(\cos a^2\) and \(\sin a^2\) represent the intensities of the ordinary and extraordinary pencils which superposed make up the emergent beam, were the crystal limpid; but in virtue of its absorbent powers, they will be reduced respectively to

\[
y_x = \cos a^2 (X_x + Y_x \sin \theta), \quad \text{and} \quad y_y = \sin a^2 (X_y + Y_y \cdot \sin \theta),
\]

so that at their emergence they will no longer make up white light, but a variable tint whose type has for its ordinate

\[
(X_x \cos a^2 + X_y \sin a^2) + (Y_x \cos a^2 + Y_y \sin a^2) \cdot \sin \theta,
\]

in which it will be recollected that \(X_x + X_y = A\), and \(Y_x + Y_y = B - A\).

To determine the individual values of \(X_x\), &c. however, we must have two more conditions, and these will be found by considering, first, that in the direction of the axis the tint must be independent of \(a\), which gives \(X_x \cos a^2 + X_y \sin a^2\) independent of \(a\), and therefore \(X_x = X_y\), and either of them = A. To get another condition, let the tints be noticed which the sphere or crystal exhibits when its axis is perpendicular to the visual ray; and, first, coincident with, next, perpendicular to, the plane of polarization, \(\text{i.e.} \) when \(a = 0\), and \(a = 90^\circ\).

These are respectively \(X_x + Y_x\), and \(X_y + Y_y\); and calling these \(a\) and \(b\), we have

\[
Y_x = a - X_x = a - A, \quad Y_y = b - A.
\]

Hence the final expression for the tint seen in polarized light will be

\[
A + \{ (a - A) \cos a^2 + (b - A) \sin a^2 \} \cdot \sin \theta,
\]

that is,

\[
A \cdot \cos \theta + \{ a \cdot \cos a^2 + b \cdot \sin a^2 \} \cdot \sin \theta,
\]

in which it will be observed that \(a\) and \(b\) are complements of each other to the tint \(B\), because

\[
a + b = X_x + Y_x + X_y + Y_y = B, \quad \text{by Art. 1064}.
\]

Such is the expression for the apparent hue of crystals with one axis, which exhibit a variable colour in common or polarized light, according to their position with respect to the incident light. The phenomenon in question may be generally termed dichroism, though the word has usually been applied only to that particular case where a marked change in the character of the tint takes place, as from red to green, &c.

The dichroism of biaxial crystals differs in many of its phenomena from those having only one optic axis. If we look through a plate, or into a crystal of any biaxial mineral, having the property in question, illuminated by natural light in such a direction that the visual ray within the crystal shall pass along, and in the immediate neighbourhood of, one of the axes, we shall perceive a phenomenon like that represented in fig. 206, consisting of two similar and equal sombre spaces \(AB\) one on either side of the pole \(P\), and of the principal section \(PP'\), and if we look along the other axis \(PP'\) a similar pair of spaces will be seen in its neighbourhood. In the mineral called dichroite by Hauy, (on account of the striking difference of its colours in different positions,) or iolite (from its violet hue) by others,\(^\ast\) of which the phenomena have been described by Dr. Brewster in the Paper already cited, these spaces are of a full blue colour, while the intermediate region towards \(O\), along the line \(OPC\), and the space beyond \(P\) towards \(G\) are yellowish white. In epidote the sombre spaces are brown, and the region around \(O\) and in the principal section green, of a greater or less degree of dilution. In this latter mineral (at least in some of its more ordinary varieties of crystalline form, \(\text{viz.}\) in long striated prisms much flattened, and terminated by dihedral summits placed obliquely, so as to truncate two of the angles of the prism) the phenomena are seen without any artificial section, merely by looking in obliquely, across the axis of the prism; and the same is true of many other minerals, as, for instance, the axinite, in which the transition of colour is extremely remarkable and beautiful.

The phenomena of dichroism in biaxial, as well as in uniaxal crystals, are evidently related to the optic axes, and depend on the planes of polarization assumed by the interrupted light, during its transit through the crystal to whose absorptive power it is subjected. Now, if we consider the form and situation of the sombre spaces where the greatest absorptive energy is exerted, we are at once struck by their analogy with those occupied by the more vividly coloured parts of the rays about the axes in the situation of fig. 179. That figure represents (Art. 900) the extraordinary set of rings as seen in a crystal whose principal section is in the plane of primitive polarization. Fig. 207 represents the ordinary or complementary set as seen around either of the axes, the pole \(P\), and the principal section being here occupied with white light, and very bright, in consequence of its containing the whole incident light, while the lateral or coloured portions occupied by the rings are less illuminated, the colours originating in an abstraction of certain rays.

Conceive now a number of such sets of coloured rings not all of exactly the same dimensions, nor having

---

\* Mohs, with his usual contemptuous disregard of, or rather hostility to, all ordinary convenience and received usage, chooses to call this mineral "prismatic quartz." Such a nomenclature must ere long work out its own destruction, but while it subsists the nuisance is intolerable. We cannot but lament, that such a cause should exist to raise up prejudice against a system in many respects so useful and valuable.
Light. precisely the same pole, but very nearly so, to be superposed on one another, then would the colours be obliterated and blended into white light by their overlapping, but still the general intensity of the light in the lateral regions would remain much feebler than in the principal section, and the effect would be precisely that of fig. 206, viz. two sombre, cloudy, fan-shaped spaces traversed by a narrow ray of vivid light, opening out from $P$ towards $C$ and $O$. Such would be the case with a limpid crystal, supposing such a slight degree of confusion of structure as to produce the non-coincidence of the rays from all its molecules. In this case, however, neither of the spaces in question would appear coloured, nor would the phenomena be seen at all without the use of polarized light and its subsequent analysis. But if we conceive the crystal, instead of limpidity, to possess the property of double absorption, the suppressed and transmitted portions will be, not white light, but light of the colour of one or other of the pencils into which it is resolved by double refraction, according to its plane of polarization and the thickness of the medium it has traversed; and the analysis of the emergent ray may be regarded as performed, at least imperfectly by the difference of absorptive powers acting differently on the two pencils. In support of this it may be noticed, that when we examine the system of rings in the usual way, by polarized light, in crystals presenting the above phenomenon, they are usually found to be very irregular, several sets evidently overlapping and interfering with one another, and rendering the non-coincidence of all the axes a matter of ocular demonstration.

In Art. 931 we investigated the law of intensity of the illumination of the polarized rays in different parts of their periphery for uniaxal crystals. As what is there said does not apply, however, to biaxal ones, and as the present subject has led us to the consideration of the more general case, it will not be irrelevant, if we digress at this point, in order to show, what modifications the statement there made must receive to embrace the phenomena of biaxal crystals.

M. Biot has stated the general law of polarization in biaxal crystals, from his elaborate researches on that subject (Mém. sur les Lois Générales de la Double Réfraction et Polarisation, &c. Mém. Acad. Sci. 1819) to be as follows:

If two planes be drawn through the course of a ray within a crystal and through the two optic axes, and a third plane bisecting the angle included between the two former, this will be the plane of polarization if the ray be an ordinary one—but one perpendicular to it if extraordinary. Thus in fig. 209, $C P$ and $C P'$ being the optic axes, and $A C$ a ray penetrating the crystal, if $P A, P'A$ be joined by arcs of circles on the sphere $H O K A$ having $C$ for its centre, and the angle $P A P'$ be bisected by the arc $A N$, the plane $A C N$ bisecting the dihedral angle between the planes $P C A$ and $P' C A$ is the plane of ordinary polarization, and a plane perpendicular to it that of extraordinary. This is the law of fixed polarization, and expresses generally the planes of polarization assumed by the two rays at their emergence from doubly refracting crystals. It is a consequence of Fresnel's general theory, (though deducible from it by a train of analytical reasoning far too intricate and refined to allow of its insertion in a treatise like the present,) and, having been experimentally established long before that theory was devised, must be looked on as a strong additional proof of its conformity to nature.

The doctrine of movable polarization, however, which, so far as respects the phenomena of the colours and intensity of the rings, has been shown by M. Biot in the same excellent paper, to represent with fidelity their various affections, whether in uniaxal or biaxal crystals, requires the resulting ray to assume at its emergence a plane of polarization alternately coincident with, and making with the primitive plane of polarization twice the angle which the plane of fixed polarization so determined would make; so that if we draw $A M$ (fig. 208) bisecting the angle $P A P'$, the emergent ray will be affected by subsequent analysis, as if polarized either in the plane of primitive polarization, or making with it an angle equal to twice $C M A$, and from this it is easy to derive the law of intensity in question, for the ray by which the point $A$ of the rings is formed consists of two portions, of which $(A)$ is affected by subsequent analysis by a prism of Iceland spar, as if it were polarized in a plane making an angle $2 C M A = \varphi$ with the plane of primitive polarization, in which we suppose the principal section of the analyzing prism was placed, and the other, complementary to this $(1 - A)$ retains its primitive polarization. The portion $A$ then will be divided between the ordinary and extraordinary image in the proportion $(\cos 2 \varphi)^2 : (\sin 2 \varphi)^2$, and (considering only the latter,) $A$ being its intensity at its emergence from the crystal, $A$ $(\sin 2 \varphi)^2$ will be its intensity in the extraordinary image, or in the primary set of rings, while the whole of the portion $1 - A$ will pass into the ordinary or complementary set, as in Art. 932, so that we have only to express this in terms of the azimuth of the crystalized plate itself, and the direction of the ray within the crystal. For this purpose, put $\theta = \angle C O P$ = azimuth of the principal section of the plate reckoned from the plane of primitive polarization, $\theta = A P, \theta' = A P'$, and let us (for simplicity) consider only at present the case when $P$ and $P'$ are near, as in nitre, so that arcs of circles may be regarded as straight lines, and spherical as plane triangles, (see Art. 907.) Now if in fig. 208 we put $\phi$ for the angle $P N A$, or the angle made by the plane of ordinary polarization with the principal section, we shall have $\psi = C M A = C O P + M N O = C O P + P N A$

\[ \sin \phi^2 = \frac{(P A)^2}{(P N)^2} \times \sin (P A N = \frac{1}{2} P A P') \]

where $\phi$ bisects the angle of the triangle $P A P'$ and cuts the base, $P N = P P' \times \frac{P A}{P A + P P'} = \frac{2 \theta}{\theta + \theta'}$ and

\[
(\sin \frac{1}{2} P A P')^2 = \frac{1}{4} (1 - \cos P A P') = \frac{4 \alpha^2 - (\theta - \theta')^2}{4 \theta \theta'}
\]

so that

\[
\sin \phi^2 = \frac{(\theta + \theta')^2 \{4 \alpha^2 - (\theta - \theta')^2\}}{16 \alpha^2} \theta \theta'
\]
Light. A more symmetrical value of $\phi$ will, however, be had by expressing the value of $\sin 2 \phi$, which being equal to $4 \cdot \sin \phi(1 - \sin \phi)$ is immediately given by substitution of the foregoing. If we execute the reductions we shall find that, putting $S$ for $\frac{\theta + \theta' + 2a}{2} = \frac{1}{2}$ the sum of the sides of the triangle $\triangle PAP'$

$$\sin 2 \phi = \frac{2(\theta + \theta')(\theta - \theta')}{(2a)^2} \cdot \sqrt{\frac{S(S - \theta)(S - \theta')(S - 2a)}{\theta \theta'}}.$$ 

Now $\frac{2 \sqrt{S(S - \theta)(S - \theta')(S - 2a)}}{\theta \theta'}$ is the well-known expression for the sine of the angle $PAP'$ included between the sides $\theta, \theta'$, and therefore calling this angle $P$, we have

$$\sin 2 \phi = \frac{(\theta + \theta')(\theta - \theta')}{(2a)^2} \cdot \sin P.$$ 

The nature of this expression renders the transition from plane to spherical triangles easy, and we may conclude consequently, that, in crystals where the axes make any angle $2a$, that if we take

$$\sin 2 \phi = \frac{\sin(\theta + \theta').\sin(\theta - \theta')}{(\sin 2a)^2} \cdot \sin P,$$

and $\psi = a + \phi$, we shall still have the intensity of the extraordinary rings represented by $A$ ($\sin 2 \psi$), and that of the ordinary by $1 - A + A \cdot (\cos 2 \psi)^2$, that is, $1 - A (\sin 2 \psi)^2$, their sum being, as it ought, unity.

The black cross which divides the system of the primary rings, is too remarkable a feature not to require express mention. Its form, it is evident, must be determined by the condition that the line $\overline{MA}$ shall be everywhere perpendicular to $\overline{COD}$, in which circumstances the locus of $A$ will be a curve marking out its central or blackest portion. The problem then is reduced to a purely geometrical one. Required a curve $\overline{PA}$ such that a line drawn from $A$ bisecting the angle between lines $\overline{AP}, \overline{AP}'$ drawn to two given points $P, P'$, shall always be perpendicular to a given line $\overline{COD}$. To resolve this, retaining the former notation, and putting $O\overline{M} = x$, $\overline{MA} = y$, $\overline{OA} = r$, we have

$$\cos AOP = \cos(AOM - a) = \frac{x \cdot \cos a + y \cdot \sin a}{r} = \frac{N}{r},$$

$$\sin AOP = \frac{y \cdot \cos a - x \cdot \sin a}{r} = \frac{M}{r},$$

putting $N$ and $M$ for the respective functions in the numerators of the fractions.

Now since $\overline{PAM}$ is half the angle $\overline{PAP'}$, it is easy to see that we must have $2 \times \angle O\overline{AM} = \angle PAO - \angle PAO$.

But,

$$\cos PAO = \frac{\theta^2 + r^2 - a^2}{2r \theta}; \quad \cos P'AO = \frac{\theta'^2 + r^2 - a^2}{2r \theta'};$$

and

$$\sin PAO = \sin AOP \cdot \frac{PO}{PA} = \frac{M}{r \theta}; \quad \sin P'AO = \frac{M}{r \theta'};$$

consequently we have, first,

$$\sin 2OAM, \text{ or } \frac{2xy}{r^2} = \frac{aM}{2r} \left\{ \frac{\theta^2 + r^2 - a^2}{\theta \theta'} - \frac{\theta'^2 + r^2 - a^2}{\theta \theta'} \right\} = \frac{aM}{2r^2 \theta \theta'} (\theta^2 - \theta'^2), \quad (a)$$

and, secondly,

$$\cos 2OAM = \frac{y^2 - r^2}{r^2} \left\{ \frac{(\theta^2 + r^2 - a^2)(\theta'^2 + r^2 - a^2)}{4M^2} + a^4 \right\}.$$ 

Now we have further,

$$\theta^2 = a^2 + r^2 - 2ar \cdot \cos AOP = a^2 + r^2 - 2aN; \quad \theta'^2 = a^2 + r^2 + 2aN; \quad \theta^2 - \theta'^2 = 4aN,$$

which substituted in the values of $\sin 2OAM$ and $\cos 2OAM$ above, give the equations

$$xy \cdot \theta \theta' = a^2 \cdot MN;$$

$$\left(\frac{y^2 - r^2}{r^2}\right) \cdot \theta \theta' = r^4 + a^4 (M^2 - N^2),$$

and, eliminating $\theta \theta'$ from these, we obtain

$$a^4 (y^2 - x^2) \cdot MN = xy \left\{ r^4 + a^4 (M^2 - N^2) \right\}.$$ 

In this it only remains to substitute for $M$ and $N$ their values $y \cdot \cos a - x \cdot \sin a$, and $y \cdot \sin a + x \cdot \cos a$, which done, the whole will be found divisible by $r^4$, and will reduce itself to the very simple equation...
The black cross then is an hyperbola, passing through the poles $P, P'$, and having the planes of primitive polarization, and one perpendicular to it (CD and cd) for its asymptotes, and which as $a$ approaches to 0, or $90^\circ$ approaches nearer and nearer to its asymptotes, with which it at last coincides in the limiting case, all which particulars are exactly comparable to fact, and may easily be verified by turning a plate of nitre round between crossed tourmalines. When the inclination of the axes is so considerable, that the rings about both poles cannot be seen at once, there will arise modifications from the substitutions of the sines, &c. of arcs for the arcs themselves, which it is not worth while to enter into.

To return now to the phenomena of dichroism. That portion of the light transmitted by a biaxal coloured medium which has relation to the optic axes, and which forms the sombre brushes of colour (in fig. 206,) and the bright spaces which divide them, have evidently for their analytical expression a function of the form

$$T = (Y, \cos 2\phi + B, \sin 2\phi') + (y, \sin \phi + b, \cos \phi); \quad (a)$$

where $Y$ and $B$ are functions of $\lambda$, and represent the ordinates of the types of two fundamental tints, $\phi$ representing as before the angle $\text{PNA}$, fig. 208, or the angle made by the plane of ordinary polarization with the principal section. But besides this, the phenomena described by Dr. Brewster, as exhibited by the iolite, require us to admit two other portions, which may be more naturally referred, not to either of the optic axes but to the line CO (fig. 209) bisecting them, and having for its expression a function of the form $a, \cos O A^\circ + b, \sin O A^\circ$. In this mineral, when exposed to common light (or to polarized, provided we place its principal section at right angles to that of polarization,) the lateral brushes $A, B$, fig. 206, are blue, and the bright rays which divide them, passing through the poles P, $P'$ are white, or yellowish white, and so far the phenomena agree with the expression (a) if we suppose $Y$ to represent a bright yellowish white, and $B$ a blue. But according to that expression alone, the blue spaces should be continued down to the equator $C a b D$, fig. 206, and there ought to be two directions $C D$ and $a b$ in which the mineral viewed transversely to the axis of the prism (which is perpendicular to the plane $C a b D$) should appear yellow, and two others, $m n$ and $p q$, in which it should transmit a blue colour, while in the direction of the axis $O$ it should appear yellow. Now, on the contrary, the equatorial colour is nearly uniform and pale yellow, while that along the axis $O$ is blue; and in proceeding from the equator toward the axis $O$ of the prism, the yellow diminishes, and the blue gains strength, whether we set out from $C$ and $D$, or from $a$ and $b$, precisely as would be indicated by the other formula

$$T = (Y, \cos 2\phi + B, \sin 2\phi') + (y, \sin \phi + b, \cos \phi); \quad (a)$$

$y$ representing a yellow white and $b$ a blue tint. If, therefore, we put $O A = \nu$, the joint expression

$$T = (Y, \cos 2\phi + B, \sin 2\phi') + (y, \sin \nu + b, \cos \nu); \quad (b)$$

will be found to represent pretty correctly the variations of colour as far as they can be judged of by the eye. Thus, at $O$ where $\nu = 0$, and $\phi = 90^\circ$, we have $T = Y + b$, which may indicate either a yellow, a white, or a blue, according as we suppose $Y$ or $b$ to be predominant. The fact being, that the tint at $O$ is blue, we must suppose the latter to express the more decided colour. As we proceed from $O$ along the sections $O C, O D$, or $O a, O b$, in both of which $\sin 2\phi = 0$, we have

$$T = (Y + y, \sin \nu) + b, \cos \nu = (Y + b) + (y - b, \sin \nu)$$

Now $y$ expressing a yellow white and $b$ a strong blue, $y - b$ will express a proportionally vivid yellow, and therefore the blue tint $Y + b$ seen along the axis will be diluted with more and more yellow as we approach the equator; at $P P'$, then, (by a proper assumption of numerical values) it will be rendered nearly neutral, after which the yellow will predominate, and, at the equator, will remain alone sensible, the expression for $T$ then becoming $T = Y + y$, at the points $C, a, b, D$. Let us next consider the case when $\cos 2\phi = 0$, or $\phi = 45^\circ$, that is to say, along the axes or most intense lines of the lateral brushes. In this case we have

$$T = B + (y, \sin \nu + b, \cos \nu) = (B + b, \cos \nu) + y, \sin \nu.$$

Now if we suppose $B$ and $b$ to represent blue tints, since (in the case of iolite) the angle between the axes or $P P' = 60^\circ 50'$ and $O P = 31^\circ 25'$, we have in the immediate vicinity of the poles, ($\sin \nu) = \frac{1}{2}$ nearly, and $\cos \nu = \frac{1}{2}$, so that in the immediate neighbourhood of $P$ the tint of the most intense part of the brushes will be $B + \frac{1}{2} b + \frac{1}{2} y$, which, on very reasonable suppositions of the numerical values of $B, b$ and $y$ will denote a full and rich blue. But as we approach the equator at $m, n, p, q$, $\cos \nu$ diminishing and $\sin \nu$ increasing, the sombre tint $B$ is continually more feebly reinforced by the tint $b, \cos \nu$ and more strongly counteracted by $y, \sin \nu$, till at length it will be overpowered, and the colour in these points, as in $C, a, b, D$, will be yellow only somewhat less decided than in the latter, its tint being represented by $T = y + B$ instead of $y + D$.

In general, if we put $A$ for the tint transmitted along the axis $O$ of the prism, $P$ for that seen along the poles, $L$ for that of the lateral branches to the origin close to the poles, and $E$ for the mean equatorial tint, we shall have for determining $Y, y, B, b, \nu$, the equations

$$A = Y + b, \quad 2 E = 2 y + B + Y, \quad P = Y + y, \sin a^\circ + b, \cos a^\circ; \quad L = B + y, \sin a^\circ + b, \cos a^\circ,$$

on elimination from these, it will appear that there is an equation of condition to be satisfied, viz.

$$2 (A - P) = (2 A - 2 E - P + L), \sin a^\circ; \quad (c)$$
and that supposing it satisfied, one of the tints, as \( y \), will (so far as these conditions are concerned) remain arbitrary, and the others will be given by the equation

\[
\begin{align*}
2y &= 2E + P - L - 2y \\
2B &= 2E - P + L - 2y \\
2b &= 2A - 2E - P + L + 2y
\end{align*}
\]

in which \( y \) must, however, be such as to render \( Y, B, b \) real tints, i.e. expressed by positive numbers.

To apply this, for example's sake, to the case of the iolite, let us regard every white ray as consisting of two complementary rays of bright yellow and bright blue of equal efficacy; and suppose that by observation we have ascertained its equatorial tint \( E \) to be a very pale but strongly luminous yellow white, consisting of 110 such yellow rays, and 99 such blue ones, producing a joint intensity = 209. Moreover, let the tint seen along the axis of the prism (\( A \)) be a blue, of a good colour, but considerably less intensity, represented by 10 such yellow + 20 such blue rays = 30. That seen along the optic axes (\( P \)) to be a white represented by 36 yellow + 36 blue = 72, and that of the most intensely coloured portions of the lateral brushes = \( L \) to be a stronger blue than that seen in the axis of the prism, such as may be represented by 28 yellow + 66 blue = 94.

These numbers are chosen so as to satisfy the equation of condition, taking \( a = 30^\circ \), and if we substitute them we shall find

\[
\begin{align*}
y + y &= 114 \text{ yellow} + 84 \text{ blue}; \\
B + y &= 106 \text{ yellow} + 114 \text{ blue}; \\
y - b &= 104 \text{ yellow} + 64 \text{ blue},
\end{align*}
\]

\( y \) remaining indeterminate; if we suppose its composition to be \( m \) yellow + \( n \) blue, we may determine \( m \) and \( n \) by the two conditions that \( b \) shall (as we have before supposed) represent, a pure blue without any mixture of yellow, and \( Y \) a very pale yellow, such as would result from a mixture of yellow and blue in the ratio of 10 to 9. These conditions are satisfied by taking \( m = 104 \) and \( n = 75 \); so that we have, finally,

\[
\begin{align*}
Y &= 10 \text{ yellow} + 9 \text{ blue}; \\
B &= 2 \text{ yellow} + 30 \text{ blue}; \\
y &= 104 \text{ yellow} + 75 \text{ blue}; \\
b &= 0 \text{ yellow} + 11 \text{ blue},
\end{align*}
\]

and these being taken for the values of the coefficients in the expression (b) Art. 1073, it will be found on trial to reproduce the tints actually observed. In fact, the extreme equatorial tints being \( y + Y \) and \( y + B \), will be respectively represented by 114 yellow + 84 blue, and 106 yellow + 114 blue; the former is a very pale yellow, but highly luminous, being equivalent to 30 rays of yellow diluted with 168 of white; while the latter is a blue so pale as to be undistinguishable from white, and also highly luminous, being equivalent to 8 rays of blue diluted with 212 of white.

The reader will perceive that the formula in question is merely empirical, and that more numerous experiments than we possess will be required to establish or disprove it. It is unfortunately, however, difficult to meet with biaxal crystals sufficiently dichromatic for the purposes of decisive experiment, and at the same time large and transparent enough to admit of being cut into the forms and examined in the directions required, through a thickness sufficient for a full development of their colours. Such are indeed hardly less rare than the most precious gems; and this circumstance is a great obstacle to the advancement of our knowledge in one of the most interesting branches of optical inquiry, which that of dichroism certainly deserves to be considered. Among artificial crystals, however, there is room to suppose that subjects fit for such experiments may be met with. One remarkable instance of dichroism among these has been mentioned in the sub-oxysulphate of iron. To this we may add the potash-muriate of palladium, which exhibits along the axis of the four-sided prism in which it crystallizes a deep red, and in a transverse direction a vivid green. (Wollaston, Phil. Trans. 1804. On a new metal in Crude Platina.) The curious property of the purpurates of ammonia, potash, &c. described by Dr. Prout, (Phil. Trans. 1808) which by transmitted light exhibit an intense red, and by reflected, on one surface, a dull reddish brown, and on another a splendid green, appears referable, not so much to the principles of dichroism properly so called, as to some peculiar conformation of the green surfaces, producing what may be best termed a superficial colour, or one analogous to the colour of thin plates, and striated or dotted surfaces. A remarkable example of such superficial colour, differing from the transmitted tints, is met with in the green fluor of Alston-moor, which on its surfaces, whether natural or artificial, exhibits, in certain lights, a deep blue tint, not to be removed by any polishing.

Dr. Brewster has shown that the action of heat often modifies in a very remarkable manner the colour of doubly refracting crystals, producing a permanent change in the scale of absorption of the crystals as affecting one of the pencils and not the other. Thus, having selected several crystals of Brazilian topaz which displayed no change of colour by exposure to polarized light, (and in which, of course, the types of both absorptions must have been alike,) and bringing them to a red heat, or even boiling them in olive oil, or mercury, they experienced a permanent change, and had acquired the property of absorbing polarized light unequally. He then took a topaz in which one of the pencils was yellow and the other pink, and by exposing it to a red heat, he found the extraordinary pencils more powerfully acted on than the ordinary, the yellow colour being discharged entirely from the one, while only a slight change was produced in the pink tint of the other. This change of colour in the topaz by heat (though not its intimate nature) is well known to jewelers, who are in the habit of thus developing in this gem a colour more highly prized. It is remarkable, that while hot the topaz is perfectly colourless, and acquires the pink colour gradually in cooling. By the repeated action of very intense heat Dr. Brewster was never able to modify or remove this permanent pink tint. How far violent compression, slow application, and abstraction of the heat, or other modifying circumstances, might prevent its development, it
would be interesting to examine; since we cannot help being otherwise struck by the force of the argument geologists may draw, from the existence in rocks of a mineral which mere elevation of temperature unaccompanied with change of composition, thus irrecoverably alters.

One general character of all dichroite bodies is, that when natural light is transmitted through a plate of sufficient thickness in any direction not coincident with one of the optic axes, the emergent beam is wholly or partially polarized by reason of the unequal action of the medium on the two pencils, and the consequent suppression of one of them. And, in general, whatever cause tends to interfere unequally with their free transmission through a medium, will produce a similar effect. Thus, for example, if the continuity of a doubly refracting medium be interrupted by a film of any uncrystallized substance, since the two pencils by reason of their angular separation are incident on this film at different angles; and since, moreover, their relative refractive indices, with respect to the medium composing the film, differ, they will undergo partial reflexion at the film in different proportions, and thus an inequality will arise in the parts transmitted. If the refractive index of the film be precisely equal to the ordinary refractive index of the crystal (supposed, for simplicity, to be uniaxal) the ordinary ray, it is evident, will undergo no disturbance or diminution, while the extraordinary will be changed in direction and diminished in intensity by partial reflexion at its ingress and egress, at every such film which may exist in the medium. If the films be extremely numerous, and if, moreover, they be not disposed in planes, but in undulatory or irregular surfaces through the medium, this will make no difference, so far as the ordinary ray is concerned, which will still pass undisturbed through the system, (except so far as any opacity in the matter of the films may extinguish a portion of it;) but the extraordinary ray will be rendered confused, and dispersed, its egress from the films not being performed (by reason of their curvature) at the same angles as its ingress, and that irregularly, according to their varying inclination. Hence will arise a phenomenon precisely such as is presented by the agate, and other irregularly laminated bodies, through plates of which, if a luminary be viewed, it is seen distinctly, but as if projected on a curtain of nebulous light; and if examined with a tourmaline, or doubly refracting prism, the distinct image, and the nebulous light, are found to be oppositely polarized. If we examine a piece of agate with a magnifier, the laminated structure and unequal refraction of the laminae are very apparent; it appears wholly composed of a set of exceedingly close layers, not arranged in planes, but in undulating or crinkled lines like a number of figures of 333333 placed close together. The planes of polarization of the nebulous and distinct image are parallel and perpendicular to the general direction of the layers, which through any very small portion of the substance is generally pretty uniform.

But the film interposed may, itself, be crystallized, and inserted between adjacent portions of a regular crystal, according to the crystallographic laws which regulate the juxtaposition of the molecules at the common surfaces of macle or hemitrope crystals. Let A D E F (fig. 210) be such a plate interrupted by a crystallized lamina B C E F, bounded by parallel planes, and let us consider what will happen to a ray S a incident at a. It is evident, that were the crystallized lamina away, or were its molecules homologously situated with those of the portions on either side of it; in the latter case, we should have an uninterrupted crystal; in the former, two prisms disposed with their principal sections parallel, and acting in opposition to each other; in either case, the emergent ordinary and extraordinary pencils separated by double refraction at the first surface will emerge parallel to the incident ray, and therefore to each other. But the principal section of the crystallized film being non-coincident with those of the two prisms A B E, C F G, it will alter the polarization of the portions a b, a c; and in place of their being, as in the former case, each refracted singly by the second prism C F G, they will now each be refracted doubly, so that in place of two emergent rays there will now be four. The subdivision of the rays within the interposed lamina may evidently be disregarded, for they will be refracted in passing from the film into the second prism in the same direction, where contiguous, as they would were an infinitely thin plate of air interposed. Now, in that case, they would emerge from the film in pairs respectively parallel to the incident rays a b, a c, and therefore to each other. Hence the refraction at the second prism will be precisely the same as if the lamina were suppressed, and in its place the rays a b, a c had received at a the polarizations they acquire by its action. Now, these being in opposite planes, it is evident that each of the rays a b, a c would undergo both an ordinary and an extraordinary refraction. Let us denote these four emergent pencils so arising by O O, O E, E O, E E, and suppose a b to be the direction taken by the ordinary refracted portion of S a, and a c that of the extraordinary. Then, since O O has been refracted ordinarily by the prism C F G, and was incident on it in the direction of the ordinary ray a b, its direction on emerging will be parallel to S a. Similarly, E E is refracted extraordinarily, and being incident in the direction b c of the extraordinary portion of S a, it also will emerge parallel to S a, and thus the two rays O O, E E will emerge parallel, and their systems of waves will be superposed. But the portions O E and E O, the one being incident in the ordinary direction, but refracted extraordinarily, the other incident in the extraordinary direction and refracted ordinarily, will neither emerge parallel to the original ray S a, nor to each other; and this will give rise to two lateral images, one on each side of the central or direct image, which will have, moreover, an intensity equal (except in extreme cases) to the sum of those of the lateral images.

If the film E B C F be very thin, or if either of its optic axes be nearly coincident with the direction in which the light traverses it, the difference of paths and velocities within it will give rise to an interference of the pairs of rays going to form either pencil emergent from the film, and thus will arise the colours of the rings in each image. Those on either side the central one will be consequently tinged with the respective colours of the primary and complementary set of rings; while the central image, being formed by the precise superposition of two similar complementary pencils will appear white.

All these phenomena actually occur, and have been described by Dr. Brewster, and explained by him on the principles here laid down, in certain not uncommon specimens of Iceland spar, which are interrupted by such...
Light.

hemitrope films, passing through the longer diagonals of opposite faces of the primitive rhomb. If we look at a candle through such an interrupted rhomb, it will be seen accompanied by a pair of lateral images such as those described, and exhibiting frequently the complementary tints with great splendour.

If the luminar from which the ray S a issues be small, the lateral images will be separated by a dark interval from each other and from the central one, but if large they will overlap. If infinite (as where the uniform light of the sky is viewed) all the images will be superposed. But the field of view will not necessarily be uniform and white. The central image will form an intense white screen, or ground, on which will be projected the lateral ones. Now, if the beam be so constituted as to have within the visible field of view of one only of the lateral images the pole of one of its sets of rings, (which will be the case whenever one of its optic axes is not very remote from perpendicularity to the surface of the plate A D, so as to admit of one of the rays O E or E O traversing the film in the direction of its axis,) that set of rings will not be seen projected centrally on the corresponding set complementary to it of the other lateral image, by reason of the angular separation of these two images. Of course its colours will not be neutralized, and it will be visible per se, though very faint, being diluted by the whole white light of the central image (O O, E E) and by the whole visible and nearly uniform portion of the other lateral one (O E).

This is not the only way in which a crystal perfectly colourless may exhibit its sets of rings by exposure to common daylight without previous polarization, or without subsequent analysis of the transmitted pencil. The general mass of the crystallized plate may have one of its optic axes in the direction of the visual ray, as in fig. 211, and the portion of it C D and c included between two films B c b and D d E will then form precisely such a combination as that above described, and will exhibit a set of rings feeble in proportion to the rarity and minuteness of the films, and the consequently small area of their outeropping surfaces B C, D E. These are not hypothetical cases. Dr. Brewster states himself to have met with specimens of nitre exhibiting their rings per se. Such are rare. But in the bicarbonate of potash it is an accident of continual occurrence; and, indeed, almost universal. The films in both cases are easily recognised, and their position and that of the system of rings seen leave no doubt of the correctness of the explanation here given. Such crystals, of which more will no doubt be hereafter recognised, may be termed idio-cyclophanous till a better term can be thought of.

§ XII. On the effects of Heat and Mechanical Violence in modifying the action of Media on Light, and on the application of the Undulatory Theory to their explanation.

It was ascertained independently, and about the same time by Dr. Seebeck and Dr. Brewster, that when glass, which in its ordinary state offers none of the phenomena of double refracting media, is heated or cooled unequally, it loses the character of indifference, and presents phenomena of coloration, &c. analogous, in many respects, to those exhibited by doubly refracting crystals. If the heat communicated be below the temperature at which glass softens, the effect is transient, and vanishes when the glass attains a uniform temperature throughout its substance, whether by the equable distribution of the calorick throughout its mass, or by its abstraction in cooling. But if the temperature communicated be so high as to allow the molecules of the glass to yield to the mechanical forces of dilatation and contraction produced in the act of cooling and take a new arrangement, the effect is permanent, and glass plates so prepared have many points of resemblance with crystallized bodies. Dr. Brewster afterwards ascertained, that mechanical compression or dilatation applied to glass, jellies, gums, and singly refractive crystals (such as fluor spar, &c.) is capable of imparting to them the same characters. If the medium to which the pressure is applied be perfectly elastic, like glass, the effect, like that of heat, is transient. But if during the continuance of the compression or dilatation, the particles of the medium are allowed to take their own arrangement and state of equilibrium, then when the external force is withdrawn a permanent polarizing character will be found to exist.

As periodical colours are not produced in phenomena of this class without a resolution of the incident light into two pencils moving with different velocities, and as a difference of velocities is invariably accompanied with a difference of refraction at inclined surfaces, it might be expected that media thus under the influence of heat or pressure should become doubly refractive. This has been verified by direct experiment by M. Fresnel, who has shown that a peculiar species of double refraction is thus produced.

As the unusual heating or cooling of glass and other substances, is well known to produce in the parts heated or cooled a corresponding inequality of bulk, and thus to bring the parts adjacent into a state of strain in all respects analogous to that arising from mechanical violence, and as, in fact, the effects of heat in communicating double refraction to glass, whether transient or permanent, are all, as we shall see, (with one very obscure and doubtful exception) commensurate with the amount of the strain thus transiently or permanently induced, we have little hesitation in regarding the inequality of temperature as merely the remote, and the mechanical tension or condensation of the medium as the proximate cause of the phenomena in question, and are very little disposed to call in the agency of a peculiar crystallizing fluid, endowed with properties analogous to those of magnetism, electricity, &c., to account for the phenomena, still less to regard media under the influence of heat or pressure as in any way thereby rendered more crystalline than in their natural state of equilibrium.

In gasiform, or fluid media, no such phenomena are observed to be developed by either heat or pressure; the reason is obvious, the pressure is equally distributed in all directions, and the elasticity of the ether (on the undulatory hypothesis) preserves its uniformity.

But in solids the case is different. The molecules cannot shift their places one among the other, and the
effect of a compression in any direction in, first, to urge contiguous particles nearer together in that direction, and thereby to call into action their repulsive forces, more than in the natural state, to maintain the equilibrium; secondly, but much more slightly to urge contiguous particles in a direction perpendicular to that of the pressure. Thirdly, it is by reason of the increase of the oblique repulsive force developed by the approach of the molecules in the line of pressure to those which lie obliquely to that line. But this action, which in fluids would cause a motion of the lateral particles out of the way, in solids is ultimately equilibrated by an increase of the attractive forces of the adjacent molecules in a line perpendicular to the line of pressure; and thus we see that every external force applied to a solid is accompanied with a condensation of its particles in the direction of the force and a dilatation in a perpendicular direction. It is probable, however, that this latter is extremely minute, on account of the rapid diminution of the molecular forces by increase of distance, rendering the diagonal action insensible. But the former may easily be conceived to produce in the ether, in virtue of its connection (whatever it be) with the molecules of refracting media, a difference of elasticity in the two directions in question, accompanied with all the necessary concomitants of interfering pencils, periodical colours, and double refraction.

The effect of dilatation will be the converse of that of compression, the direction of maximum elasticity in the one case being that of minimum in the other.

These views are in perfect accordance with the experiments described by Brewster and Fresnel on compressed and dilated glass.

According to the former (Phil. Trans. 1816. vol. 106) the effect of pressure on the opposite edges of a parallelepiped of glass is to develop in it "neutral" and "depolarizing axes," the former parallel and perpendicular to the direction of the pressure, the latter 45° inclined to them; in other words, a parallelepiped of glass so compressed, when exposed to a ray polarized in the plane parallel or perpendicular to the sides to which the pressure is applied, produce no change in its polarization and develop no periodical colours, while if polarized in 45° of azimuth with respect to those sides, it will develop a tint, descending in the scale of the coloured rings as the pressure increases.

In this case, if the pressure be uniformly applied over the whole length of each opposite side, the elasticity of the ether in every point of the plate will be uniform in either direction at every point of the plate, being a maximum in one, and a minimum in that at right angles to it. The incident light therefore if polarized in azimuth ω will resolve itself into two pencils of unequal intensity (viz. cos ω and sin ω) polarized in these two planes, and differing at their egress by an interval of retardation proportional to t x (ω' − ω), where t is the thickness traversed, and ω' − ω the difference of velocities of the pencils, which when received on a double refracting prism will (as in the case of a crystallized plate (Art. 969) give rise to complementary periodical tints in the two images, the extraordinary image vanishing when α = 0, or 90, and the contrast being a maximum at 45°. It is, of course, extremely difficult to give such a perfect equality of pressure, so that we must not be surprised if a perfect uniformity of tint over the whole surface of the glass should not take place. In the experiment, however, described by Dr. Brewster (Prop. I. of the Memoir cited) this seems to have been the case.

If we suppose the elasticity of the ether in compressed glass less in the direction of the force applied (and where consequently the medium is densest, according to the general law) than in the perpendicular, the contrary will be the case in dilated. Hence, supposing the forces equal, in two similar plates, the extraordinary waves, or those whose vibrations are performed in the direction of the pressure, and which are therefore polarized at right angles to that direction, will advance most rapidly in the former case, the ordinary in the latter. Consequently, if we regard the interval of retardation or the tint, t (ω' − ω) as negative in the former case, it will be positive in the latter; and the tints in the two cases will present the opposite characters of those exhibited by doubly refracting crystals of the two classes described in Art. 940, et seq. see also Art. 803, as negative and positive, or repulsive and attractive. Two such plates, therefore, placed homologously, or with the directions of the forces coincident, ought to neutralize each other, and if crossed at right angles should reinforce each other; and in general, if t be the thickness and f the compressing force applied to any plate (supposing the difference of velocities to be proportional to the force, and regarding dilating forces as negative) we shall have for homologously situated plates

\[ T = \text{tint polarized by any number of plates} \]

\[ = (f \cdot t + f' \cdot t' + f'' \cdot t'' + \&c.) \]

In the case of crossed plates the thicknesses of those placed transversely are to be regarded as negative, just as in the case of the superposition of crystallized plates. All these results are conformable to the experiments of Dr. Brewster.

The phenomena of contracted and dilated glass may most easily and conveniently be produced by bending a long parallel plate of glass having its longer edges polished, and passing the light through them across its breadth. In this case, as in all cases of flexure, the convex surface is in a state of dilatation, and the concave of compression, while there exists a certain intermediate line or boundary between these oppositely affected regions in which the substance is in its natural state of equilibrium, and on both sides of which neutral line the degree of strain increases as we recede from it towards either surface. Fig. 212 is a section of such a plate, much exaggerated, through which light, polarized in a plane 45° inclined to its length, has been passed and analyzed as usual. The neutral line is marked by a divided black stripe, and the tints on either side of it descend in Newton's scale, being arranged in stripes disposed according to the lines 11, 22, 33, 44, &c. The tints, however, on opposite sides of the neutral line have opposite colours, being positive on the side of the dilatation, or towards the convexity, and negative on the compressed or concave side. In a plate of glass 1.5 inch broad, State of 0.28 thick and six inches long, Dr. Brewster developed seven orders of colours before the glass broke with the bending force applied. This experiment affords an exceedingly beautiful illustration of the action of compressing and bending forces on solids, and furnishes ocular evidence of the state of strain into which their several parts
Effects of Brewster finds, that its action will be the same as the combined action of several plates each subjected to one of the forces employed. Thus a square of glass compressed equally on all its four edges exerts no polarizing action.

M. Biot has observed, that in some instances glass maintained in a state of vibration by the action of a bow or otherwise, depolarizes light, i.e., restores the vanished pencil. This is a necessary consequence of the alternate compressions and dilatations which follow each other in rapid succession in all the vibrating molecules. Nodal lines (see Acoustics) being exempt from such variations of density ought to be marked by black bands, and may thus, perhaps, be rendered evident to the eye.

When masses of jelly (especially of isinglass) are pressed between plates they acquire a polarizing action. If diluted by proper management, and in that state allowed to dry and harden, the character so impressed, according to Dr. Brewster, is permanent when the dilating force is removed; to explain which, we must consider that the exterior coats indurate more rapidly than the interior, and when they have acquired the consistency of a solid, they will be capable of resisting the subsequent contraction of the interior portions and keeping them in a diluted state, even when the original dilating force is removed.

That force only served to determine the figure and dimensions of the exterior crust, and when once that crust is fully formed and indurated, it becomes capable of maintaining them without the further aid of the cause which gave them rise. The polarizing power of isinglass thus developed is very great, and even exceeds that of some doubly refractive crystals, such as beryl; a plate of isinglass whose thickness is 624 polarizing the tint which would be reflected by a plate of air whose thickness is unity, while a plate of beryl parallel to the axis, to polarize the same tint, will require a thickness = 720. Glass compressed, or dilated, by an equal force, would require a thickness (according to Dr. Brewster) = 12580 to produce the same tint.

The immediate effect of an increase or diminution of temperature in one point of a piece of glass, is to produce a mechanical strain on all the surrounding part, which if the difference of temperature is considerable, is of the utmost violence, and capable of breaking asunder the thinnest pieces of glass; an effect with which every one is familiar. Now, as we know that strain alone develops a polarizing action, the rule of philosophy, "non plures causas admittis dobere," which forbids the admission of a second cause when one adequate to the effect is known to be in action, will hardly justify us in attributing a peculiar action to the caloric, independent of its power of altering the dimensions of matter.

When a heated iron bar is applied along the edge of a parallelepiped of glass held in a polarized beam, analyzed as usual, the vanished image is restored in various degrees of intensity in different parts of the glass. The neutral axes are parallel and perpendicular to the heated edge, and the axes in whose azimuth the tint polarized is the strongest, at 45° of inclination. Inheld in that azimuth, the first effect of the heat is to produce a line, or, as it were, a wave of white light at the heated edge, which advances gradually upon the glass, driving before it a dark and undefined wave. Nearly at the same instant, and long before the slightest increase of temperature can have reached the further extremity of the glass plate, a similar but fainter white wave advances from the edge opposite to the heated one, driving before it a similar undefined dark wave; and at no perceptible interval of time another white fringe appears in a very dilute state about the centre of the plate, advancing equally towards the heated edge on one side and that most remote on the other, and thus condensing the two undefined dark waves into two black fringes. The white tints are succeeded by tints of a lower order in the scale of colour, yellow, red, purple, blue, &c., till at length the whole scale of the colours of thin plates is seen arranged in four sets of fringes parallel to the heated edge, and having for their origins the black fringes above mentioned. At the same time, other lateral fringes are produced along the edge perpendicular to the heated one. Thus in all six sets are seen; two exterior, viz. those parallel to the heated edge, and outside of the black fringes; two interior, in the same direction, but between the black fringes; and two terminal, along the lateral edges.

The whole phenomena is as represented in fig. 213. The fringes along the heated edge A B are most distinct and numerous, those along the opposite, C D, less so, and the interior and terminal fringes least of all.

As glass is an extremely bad conductor of heat, and as culinary heat is propagated through glass entirely by conduction, it follows, that the sudden application of an elevated temperature to the edge A B must produce a dilatation in it, not participated in by the rest of the glass. If, therefore, the stratum of molecules A B were detached from the rest of the glass, it would elongate itself so as to project at its two ends beyond the edges A C, D B. When the heat of this stratum communicated itself to the next, that also would elongate itself, but in a less degree; and thus after a very long time, during which the heat had penetrated to the further extremity of the glass, its outline would assume the form a C D b, the lines a C, b D being certain curves depending on the law of propagation and the time elapsed. This would be the state of things were the glass plate composed
of discrete strata, each of which could dilate independently of all the rest. And since in each of these (regarded as infinitely thin) the temperature and strain would be uniform, there would arise no polarizing action. But, in reality, the case is quite different; every stratum is indissolubly connected along its whole extent with the strata adjacent, and can neither expand nor contract without forcing them to participate in its change of dimension. In so far, then, as two adjacent strata participate in the change of temperature they expand together; but when one is hotter than the other, the former is found to expand less, and the other more than if they were independent. Now the strain thus induced on any stratum is not, like the caloric which causes it, confined by the conducting power of the medium, but propagates itself instantly (with diminished energy) to the strata beyond, by reason of the mutual action of the molecules.

The general problem, then, to investigate the actual state of strain of any molecule at any moment is one of some complexity, inasmuch as it depends at ones on the laws of the slow propagation of heat, and the instantaneous but variable participation of change of figure necessary to establish among the particles a momentary equilibrium under the circumstances of temperature at the time; but, without attempting minutely to analyze the effects, if we content ourselves with acquiring a general idea how they arise, we shall find little difficulty.

For in fig. 214, if we conceive the stratum $AB b a$ adjacent to the border $AB$ to be dilated by the heat, the rest of the glass retaining its original temperature; if this stratum could expand separately, its edges $A a, B b$ would project out beyond the general edges $C a, D b$; and if we regard two terminal strata $CAEG, DBFH$, as detached from the interior portion $CD b a$, and free to move by the force applied at their extremities $A, B$, they would be raised by the dilatation of the portion $AB b a$ into the situation represented in the figure, turning round $C$, $D$ as fulcrums, and leaving triangular intervals $CA a, DB b$ vacant, and in these circumstances there would be no strain on any part of the system. But the cohesion of the glass prevents the formation of these vacancies, and the bars or levers $CAEG, DBFH$ cannot move into this situation without dragging with them, and therefore distending the strata of $CD b a$. Let $PQ$ be any such stratum, and let it be distended to $p q$. Then by its elasticity it will tend to draw the bars $CAEG$ and $BDHF$ together; and its action will therefore tend, first, to produce a pressure on the fulcrums $C$, $D$, urging the points $CD$ together, and therefore bringing the stratum $CD$ into a state of compression. Secondly, to produce also a pressure on $A a, B b$, or a resistance to the dilatation of $AB b a$, which its increased temperature would naturally produce. It will therefore tend to compress back the strata of $AB b a$ into a smaller length than what would be natural to them in their heated state, i.e. to bring them also into a relatively compressed state. Thirdly, the tension of $pq$ being sustained at $C, D$ and $A, B$, will tend to bend inwards the levers $ACGE, BDHF$, rendering them concave at the edges $GE, HF$, and convex at $CA, DB$, and thus distending the lines $CA, DB$, and compressing the strata adjacent to $EG, HF$.

From this reasoning it is clear, that the glass, in consequence of these various strains, will assume a figure concave on all its edges, but chiefly so at the lateral ones $AC, DB$, as in fig. 215; and that the state of strain of its various parts will be as there expressed, all the edges being compressed, but principally $AB$ and $CD$, and the interior distended. The limit between the distended and compressed portions parallel to $AB$ must necessarily be marked by neutral lines $a b, c d$ on either side of which the strain will increase, being a maximum in the middle and on or near the edges. Consequently, it ought to polarize four sets of fringes, having $ab, cd$ for their origins, and of which the two external (or those between these lines to the edge) ought to have a character opposite to those of the internal, the portion of the intumescence pencil polarized parallel to $AB$ being propagated faster than that parallel to $AC$ in the one case, and slower in the other. This opposition of characters is conformable to Dr. Brewster's observations, who states (Phil. Trans. 1816) that the parts of the glass which exhibit the two exterior sets of fringes (adjacent to the edges $AB, CD$) have "the structure of attractive crystals, while the parts which exhibit the interior and terminal sets have that of repulsive ones; meaning, of course, in the language of the undulatory doctrine, that the order of velocities of the doubly refracted pencils is reversed in passing from one region of the glass to the other, for of its actual structure we can know nothing." That the terminal fringes ought (as observed) to have the same character as the interior is a necessary consequence of the above reasoning, for the terminal regions $DB, AC$ are compressed in directions parallel to their edges, and therefore perpendicular to the direction in which the central portion is distended; and we have already seen that compression in one direction is equivalent (so far as the character of the tints produced is concerned) to distension in that perpendicular to it.

Lastly, the black lines separating the terminal fringes from the interior ones, arise from the combined action of the tension of the interior region parallel to $AB$ (fig. 214) exerting itself on any point as $q$ on the inner border of the terminal portion $DBFH$, (which we have regarded as an elastic bar, or lever,) and the distension of the line $DB$ also exerting itself at $q$, and arising from the convexity given to this line. In virtue of these two forces, every point $q$ in a certain line at a proper distance from the extreme edge $HF$, will be equally distended in opposite directions, and will therefore be in a neutral state, as to polarization, and, of course, appear black. The terminal fringes are less developed than the rest, because they arise simply from the flexure of the edges $HF, GE$, which is an indirect effect of the principal force, and is very small, (owing to the small dilatability of glass) and consequent minuteness of the versed sine of the curve into which they are distorted,) and the line of indifference separating them from the others lies near the edges; for the same reason, the tension of the convex line $DB$ being small, and therefore putting itself in equilibrium with that of the distended column $pq$ at a point $q$ near its extremity, where it is evident that the strain parallel to $pq$ must be much diminished; the greater portion of the whole tension of $pq$ being resisted by the spring of lamina situated still further from the edge than $DB$.

If a lamina of glass, uniformly heated, be suddenly cooled at one of its edges, the reverse of all these effects will arise; the outer column $AB ab$ (fig. 214) will suddenly contract and compress violently the columns...

Phenomena of a heated glass rectangle, cooled at one edge.

Effect of a crack.

Case of a circular plate heated in the centre.

1103. Singular effect of a crack allowed to close.

1104. Phenomena of unannealed glass.

Rupert's drops.

1105. Patterns exhibited by circular, square, and rectangular unannealed plates.

Light. beyond $\beta$, from which no heat has yet been abstracted, and drag inwards the ends of the terminal levers $EAGC$, $BFHD$, which will thus be violently pressed on the parts $BQ$ and $AP$ as fulcrums; and their action being thus transmitted to the opposite edge $CD$ will tend to lengthen it, and thus bring it, as well as the edge $AB$, into a distended state. The terminal edges will also be sprung outwards. The strain on every point will be exactly the reverse of what is expressed in fig. 215, and a corresponding inversion of the characters of the tints will take place; all which is agreeable to Dr. Brewster's observation, (Prop. 14 of the Memoir cited.)

When a crack takes place in a piece of unequally heated glass, the directions and intensities of the straining forces in every part, which depend wholly on the cohesion of its molecules, and the continuity of the levers, springs, &c. into which it may be mentally conceived to be divided, is suddenly altered; and the fringes are accordingly observed to take instantly a new arrangement, and assume forms related to the figure of that part of the glass which preserves its continuity. To analyze the modifications arising from variations of external figure and different applications of the heat, would be to involve ourselves unnecessarily in a wilderness of complexity. One simple case may, however, be noticed, in which the centre of a circular piece of glass is heated. Each exterior annulus of this will be placed in a state of distension parallel to its circumference, and will compress all within it by a force parallel to the radius. The central point will be neutral, being equally confined in all directions, and the annuli adjacent to the centre will in like manner be compressed both radially and circumferentially. The radial strain continues as we recede from the centre, but the circumferential diminishes, and at length, as already said, changes to a state of distension, and of course passes through a neutral state, thus giving rise to a black circle and concentric fringes of opposite characters, the whole of which will be intersected by the arms of a black cross parallel and perpendicular to the plane of primitive polarization, and which of course remains fixed while the plate is turned round in its own plane.

There is only one experiment of Dr. Brewster which seems hostile to the theory here stated. He made a partial crack with a red-hot iron in a very thick piece of glass, and allowed it to close by long standing, which it did, so as to disappear entirely. In this state, the glass, when unequally heated, exhibited the same fringes, as if no crack had existed; but the moment the crack was opened by a slight heat applied near it, they suddenly changed their figure, and assumed that due to the portion having the crack for a part of its outline. It seems, however, that a very great adhesive force takes place between the surfaces of glass when thus in optical contact; and to those who are aware how the free expansion and contraction of dissimilar metallic bars may be commanded, and the bars in consequence made to ply on change of temperature by more forcible juxtaposition, without soldering, till the difference of expansion has reached a certain point, when they give way with a snap and regain their state of equilibrium, the anomaly will not appear in the light of a radical objection. (We think it improbable that the musical sounds said to issue at sunrise from certain statues, may originate in some pyrometrical action of the kind here alluded to. We have often been amused by a similar effect produced in the bars of a grate of a fire-place.)

Such are, in general, the transient effects of a heat below the softening point of glass, unequally distributed through its substance. But if a mass of glass be heated up to, or beyond that point, so as to allow its molecules to glide with more or less freedom on one another, and adapt themselves to any form impressed on the mass, and then suddenly cooled, either by plunging into water, or by exposure to cold air, the heat is abstracted from its external strata with so much greater rapidity than it can be supplied by conduction from within, that they become rigid, while the inner portions are still soft and yielding. At this instant, there is therefore no strain in any part; but the abstraction of the heat still going on, the internal parts at length become solid, and tend, of course, to contract in their dimensions. In this, however, they are prevented by the external crust already formed, which acts as an arch or vault, and keeps them distended, at the same time that these latter portions themselves are to a certain extent forced to obey the inward tension, and are strained inwards from their figure of equilibrium. Glass in this state is said to be unannealed. If the cooling has been sudden, and the mass considerable, it either splits in the act of cooling, or flies to pieces, when cold, spontaneously, or on the slightest shock which destroys the continuity of its surface; and the pieces when put together again (which, however, is seldom practicable, as it usually flies into innumerable fragments, or even to powder, as is familiarly shown in the glass tears called Rupert's drops, which exhibit a very high polarizing energy from their intense strain, and which burst with a violence amounting to explosion, on the rupture of their long slender tails) are found not to fit, but to leave a slight vacancy; thus satisfactorily proving the state of unnatural and violent distension in which its internal parts have been held. The case is precisely analogous to that of a gelatinous substance allowed to indurate under the influence of dilating forces. (See Art. 1094.)

If the cooling be less sudden, and carefully managed, the glass, though much more brittle than ordinary annealed glass, is yet susceptible (with great caution) of being cut and polished; and in this state, if polarized light be passed through it, it exhibits coloured phenomena of astonishing variety and splendour, forming fringes, irises, and patterns of exquisite regularity and richness, according to the form and size of the mass, and the degree of strain to which it is subjected. In all these cases if the external form be varied, the pattern varies correspondingly, as it is easy to perceive it ought; for if any part of the exterior crust is removed, that part of the strain which it sustained will fall on the remainder, and on the new surface produced. Figures 216, 217, and 218, represent the patterns exhibited by a circular, a square, and a rectangular plate of about $\frac{1}{2}$ inch thick, the two latter being placed so as to have one side parallel to the plane of primitive polarization. Figure 219 and 220 represent the patterns shown by the two latter in azimuth 45°, and fig. 221 that arising from the crossing of two plates equal and similar to fig. 220, each being in azimuth 45°. In all these cases the laws of superposition of Art. 1089 are observed, when similar points of similar plates are laid together. If symmetrically, the tints polarized is the same as would be polarized by one plate whose thickness is their sum; if crosswise, their difference.
If a square or rectangular plate be turned about in its own plane, from azimuth 0°, the arms of the black cross dividing it into four quarters become curved, as in Fig. 222, and pass in succession over every part of the disc; thus showing that the positions of the axes of elasticity of the molecules vary for every different point of the plate, and in different parts of it have every possible situation. We shall not here attempt to analyze the mechanical state of the molecules in any case, as it would lead us too far; but merely mention an experiment of Dr. Brewster, which is sufficient to show the conformity of our theory of these figures with fact. According to this excellent observer, the fringes parallel to the edge A B of the rectangle (Fig. 220) arise from a compressed state of the columns parallel to A B; and the interior, from a distended. And, in the unannealed plate the distribution of the forces is almost exactly similar to that described in Art. 1098 and 1099. In fact, such a plate may be likened, in some respects, to a frame of wood over which an elastic surface is stretched like a drum. The four sides will all be curved inwards by its tension, and they will all be compressed in the direction of their length by the direct tension, independent of the secondary effect produced by their curvature. The terminal fringes in the articles referred to arise solely from the secondary forces thus developed; but the analogy between the cases would be complete, if, instead of supposing the annealed plate heated at one edge only, the heat were applied at all the four simultaneously, by surrounding it with a frame of hot iron. For a farther account of the beautiful and interesting phenomena produced by unannealed glass, we must refer the reader to Dr. Brewster's curious Paper already cited.

M. Fresnel has succeeded in rendering sensible the bifurcation of the pencils produced by glass subjected to pressure, by an ingenious combination of prisms having their refracting angles turned opposite ways, and of which the alternate ones are compressed in planes at right angles to each other, thus (as in the case of the double refraction along the axis of quartz) doubling the effect produced.

The effects produced by unequal heat and pressure on crystallized bodies, in altering their relations to light transmitted through them, are less sensibly marked than in uncrystallized, being masked by the more powerful effects produced by the usual doubly refractive powers. In crystals, however, where these powers are feeble, or in which they do not exist in any sensible degree, (as in fluor spar, muriate of soda, and other crystals which belong to the tesserall system, Dr. Brewster has shown that a polarizing and doubly-refractive action is developed by these causes just as in uncrystallized ones; and M. Biot, by applying violent pressure to crystallized substances while viewing through them their systems of rings in the immediate vicinity of their axes where the polarizing action is very weak, has succeeded in producing an evident distortion of the rings from the regularity of their form, thus rendering it manifest, that it is only the extreme feebleness of the polarizing action so induced in comparison with the ordinary action of the crystal, which prevents its becoming sensible in all directions.

In applying what is here said to heat, however, we consider only its indirect action, or that arising from its unequal distribution, inducing a strain, and thus resolving itself into pressure, as above shown. But Professor Mitscherlich in a most interesting series of researches (which we hope, ere long to see embodied in a regular form, but of which at present only the most meagre and imperfect details have reached us) has shown that the action of heat on crystallized bodies, even when uniformly distributed, so that the whole mass shall be at one and the same temperature, is totally different from what obtains in uncrystallized ones; and M. Biot, by applying violent pressure to crystallized substances while viewing through them their systems of rings in the immediate vicinity of their axes where the polarizing action is very weak, has succeeded in producing an evident distortion of the rings from the regularity of their form, thus rendering it manifest, that it is only the extreme feebleness of the polarizing action so induced in comparison with the ordinary action of the crystal, which prevents its becoming sensible in all directions.

Of this important fact, (the most important, doubtless, that has yet appeared in pyrometry,) M. Mitscherlich has adduced a remarkable and striking instance in the ordinary Iceland spar, (carbonate of lime.) This substance when heated, dilates in the direction of the axis of the obtuse rhomboid which is the primitive form of its crystals, and contracts in every direction at right angles to that axis, so that there must exist an intermediate direction, in which this substance is neither lengthened nor compressed by change of temperature. A necessary consequence of such inequality of pyrometric action is, that the angles of the primitive form will undergo a variation, the rhomboid becoming less obtuse as the temperature increases, and this has been ascertained to be the case by direct measurement; M. Mitscherlich having found, that an elevation of temperature from the freezing to the boiling point of water produced a diminution of 6° 30′ in the dihedral angle at the extremities of the axis of the rhomboid, (Bulletin des Sciences publié par la Société Philomatique de Paris, 1824, p. 40.)

M. Mitscherlich assured himself of the fact in question by direct measurement of a plate of Iceland spar, parallel to the axis, at different temperatures, by the aid of the "Sphermeter," a delicate species of calibre contrived by M. Biot for measuring the thickness of any laminar solid by the revolution of a screw whose point is first brought into light contact with the surface, and by which the 10,000th of an inch is readily appreciated and measured. The experiment is necessarily one of great delicacy, but our readers may assure themselves at least of the general fact of unequal change of dimension by change of temperature, by a very simple experiment requiring no apparatus. Let a small quantity of the sulphate of potash and copper, (an anhydrous salt easily formed by crystallizing together the sulphates of potash and of copper,) be melted in a spoon over a spirit lamp. The fusion takes place at a heat just below redness, and produces a liquid of a dark green colour. The heat being withdrawn, it fixes into a solid green colour, and remains solid and coherent till the temperature sinks nearly to that of boiling water, when all at once its cohesion is destroyed; a commotion takes place throughout the whole mass, beginning from the surface, each molecule, as if animated,
starting up and separating itself from the rest, till, in a few moments, the whole is resolved into a heap of incoherent powder, a result which could evidently not take place, had all the minute and interlaced crystals of which the congealed salt consisted contracted equally in all directions by the cooling process, as in that case their juxtaposition would not be disturbed. Phenomena somewhat similar, and referable to the same principles, have (if we remember right) been encountered by M. Achard in the fusion of various frits for glasses, &c.

The relation of the optical and crystallographical characters of bodies is so intimate, that no change can be supposed to take place in the latter without a corresponding alteration in the former. As the rhomboid of Iceland spar becomes less obtuse by heat, and therefore approximates nearer to the cube, in which the double refraction is nothing, it might be expected that the power of double refraction should diminish, and this result has been verified by M. Mitscherlich by direct measurement. More recently, the same distinguished chemist and philosopher has ascertained the still more remarkable and striking fact, that the ordinary sulphate of lime or gypsum, which, at common temperatures, has two optic axes in the plane of its lamina, inclined at 60° to each other, collapses into one, and (when yet further heated) actually opens out again in a plane at right angles to the lamina, thus affording a beautiful exemplification of Fresnel's theory of the optic axes as above explained.

This singular result we cite from memory, having in vain searched for the original source of our information; but it might have been expected, from the low temperature at which the chemical constitution of this crystal is subverted, by the disengagement of its water, that the changes in its optical relations by heat would be much more striking than in more indestructible bodies. We have not, at this moment, an opportunity of fully verifying the fact; but we observe, that the tints developed by a plate of sulphate of lime now before us, exposed as usual to polarized light, rise rapidly in the scale when the plate is moderately warmed by the heat of a candle held at some distance below it, and sink again when the heat is withdrawn, which, so far as it goes, is in conformity with the result above stated. Mica, on the contrary, similarly treated, undergoes no apparent change in the position of its axes or the size of its rings, though heated nearly to ignition. The subject is in the highest degree interesting and important, and lays open a new and most extensive field for optical investigation. It is in excellent hands, and we doubt not will, ere long, form a conspicuous feature in the splendid series of crystallographical discovery which has already so preeminently distinguished its author.

§ XIII. Of the Use of Properties of Light in affording Characters for determining and identifying Chemical and Mineral Species, and for investigating the intimate Constitution and Structure of Natural Bodies.

Newton, who "looked all nature through," was the first to observe a connection between the refractive powers of transparent media and their chemical properties. His well known conjecture of the inflammable nature of the diamond, from its high refractive power, so remarkably verified by the subsequent discovery of its one and only chemical constituent, (carbon,) was, perhaps, less remarkable for its boldness, at a period when Chemistry consisted in a mere jargon, in which salt, sulphur, earth, oil, and mercury might be almost indifferently substituted for one another, than it would have been fifty years later. His divination of the inflammable nature of one of the constituents of water is at least equally striking as an instance of sagacity, and even more remarkable, for the important influence which its verification has exercised over the whole science of Chemistry. These instances suffice to show the value of the refractive index, either taken in conjunction with the specific gravity of a medium, or separately as a physical character. The refractive indices of a vast variety of bodies have been ascertained by the labours of Newton and later experimenters, among whom Dr. Brewster and Dr. Wollaston have been the largest contributors to our knowledge. They may be grouped together in a general way, in order of magnitude, as follows:

Class 1. Gases and vapours. Refractive index from 1.000 to 1.002, under ordinary circumstances of pressure and temperature.

Class 2. \( \mu = 1.05 \ldots \mu = 1.45 \). Comprising the condensed gases; ethereal, spirituous, and aqueous liquids; acid, alkaline, and saline solutions, (not metallic.)

Class 3. Comprising, first, almost all unctuous, fatty, waxy, gummy, and resinous bodies; camphors, balsams, vegetable and animal inflammables, and all the varieties of hydro-carbon. Secondly, stones and vitreous compounds, in which the alkalis and lighter alkaline earths in combination with silica, alumina, &c. are the predominant ingredients. Thirdly, saline bodies not having the heavy metals, or the metallic acids predominant ingredients. \( \mu = 1.40 \ldots 1.60 \).

Class 4. Pastes, (glasses with much lead,) and, in general, compounds in which lead, silver, mercury, and the heavy metals, or their oxides abound. Precious stones, simple combustibles in the solid state, including the metals themselves.

\( \mu = 1.60 \) and upwards.

These classes, however, admit of so many exceptions and anomalies, and are themselves so vague and indefinite, that we shall not attempt to distribute the observed indices under any of them, but rather prefer, for convenience of reference, presenting the whole list in the form of a Table, arranged in order of magnitude, in which all these classes are mingled indiscriminately—a form, in some measure, consecrated by usage.

In casting our eyes down the foregoing Table, we cannot but be struck with the looseness and vagueness of those results which refer to bodies whose chemical nature is in any respect indeterminate. The refractive indices assigned to the different oils, acids, &c., though probably accurately determined for the particular specimen under examination, are yet, as scientific data, deprived of most of their interest from the impossibility of stating precisely what was the substance examined. Most of the fixed oils are probably (as appears from the researches of Chevreul) compounds, in very variable proportions of two distinct substances, a solid, concrete matter, (stearine,) and a liquid, (elaine,) and it is presumable, that no two specimens of the same oil agree in the proportions. This is, probably, peculiarly the case with the oil of anise seed, which congeals almost entirely with a very moderate degree of cold. An accurate reexamination of the refractive and dispersive powers of natural bodies of strictly determinate chemical composition, and identifiable nature, though doubtless a task of great labour and expense, would be a most valuable present to optical science. Frunhofer's researches have shown to what a degree of refinement the subject may be carried, as well as the important practical uses to which it may be applied. The high refractive power of oil of cassia, accompanied by a corresponding dispersion, has led Dr. Brewster to conceive the existence in it of some peculiar chemical element not yet cognisable by analysis. The low refractive powers of the oils of box-wood and ambergris are not less remarkable. It is among the artificial salts, however, that the widest field is open for the application of precise research, and one in which a rich harvest of important results would, in all probability, amply repay the trouble of the investigation, whether considered in an optical, a chemical, or a crystallographical point of view.

The fraction \( P = \frac{s^2 - 1}{s} \), where \( s \) is the refractive index, and \( m \) the specific gravity of the medium, expresses \( \text{the fraction P = \frac{s^2 - 1}{s} \text{, where s is the refractive index, and m the specific gravity of the medium, expresses...} } \)

</table>

The results marked with an asterisk in this table have probably originated in some miscalculation. As hydrogen stands highest in this scale, it is probable that fluorine, should we ever obtain it in an insulated state, would prove the lowest. The optical properties of tabasheer, in all points of view, are strange anomalies, this Table.

It will be observed, that the fraction \( \frac{s^2 - 1}{s} \) only expresses the intrinsic refractive power on the hypothesis of the infinite divisibility of matter, and the equal gravitating power of every infinitesimal molecule. But if, as modern Chemistry indicates, material bodies consist of a finite number of atoms, differing in their actual weight for every differently compounded substance, the intrinsic refractive energy of the atoms of any given medium will be the product of the above function by the atomic weight. This will alter totally the order of media from what obtains in the foregoing table. Thus, the weight of the atom of hydrogen being the least, and that of mercury one among the
The dispersive powers of bodies afford another very interesting and distinctive character. Of these, Dr. Brewster, in his Treatise on *New Philosophical Instruments*, has given the following extensive table, almost entirely from his own observation.

### TABLE OF DISPERSIVE POWERS.

</table>
Respecting the results in this table, the remark applied to that of refractive indices may be yet more strongly urged. The whole stands in need of a radical reinvestigation. Those only, however, who have had some experience of the difficulties in the way of a strict scientific examination of dispersive powers, can appreciate either the labour of such a task, or the merit of Dr. Brewster in his researches, which we must not be understood as in the slightest degree deprecating by this remark. But the refinements of modern science are every day carrying us beyond all that could be contemplated in its earlier stages, and it is matter of congratulation, rather than disappointment, to every true philosopher, to see his methods replaced by others more powerful, and his results rendered obsolete by the more exact conclusions of his successors. What is now chiefly wanted is a knowledge of the whole series of refractive indices for the several definite rays throughout the spectrum, under uniform circumstances, and for all media whose chemical and other characters are sufficiently definite and constant to enable us to identify and reproduce them in the same state, at all times. The researches of Fraunhofer and Arago have shown that accuracy in the determination of refractive indices sufficient for the purpose, may be attained, and we trust, therefore, that this great desideratum will not long remain unsupplied.

To the substances in the table many important remarks apply. In general, high refractive is accompanied by high dispersive power; but exceptions are endless, especially among the precious stones, of which diamond affords a striking instance. Particular bodies seem to carry their dispersive as well as their refractive powers with them into their compounds, and that more evidently, because by the peculiar mode in which the dispersion is represented, the state of condensation is eliminated. Thus, fluorine, and even oxygen, appear to exercise a very lowering influence on the dispersive powers of their compounds, while hydrogen, sulphur, and especially lead, act with great energy in the opposite sense. The contrast between the oils of ambergris and cassia, is at Experiment least as remarkable in point of dispersive as of refractive power. The following experiment would seem to point out the hydrogen of the latter oil, as the principle to which its extraordinary dispersion is due, and is otherwise instructive, as exemplifying strongly the independence of the two powers inter se. A stream of chlorine was passed through oil of cassia till it refused to act any farther. The oil was at first greatly deepened in colour, but as the action proceeded, it changed to a much lighter ruddy yellow, which it retained till the action was complete, (and which in a few days changed to a fine rose red.) Copious fumes of muriatic acid gas were given off during the whole process, indicating the abstraction of abundance of hydrogen, and at length the oil was converted into a viscous mass, drawing out into long threads, having entirely lost its peculiar perfume, and acquired a pungent, penetrating scent, and an acid, astringent taste, totally unlike its former aromatic flavour. It was inflammable, though less than before; burning with a flame green at the edges, indicating the presence of chlorine. Its dispersive power was very little diminished. A drop being placed in the angle of two glass plates, and close to it a drop of unaltered oil of cassia, the spectrum of a line of light was viewed at once with the same eye through both the media. They still formed a continuous line, the spectrum of the unaltered oil being more refracted by only about one-fourth the breadth of that of the altered specimen. But the dispersive power of the latter was most remarkably diminished, being brought below not only that of the unaltered oil, but even below that of flint glass. When the dispersion of the unaltered oil was corrected by flint glass, that of the altered was found to be much more than corrected; and when the angle of the glass plates was such that the dispersion of the latter was just corrected by a prism of Dollond's "heavy" flint, whose refracting angle = about 25°, the uncorrected spectrum of the former was about equal to that of the flint prism. The dispersion, then, had been diminished to half its former amount, while the refraction had suffered hardly any appreciable change. (October 7, 1825.) The angle of complete polarization of a ray reflected at the surface of a medium, affords a most valuable character in mineralogy, as it gives at once an approximation to the refractive index, sufficient in a great variety...
of cases to decide between two substances, which might be otherwise confounded together, and inasmuch as it can be measured on any single surface sufficiently polished to give a regular reflexion, thus enabling us to apply this character to minute fragments, or to specimens set as jewels, or otherwise too precious to be sacrificed; to opaque bodies, and to a variety of other cases where a direct measure of the refraction would be impracticable. It has not escaped the acute and careful observation of Dr. Brewster, that the polarizing angle on the surfaces of crystallized media is not absolutely the same in all planes of incidence; and the deviation, though excessively small when the natural reflexion is used, becomes very sensible, and even enormous, when the reflexion is weakened by covering the surface with a cement of a refraction approaching that of the medium, so as to allow only those rays to reach the eye which have penetrated, as it were, to some minute depth, and undergone some part of the action of the crystal as such. The point is among the most curious and interesting in the doctrine of reflexion, and we regret that our limits, as well as the obscurity still hanging over it, and which it will require much elaborate research to dissipate, prevent our devoting a section to it, but we must be content to refer the reader to an excellent paper on the subject by that Philosopher, *Philosophical Transactions*, 1819.

The angles included between the optic axes of biaxal crystals is a physical character of the first rank, both on account of its distinctness, its extent of range, (indifferently over the whole quadrant,) and its immediate and intimate connection with the state in which the molecules of the crystals subsist, and what may, loosely speaking, be termed their structure. It is, however, a character by no means easily determined: both axes rarely lying within one field of view, capable of being examined through natural surfaces, and requiring, in almost all cases, the production of artificial sections; at least, this is the only safe way for observations of the tints, for the angles at which, in a thin parallel plate, the several successive orders of colours are produced in situations remote from the axes, are for the most part far too vague to lead to any accurate conclusion as to the position of these lines within the plate, not to speak of the sources of fallacy highly coloured, or dichroite, crystals obviously present. With these considerations before us, we cannot but be struck with surprise and admiration at the unwearied assiduity, which could produce, almost unassisted, a table of results so extensive and so valuable as the following.

**Table of the Inclinations of the Optic Axes in various Crystals.**

Among crystals with one axis, Dr. Brewster has enumerated the Idocrase, or Vesuvian, and correctly. Had he noticed, however, in the specimens examined by him the very striking inversion of the tints of Newton's scale exhibited in the rings of that now before us, he would doubtless have made mention of it. We insert here the scale of colours exhibited by a plate cut from the specimen in question, (a fine large crystal,) as affording another remarkable case in addition to that of the hyposulphate of lime, and the several varieties of uniaxal apophyllite already mentioned, of such inversion.

Table of the tints exhibited by a plate of Vesuvian, thickness = 0.11035 inch, cut a little obliquely to a perpendicular to the axis.

</table>

The firstring, it will be observed, in calculating from this table, is contracted beyond what is due to the law of the sines, probably from the section examined not passing precisely over their common centre, and gives a polarizing power greater than that deduced from the angles corresponding to $n = 1, n = 2, n = 3$, all which agree in assigning 41.35 nearly as the measure of the power in question. See Art. 1126.

It follows from this series, that of the two images formed by double refraction in Vesuvian, and other similar crystals, the most refracted should be the least dispersed, a peculiarity we have not yet had an opportunity of verifying by direct observation. It follows, however, immediately from the theory of the rings above delivered, since the smaller the diameters of the rings for any coloured ray, the greater the separation of its pencils by double refraction. Hence, in the present case, the red rays will be separated by a greater interval than the violet in the two spectra; and, consequently, the least refracted spectrum will be the longest. In the variety of apophyllite exhibiting white and black rings, (leucocyclite) the two dispersions should be almost exactly equal, and the only difference between the two spectra ought to consist in a slight variation in the proportional breadths of the several coloured spaces in them.

Another very important optical character is the intensity of the polarizing, or doubly refractive energy. This may be concluded by measuring the actual angular separation of the images; but this is usually too small to be determined.
admit of being determined with sufficient precision, in such very imperfect specimens as are usually subjected to examination for the purpose of identification, and a much better course is to make the tint developed at a perpendicular incidence, by a plate of given thickness in a direction at right angles to both the optic axes, the object of determination. This tint (which we shall term the equatorial tint) may be derived immediately from observations of tints at any angle, by the formula

\[ N = \frac{n}{t} \cdot \frac{\cos \rho}{\sin \theta \cdot \sin \vartheta} \]

where \( N \) is the tint in question, numerically expressed as usual, and where \( n \) is the tint, (also similarly expressed) developed at an angle of incidence whose corresponding angle of refraction is \( \rho \), on a plate whose thickness is \( t \), (expressed in English inches and decimals) and where \( \theta, \vartheta \) are the angles made by the ray in traversing the plate with the two axes. This value of \( N \) is the same with \( \frac{1}{N} \) in the equation of Art. 907. The following list of a very few substances will suffice to show the great range the value of \( N \) admits, and its consequent utility as a physical character, considerations which we hope will induce observers to extend the list itself, as well as to give it all possible exactness.

1128. Compound crystals of nitre.

### Arragonite.

The usual form of the crystals of nitre, when large and well developed, is the regular hexagonal prism; but a section of this, cut at right angles to the axis, is very commonly found to consist of two or more portions, in which the optic meridians are \( 60^\circ \) inclined to each other; but the plane of division often intersects one of the lateral faces of the prism, without any visible external mark of a breach of continuity, so that but for the test of polarized light, the macled structure would never be discerned. The phenomena of arragonite, in this respect, are very similar to those of nitre.

1129. Topaz.

If a plate of Brazilian topaz, cut at right angles to the axis of the rhombic prism in which it crystallizes, be examined by polarized light, it will occasionally be found to consist of a central rhomb, surrounded by a border in which the optic meridians of the alternate sides are inclined at \( \frac{1}{2} \) of a right angle to that of the central compartment, and \( \frac{1}{2} \) a right angle to each other. In consequence, when such a rhombic plate is held with its long diagonal in the plane of primitive polarization, two opposite sides of the border appear bright, the other two black, and the central compartment of intermediate brightness. Such specimens often exhibit the phenomena of dichroism in the central compartment, while the border is colourless in all positions.

But it is in the apophyllite of the variety named by Dr. Brewster, Tesselite, that this enclosure of one crystal in a case as it were of another, is exhibited in the most regular and extraordinary manner. In one of the varieties of this singular body, whose form is the right rectangular prism with flat summits, slices taken off from either summit were found by him to be of uniform structure; but, when these were detached, every subsequent slice was
found to consist of a rectangular border enclosing no less than nine several compartments, arranged as in

Fig. 223, and separated from each other, and from the border, by delicate lines or films as these marked. Each

of these compartments possesses its own peculiar crystallographic structure, and polarizes its peculiar tints, the

law of symmetry being observed. In some specimens the triangular spaces \( p q r s \) were wanting, while in others

they seem to have consisted of two portions, separated by an imaginary prolongation of the line joining their

obtuse angles with the central lozenge.

The terminal plates, the central lozenge, and the minute stripes dividing the compartments from each other

(which are sections of laminae or films parallel to the axis of the crystal, and running its whole length) consist

of that uni axial variety, in speaking of which we have used the term leucocyclite, from the whiteness of its rings.

The rectangles \( R V, S T \), (with the exception of the portions occupied by the lozenge and partitions) consist of

a biaxal medium, having its axes \( 34^\circ \) inclined to each other, and its optic meridian parallel to the axis of the

prism, and passing through the diagonals \( R V, S T \) of these rectangles. The other rectangles are composed

of a similar medium, but with its optic meridian at right angles to the former, or passing through the diagonals

\( R T, S V \).

A still more remarkable and artificial structure has been observed by Dr. Brewster, in a variety of the Faroe

apophyllites of a greenish white hue. When a complete prism of this variety is exposed to polarized light, with

its axis in \( 45^\circ \) of azimuth, the light being transmitted perpendicularly through two opposite sides, the pattern

represented in Fig. 224 is seen, in which the central curvilinear area is red, and its complements to the surround-
ing rectangle green. The squares immediately adjacent on either side in the direction of the axis are also vivid

red in their centres, fading into white, while the rest of the pattern consists in a most brilliant succession of red,
green, and yellow, bands, for a coloured figure of which we must refer the reader to the original most curious

and interesting memoir, (Edinburgh Transactions, vol. ix. part ii.) where, as also in the Edinburgh Philosophical

Journal, vol. i. he will find the phenomena described in full detail.

The sulphate of potash offers another very remarkable example of compound structure. This salt occurs in

hexagonal prisms, and occasionally in bipyramidal dodecahedrons. But besides these forms it also occurs in

Sulphate of potash, triangles of \( 114^\circ \) and \( 66^\circ \). These Dr. Brewster found to have two axes, while the hexagonal prisms have

but one; thus affording another instance of dimorphism in addition to those of arragonite, sulphur, &c. On ex-
amining the dodecahedrons, however, he found them to consist of six equilateral triangular prisms, of the biaxal

variety, grouped together, and having their optic meridians all converging to the common axis; the molecules

being so disposed in each opposite pair of individuals as to make the angle between the opposite faces of either

pyramid \( 114^\circ \) equal to the obtuse angle of the rhomboid.

The structure and mode of action of the analcime, described by Dr. Brewster in vol. x. of the Edinburgh Trans-

actions, part i. p. 187, are so extremely singular, that it is difficult to say whether it should be regarded as a

grouped crystal, consisting of independent portions adhering together, or as a mass the distribution of the ether in

whose parts is governed by a general and uniform law; the latter, however, is probably the truth. The form of

this crystal is the icositetrahedron, contained by twenty-four similar and equal trapezia, and may be regarded as
derived from the cube by the truncation of each of its angles by three planes symmetrically related to the edges

including it. If we conceive from the centre of this cube, (in its natural situation with respect to the derived

figure) planes to pass through each of the edges, and through each of the diagonals of the six faces, they will

divide the cube into twenty-four irregular tetrahedra; and of these, all the faces which pass through edges of the

cube will also pass through diagonals of the faces of the derived figure, while those which pass through diagonals of faces of the cube will also pass through diagonals of the faces of its derivative, bisecting their obtuse angles. Now it appears

from Dr. Brewster's observations, that all the molecules situated in any part of any one of these planes are devoid

of the power of double refraction and polarization; and that in proportion as a molecule is distant from all such planes, its polarizing power is greater. In this respect it differs entirely from all crystals hitherto examined, every particle of which, wherever situated, so long as they belong to one and the same crystalline system, being

equally ended with the polarizing virtue. Nor is there a closer analogy between the mode of action in question, and

that of unannealed glass and similar bodies; for in these a change of external form is always accompanied with

a change of the polarizing powers, while in the analcime each particular portion, whether detached from the mass,
or in its natural connection with the adjacent molecules, possess the very same optical properties. The action

too of the portions which possess a polarizing power is not related to axes given only in direction, and passing

through every molecule, but to planes given both in direction and in place within the mass, (the planes above

mentioned,) the tint developed at any point of a plate being as the square of the distance from the nearest of such planes, and the isochromatic lines being, in consequence, straight fringes of colour arranged parallel to the dark

bands marked out by the intersection of such planes with the plate examined. The phenomena described are

accompanied with a sensible double refraction. The reader is referred to the memoir already cited (which is one of

the most interesting to which we can direct his attention) for further details: and to a work understood to be

forthcoming from the pen of the eminent author here and so often before cited, on optical mineralogy, for what

we are sure will prove a treasure of valuable information on every point connected with this important application

of optical science.

§ XIV. On the Colours of Natural Bodies.

It was our intention to have devoted a considerable share of these pages to the explanation of such natural

phenomena as depend on optical principles, but the great length to which this essay has already extended, renders

it necessary to confine what we have to say on such subjects within very narrow limits, and to points of promi-

nent interest.
Light.

Newton's theory of the colours of natural bodies.

1. All bodies are porous; the pores or intervals vacant of ponderable matter, occupying a very much larger portion of the whole space filled by the body, than the solid particles of which it essentially consists.

2. These solid particles have a certain size (and perhaps figure) essential to them as particles of that particular medium, and which cannot be changed by any mechanical action, or by any means not involving a change in the chemical nature or condition of the medium. They are, in short, the ultimate atoms; to break which, is to destroy their essence, and resolve them into other forms of matter, having other properties.

3. These atoms are perfectly transparent, and equally permeable to light of all refrangibilities, which, having once passed their surfaces, is in the act of pursuing its course through their substances.

Newton, indeed, makes his atoms only "in some measure transparent." But he never refers to this limitation, and his theory depends essentially on their perfect transparency, as is indeed obvious from his account of opacity, which is contained in the next postulate.

4. Opacity in natural bodies arises from the multitude of reflexions caused in their internal parts.

It is obvious, therefore, that unless we admit a cause of opacity in atoms different from that which, on this hypothesis, causes it in their aggregates constituting natural bodies, the former cannot be otherwise than absolutely pellucid, since no reflexions can take place where there are no intervals, and no change of medium. Of the sufficiency of this cause, either in natural bodies or atoms, however, we confess there does appear to us some room for doubt, as it seems difficult so to conceive these internal reflexions, that the rays subjected to them shall be all and for ever retained, entangled as it were, and running their rounds from atom to atom, without a possibility of reaching the surface and escaping; which, were they to do, it is evident that every body so constituted, receiving a beam of light, would in fact only disperse it in all directions in the manner of a self-luminous one.

5. The colours of natural bodies are the colours of thin plates, produced by the same cause which produces them in thin laminae of air, glass, &c. viz. the interval between the anterior and posterior surfaces of the atoms, which, when an odd multiple of half the length of a fit of easy reflexion and transmission for any coloured ray moving within the medium, obstructs its penetration of the second surface, and when an even, ensures it, (see Art. 655.) The thickness, therefore, of the atoms of a medium, and of the interstices between them, determines the colour they shall reflect and transmit at a perpendicular incidence. Thus, if the molecules and interstices be less in size than the interval at which total transmission takes places, or less than that which corresponds to the edge of the central black spot in the reflected rings, a medium made up of such atoms and interstices will be perfectly transparent. If greater, it will reflect the colour corresponding to its thickness.

It may be objected to this, that all natural colours do not of necessity find a place in the scale of tints of thin plates, even those of bodies whose chemical composition is uniform; but to this we may answer, that the colours reflected from the first layer only of molecules next the surface ought to be pure tints, those from lower layers having to make their way to the eye through the upper strata, and thus undergoing other analyses, by transmutations and reflexions, and the condition of which, whatever shape we attribute to the atoms, it is impossible that all rays shall penetrate them so as to traverse the same thickness of them, unless we regard them as mere laminae without angles or edges, and of enormous refractive power. The same answer must be made to the objection, equally obvious, that the transmitted tint ought to be in all cases complementary to the reflected one, and that therefore cases like that of leaf gold, opalescent glass, and infusion of lignum nephriticum, all which reflect one tint and transmit another, in all which this condition is violated, form exceptions to the theory. But, in reality, the transmitted rays have traversed the whole thickness of the medium, and have therefore undergone, many more times, the action of its atoms, than those reflected, especially those near the first surface, to which the brighter part of the reflected colour is due.

The infusion of lignum nephriticum is a very singular case, and its peculiar properties have been explained by Dr. Young, on the supposition of minute particles of definite magnitude suspended in it. Though very transparent, it yet reflects a bluish green colour, while the light transmitted is yellow or wine-coloured, in this respect offering almost the exact converse of leaf gold. It is, however, no doubt a case of opalescence, and is exactly imitated by certain yellow glasses, in which a very thin film of opalescent matter near the surface reflects to the eye a bluish green tint, while yet the colour transmitted has the yellow tint belonging to the glass.

The reflexion proceeds from particles which have nothing to do with the transmitted light.

But, in fact, the objection (as appears to us) is not yet fully answered. Transparent coloured media (clear liquids in which no floating particles exist,) have no reflected colour. When examined by pouring them into an opaque vessel, blackened internally and filled to the brim, and when the colourless reflexion from their upper surface is destroyed by reflexion in an opposite plane at the polarizing angle, it is seen at once that no light is reflected from within the medium, either near the surface, or at greater depths; and if this mode of examination be regarded as objectionable, as perhaps destroying the internal as well as external reflexion, it is equally satisfactory to observe, that the image of a white object reflected from the surface of a fluid in a black opaque vessel is always purely white, whatever be the colour of the reflecting fluid. We are not aware that the objection so put has been sufficiently considered, or even propounded. To us its weight appears considerable.

* Newton appears to have been fully aware of the necessity of taking this into consideration. Prop. vii. book ii. Opt. versus finem.
and we cannot but believe that some other cause besides mere internal reflexions must interfere to prevent the complementary colour from reaching the eye; and that absorption, with its kindred phenomenon, or rather its extreme case, opacity, is not satisfactorily accounted for in this theory, but must rather be admitted as (at present,) an ultimate fact, of which the cause is yet to seek.

If this be granted, the colours of all bodies may be distinguished into true, viz., those which arise from rays which have actually entered their substance and undergone their absorptive action, (as the colours of powders of transparent coloured media, cinnabar, red lead, Prussian blue, those of flowers, &c.) and false, or superficial, or those which originate obviously in the law of interference; thus, the variable colours of feathers, insects' wings, striated surfaces, oxidized steel, and a variety of cases to which the Newtonian doctrine strictly applies, for there is no denying that cases of colour, not merely superficial, do occur, in which the Newtonian doctrine, to say the least, is highly probable. To instance one or two only. If a few drops of an extremely weak solution of nitrate of silver be added to a very dilute solution of hyposulphite of lime, a precipitate is formed of an opalescent whiteness and extreme tenuity. If more of the nitrate be added, the precipitate increases in weight and aggregation, and at the same time changes its colour, becoming first yellow, then yellow brown, then a rich orange brown, then a purplish brown, and, finally, a deep brown black. The precipitate, meanwhile, continually acquires density, and, finally, sinks rapidly to the bottom. It is impossible, in this series, not to trace the tints of the first order of reflected rings, produced by the thickening of the minute particles in the act of aggregation, but equally impossible not to recognise the agency of a cause totally different, acting to increase the opacity of the compound by an absorptive action far superior to, and independent of, the action of the particles as thin plates. The phenomena of Hematnie, described by Chevreul and cited by Dr. Brewster, (Encyc. Edin. Optics, p. 623; see also Biot, Traité de Phys. tom iv. p. 184, there referred to,) afford too close an approximation to the series of tints of the second order not to authorize a presumption that the Newtonian theory may apply to this case also. The diffused light and blue colour of the clear sky, affords another very satisfactory instance. This blue is, no doubt, a blue of the first order, reflected from minute aqueous particles in the air. The proof is, that at 74° distance from the sun, it is completely polarized in a plane passing through the sun's rays.

Another objection, no less obvious, to the Newtonian doctrine, has been successfully answered by Newton himself. A change of obliquity of incidence, it may be urged, should cause a change of colour, as a plate of given thickness reflects a different tint at oblique and perpendicular incidences. But this variation is less, the greater the refractive power of the medium; and as the refractive power increases with the density, that of the dense ultimate atoms of bodies must be exceeding great, so that the tint reflected from them will vary little with a change of incidence, (art. 669.) The colours of oxidized steel afford an excellent case in point. The refractive power of this oxide, though great, (2.1), is, doubtless, not to be compared with that of the ultimate atoms of bodies, yet the tints on the surface of blue steel vary but little with a change of obliquity. We may add, too, that the colour exhibited by any body of sensible magnitude, is in reality an average of the colours reflected from all its molecules at all possible incidences, so that no change of incidence ought to be expected to affect it.

Of the extreme tenuity of the ultimate molecules of bodies, Newton seems to have had but an inadequate idea, as he supposed that they might be seen through microscopes magnifying three or four thousand times. We have viewed an object without utter indistinctness, through a microscope by Amici, magnifying upwards of three thousand times in linear measure, and had no suspicion that the object seen was even approaching to resolution into its primitive particles. But it should rather seem that Newton regarded his colorific molecules as divisible groupes of atoms of a yet more delicate kind, and yet more dense, and these again as still further resolvable till the last stage of indivisibility be reached. M. Biot has given a striking, and, we may almost term it, picturesque account of this doctrine, in his Traité de Physique.

§ XV. Of the Calorific and Chemical Rays of the Solar Spectrum.

It has long been a matter of everyday observation, that solar light exercises a peculiar influence in altering the colours of bodies exposed to it, either by deepening or discharging them, even when totally secluded from air, and that various metallic salts and oxides, especially those of silver, are speedily blackened and reduced when freely exposed to direct sunshine, or even to the ordinary light of a bright day. Whether these effects were owing to the heat of the rays, or to some other cause, remained long uninquired. The first step was...
Light.

Other effects of solar light, made by Scheele, who ascertained that muriate of silver is much more powerfully blackened in the violet rays than in any other part of the spectrum. (Traité de l'Air et du Feu, § 66.) The experiments of Sir W. Herschel, on the heating power of the several prismatic rays, on the other hand, which appeared in 1800, showed satisfactorily that the more refrangible rays possess very little heating power, the calorific effect being at its maximum for the extreme red rays, and even extending considerably beyond the limits of the spectrum in that direction. This remarkable discovery, which established the independence of the heating and illuminating effects of the solar rays, led Professor Ritter, of Jena, in 1801, to examine whether a similar extension beyond the limits of the visible spectrum might not also have place in the chemical or deoxidating rays, and on exposing muriate of silver in various points within and without the spectrum, he found the maximum of effect to lie beyond the visible violet rays, the action being less in the violet itself, still less in the blue, and diminishing with great rapidity as he proceeded towards the less refrangible end. Dr. Wollaston independently arrived at the same conclusion.

The solar rays, then, possess at least three distinct powers: those of heating, illuminating, and effecting chemical combinations or decompositions, and these powers are distributed among the differently refrangible rays, in such a manner as to show their complete independence on each other. Later experiments have gone a certain way to add another power to the list—that of exciting magnetism. Without calling in question the accuracy of the observations which are directed to establish this point, we may be permitted to hope that further researches will, ere long, explain the causes of failure in those numerous cases where such effects have not been produced.

The calorific rays appear, from experiments of Berard, to obey the laws of polarization and double refraction, like those of light. Those of interference could not be made without excessive difficulty. In the case of the chemical rays, the same difficulty is not experienced; and Dr. Young, and after him, by more delicate means, M. Arago, have satisfactorily demonstrated that these conform to the same laws of interference, whether polarized or otherwise, that are obeyed by the luminous rays similarly circumstanced. Thus, a set of fringes formed by the interference of two solar pencils with a common origin, being kept very steadily projected for a long time on one and the same part of a sheet of paper rubbed with muriate of silver, a series of black lines became traced on it, the intervals of which were smaller than those of the dark and luminous fringes formed by homogeneous violet light.

Dr. Wollaston having observed that gum guaiacum is turned green by exposure to solar light in contact with air, took two specimens of paper coloured with a yellow solution of this gum in alcohol, and exposed one of them to air and sunshine, the other to air in the dark. The former was turned perceptibly green in five minutes, and the change was complete in a few hours, while the latter was no way discoloured after many months. He then concentrated the violet rays on paper so coloured, by a lens, and the change was speedily performed, while in the most luminous there was no change of colour, and, in the red rays, the green colour was not only not produced, but when induced by exposure to the violet, was again destroyed, and the original yellow colour restored. This seems, however, to have been merely an effect of the heat, as the warmth from the back of a heated silver spoon discharged the green colour just as effectually.

Mr. Faraday has observed that glass tinged purple with manganese, has its hue much deepened by the passage of solar light through it, and that two portions of the same plate, one preserved in the dark, the other exposed freely, after some time differ materially in intensity of colour.

The direct action of solar light, or, possibly, of its heat also, produces other chemical effects, such as the immediate combination of the elements of phosgen, the explosion of an atomic mixture of chlorine and hydrogen, and other phenomena, all indicative of powers resident in this wonderful agent, of which we have, but a very imperfect notion at present. The green colour of plants, and the brilliant hues of flowers, depend entirely on it. Tansies which had grown in a coal pit, were found totally destitute either of colour or of their peculiar and powerful flavour, and the bleaching and sweetening of celery by the exclusion of light, is another familiar instance of the same cause. How far the differently coloured rays are concerned in these effects, has never yet been accurately investigated, though attempts have been made; but we hope, from the distinguished ability of an eminent individual who has recently taken up this most interesting inquiry, that our stock of knowledge will soon receive material accessions.

We cannot close this Essay without an expression of regret, that the Memoir of Professor Airey, on the Spherical Aberration of the Eyepieces of Telescopes, just on the point of publication in the Transactions of the Cambridge Philosophical Society, reached us too late to allow of our attempting to condense its valuable contents, and we can only recommend it to the notice of our readers in lieu of, and in preference to, anything we could ourselves say on that subject. A similar expression of regret applies to the interesting "Theory of Systems of Rays," by Professor Hamilton of Dublin, a powerful and elegant piece of analysis, communicated to the Royal Irish Academy in 1824, and only now in the course of impression, but of which enough has reached us, by the kindness of its Author, to make us fully sensible of the benefit we might have derived from its perusal at an earlier period of our undertaking.

Slough, December 12, 1827.

J. F. W. HERSCHEL

CHEMISTRY.

Historical Introduction.

CHEMISTRY is that Science which investigates "the mutual agencies of the elementary principles of matter." It attempts the resolution of all compound bodies into their simple constituent parts; and it examines the action of these elements upon each other, as well in their simple state, as in their most varied forms of combination.

By an elementary body we mean a simple substance: one which we are at present unable to separate into constituent parts, having dissimilar Chemical properties. Thus Oxygen, Hydrogen, Gold, &c.; are considered Chemical elements.

It is not always desirable to separate a Chemical compound into all the elements of which it consists, but into certain groups of these elements, each of which groups, possessing definite characteristics, and forming by itself a true Chemical compound, is called a proximate element. Thus, for example, sulphuric acid consists of sulphur and oxygen; these two substances it may be separated, but no further, therefore, sulphur and oxygen are called its elements, or sometimes, for distinction sake, its ultimate elements. But if we take nitrate of lead, it may be separated into nitric acid and oxide of lead, and these two are only called its proximate elements: because, by a further analysis, we may separate the nitric acid into oxygen and azote: and the oxide of lead into lead and oxygen. Here then azote, oxygen, and lead, are called the ultimate elements of the compound.

By the definition above given we exclude from true Chemistry the principles of Heat, Light, Electricity, and Magnetism, as objects of investigation, though, as agents, some of them are perhaps always present. As agents also their assistance is continually required in every department of Chemical investigation. In the exclamatory elements of Chemistry by Professor Thomson these four are termed the IMPONDERABLE BODIES.

Now, although it is the belief of many that the physical effects of Heat, Light, Electricity, and Magnetism are, in each case, due to the actual presence of a fluid body; yet as the real existence of such fluids has never been fully demonstrated, and as their ponderability, if it exist at all, must be placed at a prodigious distance from that of the most attenuated of our known Chemical elements; we have preferred in this Work to treat of these principles (be they of what nature they may) which produce Heat, Light, Electricity, and Magnetism, under separate divisions; as branches issuing from the great stem of PHYSICAL SCIENCE. Hence, in the Paper now before us, we have only to refer to preceding Treatises for the general doctrines of these IMPONDERABLE AGENTS; but as far as they are instrumental in changing those forces which regulate the elementary constitution of matter, so far must this agency be made the subject of the Chemist's estimation and inquiry.

To what extent the researches of future times may prove all these agents to be modifications of some universal all-pervading principle, it is not for us to determine: but at present it seems generally admitted that all these subjects gain perspicuity by being made separate branches of Science.

Various etymologies have been proposed for the word Chemistry and its equivalents, in the languages of modern Europe. Besides the χημία of Vossius, which we have noticed in another part of our Work, it may be immediately deduced either from χημικα of the Greeks, or Alchemy of the Arabs. If we could prove that the Greeks had used the word χημικα previously to the VIIIth century, at which time the Arabsians derived their knowledge of the Science from the Greek writers, it would be evident that they had adopted the name also from their teachers. But whether the Arabians (the more modern writers of the two) obtained their word through the Greeks or not, it is evident that the words of both nations have one common origin. Hence the most probable etymology is that which deduces both words from Chēmi, or Kēmi, the indigenous name of Egypt. Chemia, or the Egyptian Art, as it was called by the Greeks, may have been transcribed Kēmā, or Kimā, by the Arabs, and the article which they frequently add has been retained in the Latin versions of their writings made in the dark Ages, as an integral part of the word Alchemy.

Having thus described the object of the present Treatise, we may proceed with a very brief statement of the origin and progress of our Science. The time is gone by in which it was necessary to stimulate the curiosity of the reader, or to awaken his interest by assuring him that almost all the phenomena of nature are in some shape or other to be traced up to Chemical principles; we need not remind the manufacturer, or the purchaser of manufactured goods, that in by far the greater proportion of those operations, by which one species of the produce of nature is converted into some other form, better suited to the wants or comforts of mankind, Chemical affinities are employed. Hence, the value of this study; and the reasonable prospect of advantage to be derived from it, is that which arises from a skilful calculation of effects arising from measured causes: all the old processes being such as might be expected from the rudest tentative methods, unguided by Scientific principles or inductive research. To Chemistry, the Science of Medicine has long been under the deepest obligations. The most efficient remedies have for many years been derived from mineral substances, which have undergone those purifications and ameliorating combinations which Chemistry alone can devise and execute. But in this particular, the same powerful Science is probably about to work a further change: numerous experiments have
within the last ten years been made upon the most
powerful of the vegetable tribe in the *Materia Medica,*
and from these it would seem that it is possible, in very
many cases, to separate the active medical principle
from the ligneous and inert matter by which it is
accompanied, and to present it in a pure crystalline
form. By this process two objects of considerable im-
portance are attained: the one, that the woody matter
which (as in the case of bark) frequently disordered the
stomach, is got rid of: and the other that the uncertain-
tainty as to the strength of dose, which in vegetable
substances varied greatly, is altogether obviated. There
are also other minor advantages of portability, &c.;
which are by no means unworthy of attention in a
question of such extensive public importance.

Chemistry, according to the definition we have given
to it, is but a Science of very recent introduction: it
can scarcely be said to have existed two hundred years.
But it has been usual to connect its History with that
of another Science, possessed of considerable similarity
in many of its processes; though differing widely in
the objects at which its professors aimed. Every labour
of the Alchemist and all his ingenuity was directed
towards one or other of the following objects: the
transmutation of the baser metals into gold; the
preparation of an universal medicine, which should
arrest the progress of all disorders incident to the
human frame; and thus prolong the life of the success-
ful adept to an indefinite period of duration. Of the
labours of the Alchemists there are abundant records
remaining. Numerous manuscripts yet exist in exten-
sive Libraries, especially in those of Paris and Leyden,
written in Arabic, in Greek, in Latin, as well as in the
languages of modern Europe. Besides this, the
Press poured forth its thousands of volumes of this descrip-
tion during the XVth and XVIth centuries: and, by
way of offering some idea of the prolific industry of
these authors, we may mention that Petrus Borellus has
given a catalogue of more than four thousand such
publications up to the year 1654. It is to be remarked,
however, that in this catalogue he has admitted the
names of many Alchemists whose works have never
been published, and perhaps never committed to paper:
but, on the other hand, the list might be greatly in-
creased by names which he has omitted, or which had
not appeared at the time of his publication.* The
writings of the Alchemists, though not altogether
unworthy of perusal, are of very various degrees of
merit. In some we may trace the bold impostor, who
came forward declaring that he possessed powers and
secrets which he must have known that he had not;
and who attempted to make a gain of the credulity of
others, when, had he really been able to effect the *opus
magnum,* far other evidences would have been brought
forward than a mere appeal to the liberality of others
to supply the fire of his furnaces. In others we find
only the patient, mindless plodding of those who en-
deavoured to follow instructions of such studied
obscurity, that at each successive failure the unhappy
Alchemist only thought that he had misunderstood the
directions of his master; and never suspected the
knowledge or sincerity of the guide he was blindly fol-
lowing. In this crowd of writers there are, indeed, a
few deserving higher estimation, men who worked in-
dustriously and described faithfully their attempts, their
failures, and consequent disappointments. Had the
labours of this class been guided by any thing like
inductive reasoning, or had they even studied to vary
the substances upon which they operated, as seda-
ously as they did to vary the mode of their operation
and the forms of their apparatus, we might even now
look back to their writings for experiments isolated,
indeed, and devoid of order; but still valuable as
recorded facts. Instead of this, however, the very
best of them went on torturing the same vessel of
quicksilver, with precisely the same operation fifty
times repeated: and subjected the same portion of
spirit of wine to three hundred consecutive distillations.

Can we wonder then that the latest Alchemist, as he ri-
gidly persevered to walk in the steps of his predecessors,
should in reality be as far from having any true Che-
metric knowledge of the constitution of nature as Geber
or even Hermes himself. It would appear, further, that
much as the Alchemists professed to reveal of their
Arcana, each one was unwilling to put the rest of the
world in full possession of anything of value at which
he might have arrived. This might in part arise
from a desire which many of them obviously pos-
sessed of inducing a general belief in the supe-
riority of their own individual attainments. Thus
Roger Bacon, a man second to no one of his day
in all that then constituted learning, and of consum-
mate ability, yet when he describes (as we fully think
he does describe) the preparation of gunpowder, names
at once the *salis petra et sulphurus,* but conceals the
remaining ingredient, the *carbonum pulvere,* under the
anagram of *laru mone cap ybura.*

We may smile at the pertinacity with which the Al-
chemist pursued his lengthy processes of cohabation
and digestion, through wearisome days and sleepless
nights, wasting his money and wearing out his vessels
with perpetual fires: and, perhaps, it is lawful to ex-
press some little surprise that the repeated failure of his
hopes, and the evidence of his own experimental facts,
did not force upon him this obvious truth; that the
thing he sought was impossible or impracticable. But
in his defence be it said that he had abundance of at-
testation that others had actually succeeded in the
process of transmutation; and the studied obscurity in
which all the instructions of the most celebrated adepts
were enveloped, might always leave him in doubt whe-
ther his failures were not chargeable to his own misap-
prehension. Besides, there were, in favour of the
possibility of transmutation, some simple and well
known experiments which had wonderfully the sem-
bance of such an operation. Such, for instance, is the
precipitation produced by dipping a polished iron rod
into a solution of a salt of copper.

Many adepts professed to have obtained the secret
of metallic transmutation, and, by the help of good
legendedr, some well attested instances of their suc-
cessful operations are on record. Few, however, were
like Paracelsus, bold enough to profess to have found
out the *Elizir of Life,* the *Universal Medicine.* It is
needless to say that these few gave rather an unfavour-
able attestation to their roguery or credulity, by sub-
mitting, like their neighbours, to the common lot of
mortality. Yet even these were not quite without a
reason in their folly; for, in the first place, the opera-
tions of Chemistry had, recently, so prepared some

* Upon the best estimate that we can form, the Alchemical
Authors amount to about one thousand; and their Treatises to about
three times that number.
Chemistry. metallic bodies, as to render their effects little short of miraculous in arresting the progress of disease; therefore they might well hope to see still greater effects produced by further investigations. And, as to the question of the duration of life, there are some, even while we now write, who seem to think that "the disease of death" is one which, by a proper combination of circumstances, might be altogether avoided.

Alchemy is generally considered the parent of Chemistry. We have shown, however, that the objects of the two Sciences differed considerably from each other; and we are inclined to believe that Chemistry would have sprung into existence much about the time that it did so, even had Alchemy never been practised. That spirit of investigation, which spread its active energies throughout Europe early in the XVIIth century, must, we think, speedily have demanded and created for itself the exercise of those investigations which we now call Chemical. However, be this as it may, the Chemists found the instruments of the Alchemists ready fitted to their hands; they found also some useful facts recorded, though these were, in number, by no means equivalent to the labours, and the time, that had been expended in amassing them. At the dawn of Chemical Science, the wisest among the Alchemists, quitting their ancient chimerical pursuits, embarked in the legitimate processes of experimental Chemistry. Hence the one may well hope to see still greater effects reward the more recent Chemist with a brilliant discovery. But even this project we must, in a great measure, abandon for the purpose of devoting all the space which can be allotted to us, to a condensed statement of those observed facts, and a description of those modes of experiment, an acquaintance with which constitutes Chemical Science.

If we look to the Alchemists for the early History of their own Science, we shall find that it is carried up to the most remote antiquity. Though the ancient Alchemical writers have said nothing satisfactory as to the origin of their craft, Borrichius, and later authors, who felt that many of the processes of the artificer were dependent upon Chemical agencies, thence inferred that they were the result of Chemical knowledge. On these grounds, Tubal Cain, the first artificer in iron and brass, has been considered the father of Metallurgic Chemistry. There is also a story in Vossius which was believed by Tertullian, that the knowledge of Chemical Principles was among the gifts bestowed by the Angels who were led from heaven by the beauty of the daughters of the earth. Others, more moderate, deem Noah the first Chemist, because he is said to have discovered the art of making wine. Ham, the son of Noah, and his descendants, to whom the Arts and Sciences seem to have been a heritage, are thus celebrated by some. Du Fresnoy, for instance, says, Si Mezraim fils de Cham n'exerça pas lui-même la Chimie, l'on croit du moins qu'il la fit exercer par son fils ainé Thaou ou Athotis, nommé aussi Hermes ou Mercure, que devint Roi de Thèbes. Cham porta donc, vraisemblablement, cette science en Égypte, ou du moins son fils Mezraim, et c'est donc que nous la voyons se répandre dans l'univers.

From these general remarks, we proceed to a very short outline of the History of these two Sciences. We could, indeed, with pleasure, enter upon the neglected reveries of the Alchemists as a matter of amusement; and many a choice and quaint passage could we adduce from their writings; but this would, we fear, be offering amusement without instruction; and therefore, we shall pursue it only to a limited extent. With regard to the Chemists, it would be equally interesting and far more instructive were we to bring each in chronological review before us. Taking their published Works, we might, as it were, cause them to live over again, and observe the industry of one, the acute reasoning and well-directed research of another; or, with the aid of modern powers, we should frequently perceive how slight has been the interval between some ancient experiment and some important fact which remained to reward the more recent Chemist with a brilliant discovery. But even this project we must, in a great measure, abandon for the purpose of devoting all the space which can be allotted to us, to a condensed statement of those observed facts, and a description of those modes of experiment, an acquaintance with which constitutes Chemical Science.

History of Alchemy.

Origin of Alchemy.

From Egypt, then, it is really probable that the Hermetic Philosophy might pass to the Israelites, and Moses has been claimed as an adept, because he is recorded to have been skilled in all the learning of the
Arabia. in Arabia, the general belief is, that Alchemy in. Respecting the origin and progress of Chemistry in the time of Xerxes, we arrive at Democritus the Greek Philosopher, who lived in the 5th century before Christ. There are several manuscript copies of a Treatise in Greek, attributed to this author, which Treatise has been printed, together with an ancient Commentary by Synesius, Bishop of Ptolemais.

Of Comarius or Comanus, an Egyptian Priest, there is a MS. treatise on Alchemy in Greek. He lived about 50 A.D. and is said to have instructed Cleopatra in the Hermetic Science. There exist also Treatises which pretend to have been written by this queen, and the solution of a pearl to form a costly potion, is added as a proof of her Philosophical attainments.

The Hermetic Science had passed into Rome also. Pliny informs us (lib. xxxiii. cap. 4.) that Caligula attempted transmutation on a large scale: et planè fecit aurum excellens, sed ita pari ponderi, ut detrimentum sentiret.

Some check was, at length, given to the pursuits of Alchemy in Egypt; for we are informed that Diocletian, A.D. 284, caused the Hermetic writings of the Egyptians to be collected and burned: supposing that it was by means of the gold thus fabricated, that they were enabled to procure supplies during their rebellions against his government. If any manuscripts of importance escaped from this search, it is probable that they subsequently perished with the thousands of others destroyed at the taking of Alexandria by the Saracens, under the Caliph Omar.

The Alchemical fire, however, if we may believe its Historians, still continued to burn steadily if not strongly: and the following series of writers is mentioned by various authors, as having left Treatises which yet exist.

Alchemy in Arabia. Respecting the origin and progress of Chemistry in Arabia, the general belief is, that previous to the time of Mahomet, the Arabs entirely neglected the cultivation of Philosophy of every kind. "During the reign of their fourteen first Caliphs, viz. from A.D. 661 to A.D. 748, they were solely employed, as their ancestors, in preserving the purity of their language; in the study of the Koran; with the addition of some medicinal knowledge, which they found a matter of practical utility."

The contempt for every species of Science which the followers of Mahomet long retained, has been illustrated by the following well known anecdote, which is thus given by Du Fresnoy, "Amru, the Arabian General, having made himself master of Alexandria, (A.D. 640.) found in that celebrated city a Library well stored with numerous Philosophical writings. John Philoponus, an able commentator on Aristotle, was then a teacher in that city. He requested the Mohammedan General to grant him all the Philosophical works which might be found in the Library. Amru dare not take upon himself to make this present to Science. He therefore wrote for instructions from Omar, the second Caliph: but the answer which he received was fatal to the works and to Science. The Caliph remarked that if the writings were found contrary to the Koran, they must be destroyed, as being pernicious: but that if they were conformable to its dogmas, they became useless, as the Koran was all-sufficient. Thus none were preserved; all underwent one common fate and were destroyed. They were employed in heating the baths at Alexandria, and were more than six months in being consumed, though there were then more than 4000 baths in the city."

The dynasty of the Abbasides was, however, more favourable to Science. Almansor, the second, and Haroun al Rasched, the fifth Caliph of that race, were its able promoters.

In Bishop Pocock's translation of Abul Farraj, we find that Mamun Ben Rasched, (who lived A.D. 813.) "amabat scientias et sapientes ac viros celebres: ejus tempore translati sunt multi libri ex Graecae lingua, in lingam Arabicam." p. 246. It is to this period that we think we may justly refer the passage of Chemistry (such as it then existed) from the Greeks to the Arabs.

The following may serve as a brief note of some Arab Alchemical writers mentioned by Borrichius and Du Fresnoy. A MS. in Arabic, in the Library at Leyden by Ostanes: M. Du Fresnoy considers this a translation from the Greek. The Commentary of Eidi-mir Ben Ali on Abul Hassam, and the Treatise of Gel-dek are both in the same depository. Geber who, after Hermes, is in the greatest repute with the adepts, left many Treatises. Borrichius supposes him to have lived prior to A.D. 830. His works were imperfectly printed until 1652, when a correct edition appeared at Danzig, copied from a MS. in the Vatican. The next cited, in chronological order, is Rhazes or Mohammed Ben Zakaria of Korhassan, who died A.D. 932. He has the reputation of having first applied Chemical Science to that Materia Medica, and was an expert Physician. Farabi was a great traveller, and is reputed to have acquired a large and varied fund of Philosophical knowledge. He was murdered by robbers in the woods of Syria, A.D. 954. His works, which are numerous, are stated to be in MS. in the Library at Leyden. The time at which Michael Psellis lived is not certain, he was of Constantinople. Leo Allatus de Psellis, &c. Roma, 1634. There is a pretty little story made out of the history of Adlar, a sage Arabian adept. Morienus, a Roman, left his Country for the sake of participating in the Hermetic learning of Adlar and Kalid, who is reported to have been a Caliph or Sultan of Egypt; to these Morienus communicated the arcanum magnum, and then mysteriously withdrew himself from Royal favour, returning to his original solitude in Jerusalem. Morienus's Treatise was written in Arabic, but translated into Latin by Robertus Castrensis, A.D. 1182. Morienus is supposed to have lived at the middle of the Xth century; he was much younger than Adlar, and probably rather older than Kalid. The translation of a work referred to Kalid, may be seen in Mangetus.

The last Arabian writer whom we need cite is Ebn...
Alchemy.

In concluding this very brief sketch of the History of Alchemy, it would have been possible to have cited Alchemical writings of a date still more recent than these above mentioned. In fact, we hold it extremely probable, that there may be persons yet living, who believe in Alchemy, and even pursue the visionary prospects it holds out. Some there may be, too, who despairing of obtaining the Elixir of life, or the universal medicine, nevertheless, led by fallacious assertions and false analogies, are in hope of attaining to the transmutation of metals. Or, perhaps, they might with one of the later English writers, prefer to avoid the term transmutation: he says, "It is therefore in very deed a chaos which is related to all metals as a mother; for out of it I know how to extract all things, even gold and silver without the transmuting Elixir: the thing which whosoever doth also see, may be able to testify it." Page 5 of "Secrets revealed, &c. &c. by a most famous Englishman, styling himself: Anonymus or Erynnous Philalethes Cosmopolita; who, by inspiration and reading, attained to the Philosopher's Stone at his age of 23 years, a.d. 1645." To the latter part of this Adept's sentence we fully subscribe, frauds ever excepted.

It has been remarked, that many of the Hermetic Philosophers were Ecclesiastics of different professions. This does not seem strange when we consider to how great an extent Learning was confined to that order, in the periods to which we now refer. There runs through many of the Alchemical writings a strong vein of piety, which has frequently every appearance of having been sincere. Prayers, and fastings, and almsgivings, are frequently essential parts towards the magnum opus and there is every reason to believe that by some they were strictly performed. We cannot be surprised at finding the mystic Divines involving Alchemy among their speculations; and it may be somewhat amusing, though we feel it rather an humiliating specimen of the human mind, to produce a passage or two actually published in England so late as the year 1815.

"Attraction is the first principle of motion in nature: the origin of attraction is beyond nature, and is therefore incomprehensible to the human understanding. Repulsion is the second principle: it is a necessary consequence of the first by reaction. Circulation is the third principle: it proceeds from the conflict of the attraction and repulsion." This is, as the author seems to think developed in five more pages of matter, wherein the Alchimest is fully described and illustrated by a most sublime diagram, which is a delightful caricature representation of the genuine modern Chemical processes. The author concludes, "When the mechanical part of these principles passed into the hands of its proper manufacturers, equally and generally in all Countries, and that all Governments provide for the alteration; the school of the Adept will then
Chemistry.

Alchemists, we know of no other account than the following, given in the History prefixed to Mr. Brande's Chemistry, vol. i. p. 25.

"In later times we have had two or three believers in transmutation. In the year 1782, Dr. Price of Guildford, by means of a white and a red powder, professed to convert mercury into silver and gold, and is said to have convinced many disbelievers of the possibility of such change; his experiments were to have been repeated before an adequate tribunal, but he put a period to his existence by swallowing laurel-water."

Another true believer in the mysteries of this Art, was Peter Woulfe, of whom it is to be regretted no biographical memoir has been preserved. I have picked a few anecdotes respecting him from two or three friends who were his acquaintance. He occupied chambers in Barnard's Inn while residing in London, and usually spent the summer in Paris. His rooms, which were extensive, were so filled with furnaces and apparatus, that it was difficult to reach his fire-side. A friend told me that he once put down his hat, and never could find it again, such was the confusion of boxes, packages, and parcels that lay about the chamber. His breakfast hour was four in the morning: a few of his select friends were, occasionally, invited to this repast, to whom a secret signal was given by which they gained entrance, knocking a certain number of times at the inner door of his apartment. He had long vainly searched for the Elixir, and attributed his repeated failures to the want of due preparation by pious and charitable acts. I understand that some of his apparatus is still extant, upon which are supplications for success, and for the welfare of the Adepts. Whenever he wished to break with an acquaintance, or felt himself offended, he resented the supposed injury by sending a present to the offender, and never seeing him afterwards. These presents were sometimes of a curious description, and consisted usually of some expensive chemical product or preparation. He had an hermetic remedy for illness: when he felt himself seriously indisposed, he took a place in the Edinburgh mail, and, having reached that city, immediately came back in the returning coach to London. A cold taken on one of these expeditions, terminated in an inflammation of the lungs, of which he died in 1805. He is the author of several papers in the Philosophical Transactions.

We conceive that our time may easily be employed more advantageously to our readers, than by repeating here the histories and attestations that have been handed down to us in favour of successful transmutations. Such, however, may be seen in the works of Boyle and Boerhaave. There is also an amazing tale of the kind in Helvetius's Golden Calf. The following, however, has been pointed out to the writer of this Paper by a friend, and is given as, perhaps, the latest recorded instance of expert juggling of this kind; especially as it proves that there are yet followers of Alchemy in the East.

"A few days before my arrival at Bassora in August, 1814, (says Major MacDonnell Kinneir,) Mr. Colquhoun, the acting resident at that place, received a message from an Arabian Philosopher, requesting a private interview, in order to communicate a most important secret. Mr. G. consented; and next morning the mysterious stranger was introduced to him: embracing the knees of the resident, he said he was come to supplicate the protection of the English from the cruel and continued persecutions of his countrymen, who, having
Alchemy in China.

Chemistry, understood that he had the power of transmuting the basest metals into gold, daily put him to the torture to wring his secret from him. He added, that he had just made his escape from Grane, where he had long been starved and imprisoned by the Shek, and that he would divulge every thing that he knew to Mr. Colquhoun, provided he was permitted to reside in the Factory. My friend agreed to receive him, and in return he faithfully promised to afford a convincing-proof of his skill. He accordingly retired and soon afterwards returned with a small crucible and chafing-dish of coals, and when the former had become hot, he took four small papers containing a whitish powder from his pocket, and asked Mr. C. to fetch him a piece of lead: the latter went into his study, and taking four pistol bullets, weighed them unknown to the Alchemist: these, with the powder, he put into the crucible, and the whole was immediately in a state of fusion. After the lapse of about twenty minutes, the Arabian desired Mr. C. to take the crucible from the fire, and put it in the air to cool: the contents were then removed by Mr. C., and proved to be a piece of pure gold, of the same weight as the bullets. The gold was subsequently valued at 90 piastres in the Bazar. It is not easy to imagine how a deception could have been accomplished, since the crucible remained untouched by the Arab after it had been put upon the fire; while it is, at the same time, difficult to conceive what inducement a poor Arab could have had to make an English gentleman a present of 90 piastres. Mr. C. ordered him to return the next day, which he promised to do, but in the middle of the night he was carried off by the Shek of Grane, who, with a body of armed men, broke into his house and put him on board a boat, which was out of sight long before day-break.

We have, hitherto, passed by the claims of the Chinese to an early knowledge of Alchemy. Martini in his Historia Sinica, and Le Comte in his Mémoires sur la Chine, state that the Chinese assert Alchemy to have been known among them 2500 years before the Christian era, but that they have no manuscripts on the subject. In the Mémoires de l'Acad. de St. Pétersb. for 1807 and 1808, vol. ii. there are some extracts from a MS. on Chemistry, brought from China by M. Bournon. The title, when translated, runs thus: Confessions du païsable Dragon, composé par Mâb-hhôa dans le royaume de l'Empero Ëssou-dsöüň, de la dynastie de Tànn, which is equivalent to a. n. 756.

In the first chapter the author says, "Tout ce que l'homme peut sentir et observer par ses sens, et tout ce qu'il peut concevoir par son esprit et par son imagination, est composé de deux principes fondamentaux le Yân et la Yne, qui désignent le parfait et l'imparfait. Le Yân est la matière ou l'accompli, et le Yne lui est diamétralement opposé."

Of the Atmosphere (Hhiá-chenn-kś) he says; this Hhiá-chenn-kś is the kš which rests on the surface of the earth, and elevates itself to the clouds. When the proportion of the Yne which makes part of its composition is too great, it is not so perfect as the kś beyond the clouds. We might conceive the Hhiá-chenn-kś by the sense of touch, but the elementary fire with which it is mingled, renders it invisible to our eyes. There are many methods which purify it and deprive it of a part of its Yne. This is done by substances which are modifications of Yán, such as metals, sulphur (liéû-hhouân,) and Tâne, or charcoal. These ingredients, when we burn them, amalgamate themselves with the Yânn of the air, and give new combinations of the two fundamental principles.

On the whole, although we suppose it just possible that the pursuits of Alchemy may have extended themselves into China, yet there seems little evidence on the subject. We have almost felt it a waste of room to notice M. Bournon's MS., for it is in perfect accordance with the well known character of the Chinese for devising such frauds, and for great skill in executing them, to suppose the whole a forgery, the object of which has been to produce an evidence of Chemical knowledge having existed among them, prior to its appearance in Europe. Thus they would pretend that the constitution of the atmosphere, and the nature of its ingredients, was known in China during the VIIIth century; precisely as explained in Europe at the close of the XVIIIth.

History of Chemistry.

We have admitted that it is to the medical writers of the XVIth century, that we are indebted for changing the pursuits of Alchemy into those of true Chemistry. The knowledge which the Adeptas had gained by their unwearyed efforts, all directed to one or two points, was, of course itself limited; but it was upon that, as a foundation, that Basil Valentine, Paracelsus, and Van Helmont commenced their superstructure. These writers, to all of whom we are in various ways indebted, were busily employed in making the processes which they received from the Alchemists, subservient to the preparation of active medicines chiefly drawn from the mineral kingdom: while, at the same time, they had the difficult task of combating the established usages of the more mild, but less efficacious, preparations of the Galenical school of Physic.

While thus Medicine adopted Chemistry as an immediate auxiliary, Philosophy claimed its aid as a method of interrogating nature. On this ground there is no name so deserving of attention, as that of Francis Bacon. Lord Verulam. This extraordinary man, whose writings bear the deepest stamp of originality and genius, pointed out to all the world the just paths to be pursued in Scientific investigation: nay, more, he set the example, by himself walking in those paths not unprofitably; making Science his relaxation from the cares of State, as it afterwards became his solace in years of degradation and affliction.

In the subsequent part of this introduction, we may name two or three of the great changes which Chemical creeds have hitherto undergone; but the nature of this work will by no means admit of that fulness of Historical detail, which we could with pleasure undertake. We have said more of the Alchemists than we intend to say of the Chemists, because we feel that we have parted from them for ever; but it may be possible yet to acknowledge our obligations to the Chemists, though briefly, when each substance, which their sagacity brought to light or investigated, shall come individually in review before us.

Basil Valentine describes several processes for Basil obtaining nitric or sulphuric acids, and in his Curraus Triumphalis Antimonii he explains the composition and properties of numerous medicines formed from that metal.

Paracelsus was a bold and successful Physician, his Paracelsus. writings do not seem to have tended so much to the
Boyle.  
Hooke.  
Glauber.  
Stahl.  
Brandt.  
Kunckell.  
Wan Helmont.  
Chemistry.  advancement of Chemistry, as to the defence of the active Chemist Articles recently introduced into the Materia Medica, such as calomel and the antimonial preparations. He sank at an early age under the consequences of a life of irregularity, and is buried at Salzburg.

Van Helmont.  
A Physician of Brussels, succeeded to the knowledge, and supported the credit of the medicines of the two last named authors. His writings convey to us a favourable impression of a mind honestly searching for Truth; but his energies are directed more towards Medicine than to pure Chemistry. He first used the term Gas to designate all aërisomorphic substances, atmospheric air excepted.

Kunckell.  
Kunckell wrote on Glass-making, and he also discovered the method of obtaining Phosphorus, having, however, had some shown to him by Brandt, a Chemist of Hamburg, its first discoverer, who concealed the process from Kunckell, though he revealed it to Kraft of Dresden.

Glauber.  
Glauber of Amsterdam was an experimentalist of first rate excellence; he wrote much, but he also worked much, and introduced many valuable improvements into the manipulations and apparatus of Chemistry. He introduced the process for obtaining muriatic acid, and described the method of separating ammonia from bones; he formed also the salts of that acid. His discovery of the product of vinegar by the distillation of wood in close vessels, has not, until very recently, obtained the attention it deserved, though now it forms an important branch of our Manufactures.

The formation and incorporation of the Royal Society in 1662, by Charles II., together with a similar institution, the French Royal Academy of Sciences, formed in 1666 by Louis XIV., were great National measures, which, though at first they may be said to have owed their origin to the calls and claims of Science, in the end acquitted themselves of the obligation by ennobling its purposes, concentrating its energies, and enrolling among its votaries the most learned and dignified characters of the country.

The Royal Society originated at Oxford, but its members removed their sittings from that place to London for the sake of greater assistance and more extensive utility. Among its earliest members was the Honourable Robert Boyle, a most amiable man, a diligent Philosopher, and a sound Christian. He wrote and published much, and with good effect, though originality of genius does not seem to have been his characteristic.

Dr. Hooke was the contemporary of Boyle, of a disposition far less amiable, but of genius more acute. Boyle and Hooke satisfactorily demonstrated the necessity of atmospheric air to the process of combustion; and the views which Hooke entertained were subsequently supported with great ability by Mayow. The opinions of Boyle, Hooke, and Mayow, upon the subject of combustion, though, as we now believe, the more accurate of the two, seem to have given way to the foreign doctrines advanced by Beecher and Stahl.

Ernst Stahl, a Chemist of great and deserved reputation, was the chief author of what is termed the Phlogistic Theory of Combustion. In this theory Phlogiston is considered an element of extreme subtility, capable of existing as a constituent part of some bodies, and causing the appearance of fire whenever its particles are so liberated as to assume a violent vibratory motion that is natural to them. Every substance that it was possible to burn was supposed to contain Phlogiston, and every substance when it had been burned was thought to have parted with its Phlogiston. This continued to be the general belief for more than half a century, though the reasoning of Boyle, Hooke, and Mayow, together with the experiments of Rey, showings that metals did not lose but gained in weight by combustion, were decidedly opposed to such an hypothesis.

Hooke recognised the combination of oxygen in nitre, though that term was not applied to it till long afterwards. Mayow called it the Nitro-aërial substance, and demonstrated its necessity to animal respiration. He also obtained hydrogen by the action of iron upon diluted sulphuric acid. His examination of the mutual actions of saline bodies is, perhaps, the first germ of the doctrines of analysis depending on composition and decomposition. The sulphures, both metallic and alkaline, are ably treated of in his works, and much of that system which is so forcibly sketched in the small portion of Newton's writings that is devoted to Chemistry, may be traced to the experiments, if not to the views, of Mayow. The whole of the doctrine of Chemical Attraction underwent great changes and improvements subsequently in the hands of Geoffroy, Bergman, Berthollet, Pflaum, Proust, Wenzel, Richter, Higgins, Dalton, Wollaston, Gay Lussac, and Prout.

Although, in the divisions of Science to which we adhere, Heat does not form a part of Chemistry, yet as the Chemists of the period we are examining invariably united these branches, we must now mention the discovery of the thermometer, an event which produced a decided and beneficial influence upon the progress of Chemistry in general. In regard to priority of claim to this valuable invention, authors are divided between Drebël, of Amsterdam, and Santorio, of Padua: both lived in the latter half of the XVth century. The Florentine Academicians, however, were the first to reduce the instrument to purposes of practical utility. But all their instruments wanted the essential of comparability. It seems doubtful; but Dr. Halley is said to have introduced as one fixed point of comparison, the boiling point of water, and Newton certainly made use of both this and the freezing point of water: thus obtaining two fixed points universally attainable, and rendering all thermometric indications comparable with each other. Van Swinden, Fahrenheit, Martini, De Luc, Saussure, Siz, and Leslie, have published further illustrations, or have suggested improvements in this instrument.

To Dr. Hales, the author of the Statistical Essay, we must award the praise of having been the chief author of Pneumatic Chemistry, though it in some degree commenced with Mayow and Hooke. He refused high preferment in order that he might continue his Philosophical pursuits, which served for his amusement amidst the zealous discharge of parochial duty, a course which only closed with his life in 1761, at 84 years of age. His experiments on the gases were very numerous and of a miscellaneous character; but those in which he applied the same industry to investigate the respiration and chemical agency of plants are better directed, and still form an important portion of our knowledge in this branch of vegetable organization.

Herman Boerhaave, of Leyden, was about Boerhaave.
CHEMISTRY.

contemporary with Hales. He was a distinguished
physician, a good chemist, and an excellent man. His
life by Johnson is well known, and justly admired.

Dr. Black was Professor of Chemistry at Edin-
burgh. In chemistry, his great discovery was that of
carbonic acid gas, which he obtained from decomposing
the alkaline and earthy carbonates. But even this,
great as it was, was exceeded, in originality and beauty,
by the grand addition which he made to physics of
the knowledge of Latent heat, about the year 1760.
(Vide heat, Art. 249.) The practical importance of
this discovery was readily seen and employed by the
vast mechanical genius of Watts.

Following a sort of chronological order, the name of
Bergman next occurs. He was of Upsala, in Sweden,
and may be considered, in some sense, the earliest
regular analyst whose name occurs in the history of
chemistry. His labours tended to the acquisition of
a more intimate acquaintance with the properties of
acid substances, for the purpose of their separation, and also
to those metallic processes so important to his
country in particular. He died at the early age of 49,
as a martyr to his assiduity in the cause of science.

The more prominent facts which were brought to
light by the high talents of Mr. Cavendish, most as-
sumingly, yet cautiously exerted, were the complete
knowledge of hydrogen gas, which, though the sub-
stance had been obtained before, was quite disregarded
until his time. These researches led him to the brilli-
ant discovery of the composition of water, which he laid
before the Royal Society in 1784. (Vide heat, Art. 167.) Thus was the synthesis of water
accomplished.

The more prominent facts which were brought to
light by Bergman, who wrote the Introduction to the
first work of the former, Chemical Experiments and
Observations on Air and Fire. It seems that Scheele
discovered, independently of Priestley, many of the
important phenomena made known by the latter about
the same time. His observations on the radiation of
heat are highly interesting; but the discovery of chlor-
ine (or phosphorous acid, as he called it) must be considered his noblest achievement. This
took place during his excellent examination of man-
genee. He also commenced the genuine Chemical
examination of the vegetable acids. Lastly, the Essay
on Prussian Blue must be mentioned with high com-
mandation. He died at the early age of 44.

We have now arrived at the era of Lavoisier,
which produced another great revolution in the Chemical
theory of combustion. The admirable Philoso-
pher, whose name we have just cited, may be con-
sidered as the chief opponent to the doctrine of
phlogiston as introduced by Stahl. That there existed
no such body as phlogiston was asserted by Lavoisier,
chiefly on the ground that substances which had under-
gone combustion weighed more than they had originally
done; which they ought not to do if they had parted
with some element previously combined. This opera-
tion was traced to the union of oxygen with the combus-
tible body. The last and the ablest of the sup-
porters of phlogiston was Mr. Kirwan, a distinguished
native of Ireland. He published a small work in
dependence of his views. This work was answered by
Lavoisier, and his associates Berthollet, Monge, Four-
croy, and De Morveau, who, having taken Kirwan's
work, republished it with their arguments and expe-
riments, attacking each chapter separately. Never
was there a contest more purely conducted towards the
investigation of Truth; and never one in which the
eroneous combatant gained for himself, by his can-
dour, the admiration of impartial judges more com-
pletely than Mr. Kirwan. From that day phlogiston
has disappeared from all chemical writings. It seems
to us most extraordinary that a belief in it ever should
have prevailed to the extent that it did: for there
were abundance of facts and experiments which ought
to have overturned it long before. These facts, how-
ever, Lavoisier has the merit of having systematized
and brought to bear upon the question. But here we
stop, and do not concede to him the merit of absolute
originality in those experiments by which the antiphlo-
gistic doctrines were supported. On this subject we
fully agree with Mr. Brande, in the following observa-
tions taken from the Historical Introduction prefixed to
his Chemistry, published in 1821.

"If we look to the abstract facts on which it (the
antiphlogistic theory) rests, we shall search in vain,
either in the works of Lavoisier, or in those of his con-
temporaries; they were exclusively furnished from
other quarters; and, without any undue prejudice, of
which indeed Science should always stand divested, they
will I think chiefly be found in the writings of Mayow
and Hooke, and in those of Priestley and Scheele. The
prominent features of the French theory are its expla-
nation of the theory of combustion and acidification,
the presence of oxygen being deemed essential in both
cases. That air is the food of fire was known in the
remotest ages; that it causes the increase of weight
sustained by metals during their fusion and calcination,
was shown by Rey early in the XVIIth century; that
a part only of the atmosphere is concerned in the

WOL. IV.
Chemistry. support of flame, was explained by Hooke in 1667; and that the vital or igneous spirit (as he terms it) of the atmosphere, is concerned in the formation of acids, was asserted by Mayow in 1674. Here, without advancing into the XVIIIth century, we have in explicit detail, all the facts and arguments requisite for the construction of the French theory; but if to these we add the discovery of oxygen by Priestley, and of the composition of water by Cavendish, what then becomes of its claims to originality?—p. 182.

The name and talents of Lavoisier did much for the introduction of the new system of Chemical nomenclature. From considering it the principle of acidification, he gave its present name to oxygen gas; azote, hydrogen, and carbonic acid gas, are also terms of the same era. Lavoisier's principal discovery, was the actual combustibility of the diamond, which had before been suspected by Newton; showing also its Chemical identity with common charcoal.

For the last and greatest advancement in Chemistry, we are indebted to the aid of Electricity. Dr. Priestley is, perhaps, the first who thus called in the powers of a sister Science. At least he seems first to have noticed and examined an experiment of Warltires, tending towards the synthesis of water by firing a mixture of oxygen and hydrogen gases. Mr. Cavendish pursued these researches, and was thus the first to demonstrate the composition of water. This was in the year 1781; and in 1789, the associated Dutch Chemists, Facts, Van Troostwyck, and Dieman, effected its decomposition by a varied application of the same agent. It is not, however, to ordinary Electricity that Chemistry is indebted for its greatest advancement, but to that species of action which arises from the Voltaic pile.

In repeating Galvani's experiment upon what he called the Animal Electricity, made by placing some zinc in contact with the nerve, and some copper in contact with the muscle of a recently killed frog, and then forming a contact between the two metals, by which a muscular convolution was produced, Volta was led, about the year 1791, to the discovery of that beautiful series of mutual electric actions between the metals and other substances, which has subsequently borne his name. Mr. Cruickshank improved the construction of the pile by converting it into a trough; and in 1800, Messrs. Nicholson and Carlisle may be said to have first witnessed the Chemical action of the pile in a most important instance, namely, the decomposition of water. In 1803, Hisinger and Berzelius greatly extended the knowledge of Electro-chemical agencies, by publishing a beautiful series of experiments developing the law that "oxygen and acids are accumulated round the positive pole of the battery, while hydrogen, alkaliks, earths, and metals are accumulated round the negative pole."

The Philosophical Transactions for 1807 contains Sir Humphry Davy's Paper, in which the Chemical agencies of Electricity are still further developed; and the brilliant experiment of the decomposition of the alkalis, with considerable evidence of the real nature of the alkaline earths, is described in one of the most interesting Memoirs ever presented to Science. From this period the History of Chemistry does not present any very marked features to arrest our attention. It has continued steadily to advance, but without making any of those gigantic strides which we have felt it necessary thus briefly to mention. Analysis of all kinds has been in a state of successive improvement. In France, this most important branch of the Science has been most successfully directed to the examination of the vegetable contents of the Materia Medica, with a view to practical purposes: while, at the same time, Dr. Prout in England, and Professor Berzelius in Sweden, have laid the foundations of noble researches in the Chemical physiology of animal bodies: from which ultimately the healing Art will unquestionably derive signal advantages.

In concluding this most circumscribed outline of the History of Chemistry, we may perhaps be allowed to express a faint shade of regret, which nevertheless has frequently passed over our minds within the space of the last five or six years. Admiring, as we most sincerely acknowledge that we do, the Electro-magnetic discoveries of Professor Oersted and his followers, we still as Chemists fear that our Science has suffered some degree of neglect in consequence of them. At least, we remark that during this period good Chemical analyses and researches have, with a few exceptions, been rare in England; and yet it must be confessed there is an ample field for Chemical discovery. How scanty is our knowledge of the suspected Fluorine! Are we sure that we understand the nature of Nitrogen? And yet these are among our elements. Much has been done by Wollaston, Berzelius, Gay Lussac, Thenard, Thomson, Prout, and others, with regard to the doctrine of Definite Proportions, but there yet remains the Atomic Theory. Is it a representation of the laws of nature, or is it not? This is a point of vital importance to Chemistry: it yet remains undetermined. Let the Chemist and the Mathematician (for both are required) unite their powers for the solution of this problem.

For the History of Chemistry the reader may consult Borrichius, de ortu et progesse Chemie, 4to. (reprinted in Mangetus;); Bergman, de primordiis Chimiis, Opuscula, vol. ii. or Upsal, 1779. Chemical Apparatus.

Before any attempt is made to explain the principles of the Science, it may be advisable to describe the Instruments employed in Chemical researches.

The Laboratory is the building or room wherein the Chemist carries on his operations. In describing such a building with its requisite furniture, it is intended to mention, as far as our limits will allow, all that is necessary for an ample range of Chemical research: but lest the extent of the apparatus should appear a formidable obstacle to the commencement of this fascinating and important study, it must be premised that we are about to describe more than it may be in the power of every person to command. It will be easy, however, for any one to select whatever instruments are essential to that particular branch of the Science which he may design to investigate. From the very great improvements which the last twenty years have produced, the cumbersome vessels and tedious processes of the early Chemists have given place to simpler and more delicate modes of experimenting. Formerly, the Instruments of the experimentalist and the manufacturer were identical; to the latter they remain the same, as quantity is his object, but in the present improved state of Chemistry, the blast-furnace and the evaporating pan have in most instances given way to the blowpipe and the watch-glass. It is true, that in a well-appointed Laboratory they are still essential, but the command of a spare room and a small stock of instruments will enable any person to verify processes, and even to prosecute new objects of research with little cost or inconvenience.

It scarcely need be remarked, that in a Science depending so much on manipulation, and the habit of accurate observation, a little practice will teach more than volumes of reading. Numerous minutiae, too important and tedious for description, may easily be gained by experience, or by the aid of a skilful instructor. A Work, however, expressly devoted to this branch of the subject, has been recently published by Mr. Faraday, of the Royal Institution; it will be found ample in its details, and invaluable to any one entering upon Chemical studies.

Perhaps, on the whole, the most advantageous form for a Laboratory, would be that which allowed of one ground-floor room, a cellar beneath, and a chamber above. The cellar serves as a convenient store-room for glass and earthen vessels not constantly in use, carboys of acids, and other things that require to be kept in large quantities; but the main object of this arrangement, is to keep the ground-floor room free from dampness, which is extremely injurious to the furnaces and to all iron work, detaches the labels from vessels, and dissolves the delicate substances that they imbibe. On the ground floor, a space of at least six feet in width along one side should be appropriated to the range of furnaces, and under this part the cellar ought not to extend, as no floor could support the weight without arches, and no wood ought to enter into its structure. The floor of this part should be brick or stone, but the remaining part of the room may have a boarded floor. Over the whole of this fire-proof space, a chimney should extend, and may taper upwards, so as to become of the ordinary size at the top of the building. If the front of this chimney be supported by pillars or arches, the height should everywhere be sufficient for a person to walk freely under without stooping. The main object of this spacious chimney, is for the purpose of allowing all acid fumes and noxious gases to escape without being diffused throughout the air of the room.

Under this open chimney, the flues from all furnaces may be made to terminate. In the arrangement of these furnaces, convenience must principally be studied; and for their construction individually, we refer to the descriptions hereafter inserted. It is desirable so to arrange, that as some one fire must always be kept in the Laboratory, that one should heat a sand bath, in which evaporations may be going on simultaneously with other operations. Of all the fur-
Francis R. H. Sheriff, in the Laboratory of the Royal Institution, standing quite free from any wall, seems the most simple and useful. Its construction may be seen in p. 90 of Mr. Faraday’s Work.

We now proceed to describe the furniture of the Laboratory in alphabetical order, for the convenience of reference.

**Air-pump.** For a description of this instrument, see Pneumatics.

**Alembic.** See Distillatory Apparatus.

**Balance.** For the particular description of this most important instrument, with a review of those mechanical and statical considerations which influence its construction, we refer to the word Balance, in the Miscellaneous Division of our Work. A well-furnished Laboratory ought to contain three Balances, at least; the largest, capable of weighing several pounds; a middle size, for weights from a thousand grains to about one pound; and, lastly, a very delicate beam for the purposes of accurate analysis. Some Balances have been constructed so as to possess great sensibility, even when bearing a considerable weight in each scale, but such are very expensive. The Royal Society is in possession of a remarkably fine instrument of this description, made by Ramsden. (Jour. de Phys. xxxiii. p. 144.) The scales in common use will turn with TAY lye of a grain, and may be loaded with 1000 grains in each pan, without materially diminishing the sensibility. The beam ought to be made of some metal which will resist the acid fumes of the laboratory; and for this purpose platinum has been sometimes employed, but it is expensive, and rather liable to permanent derangement of form. Bell-metal has recently been suggested, as, although it is flexible, the form is restored by its elasticity. The pans, and even the lines by which they are suspended from the beam, should be of platinum. The instrument ought always to rest under the protection of a glass case. The weights also should be of platinum, as not being liable to oxidation or corrosion, and admitting a ready purification from grease and dirt by exposing them to a red heat.

**Balloon.** A large glass globe used as a receiver, having a short neck adapted to the reception of the beak of a retort. See Plates, Chemistry, fig. 1.

**Barometer.** A general description of this instrument will be found in Pneumatics and Barometer.

In the Laboratory it is essential to ascertain the atmospheric pressure during any quantitative experiment on a gas; as, without such observation, we cannot know the real mass of any compressible fluid confined in a vessel of given capacity. There is, however, another important consideration attendant upon this problem; for, supposing both the volume of the gas, and the atmospheric pressure, the same in two cases, yet if the temperatures differ, it is obvious that owing to the very great change which heat produces in the elastic force of gaseous bodies, the quantities in the two cases will not be the same.

All experiments, therefore, are referred to a standard pressure and temperature; and as they are necessarily made under great variety of circumstances, it becomes necessary to reduce the results, when so obtained, to what they would have been, had the standard pressure and temperature existed. The rules for this calculation will be given in a subsequent part of this Paper, in describing the Physical Properties of Gases.

Bladders are frequently employed for the transfer of gases. Those of the calf and ox are preferred; stop-cocks are fastened to the neck so as to make them airtight, and they are then fit for use. It has been attempted to cover them with a coat of oil-paint; this, however, soon cracks and peels off. Perhaps a delicate varnish holding caoutchouc in solution might be advantageously adopted. Bags of fine silk thus varnished have been sometimes substituted for bladders.

Blowpipe. For an ample description of this instrument, which belongs not to Chemistry only, see the word in the Miscellaneous Division of this Work.

**Capsule.** A small evaporating dish.

**Crucibles** are vessels for containing substances that are to be exposed to very violent degrees of heat. They are made of various forms, figs. 3, 4, 5, 6, and 7. Some have lids, and some have not. The materials of which they are made are various, according to the purposes for which they are designed. Platinum renders on this occasion essential assistance to the Chemist from its insusceptibility in all furnaces, but it does not well withstand the continued action of alkalis, and, still less, that of one genus of salts, the nitrates; and, if exposed without protection in a common coal fire, the vessel is frequently rendered brittle, and spoiled by the action of sulphur which is formed in some varieties of coal. Pure silver Crucibles are extensively used in the analysis of minerals, as they resist the action of alkalis; and though they are unable to bear more than a low red heat, yet that is amply sufficient for the analyst’s purpose. Indeed it would appear, that even if the Crucible would bear it, little is to be gained by a greater elevation of temperature. In all cases, if possible, it is better that the platinum, or silver Crucible, be imbedded in sand within a common earthen one: thus the heat is more gradually applied, and the crucible is protected from the immediate action of the fire. Crucibles are also made of iron, but such are seldom used by the experimental Chemist. A very delicate and cleanly sort of Crucible is made of porcelain or Wedgewood ware, but these are extremely liable to crack, if either heated or cooled without great caution.

In using platinum Crucibles care should be taken to avoid those substances from which Chlorine may be disengaged. Also not to fuse nitre, nor either of the caustic fixed alkalis in them, for, in this case, a protoxide of platinum is formed and dissolved in the salt. Not to calcine in them such bodies as may leave a metallic residuum, such as the metallic salts from vegetable acids, nor mixtures which may produce phosphorus. When such metallic oxides are calcined as have but feeble affinity for oxygen, (as lead, bismuth, copper, cobalt, nickel, antimony, &c.) the temperature must never be raised above a moderate redness; for although these oxides are not decomposable per se, their reduction may take place at a high temperature, in consequence of the affinity of their metals for platinum. In long continued calculations, the Crucibles must be protected as much as possible from the immediate contact of the fuel; for the metal is very apt to receive injury from substances accidentally met with, though in small quantities in the coke or coal, as we have already remarked; and even when these are the purest, silicon is present, which in the course of time unites with and injures the Crucible, by rendering it brittle.

For enduring a violent furnace heat, the common Hessian Crucibles, made of clay and sand, are to be
S-v- are, of course, slightly acted upon by alkaline fluxes and volatile oxides, but are, on the whole, the best for metallic reductions. In some cases, to prevent the adhesion of the metal to the bottom of the Crucible, it is advisable to smoke the inside well over a lamp, or even to line the interior of the Crucible with pounded charcoal, made into a paste with a small quantity of linseed meal and water. The black-lead Crucibles are made of that mineral and fine clay; they bear the most violent heats, and are little disposed to crack, but they are quite unfit for retaining fluxes. Their principal use is for the fusion of metals; and the larger kinds are easily converted into most convenient portable furnaces.

**Distillatory Apparatus.** The process of distillation depends upon this principle, that by the application of heat many liquids, and even solids, may be raised in the state of vapour, and again condensed when that vapour arrives in such a situation as to lose the heat which had been communicated to it. Thus a separation of pure from impure is effected. For instance, in the Laboratory it is essential to have a copious supply of pure water. Now the common spring water is usually contaminated with earthy and alkaline salts, and with some mineral acids. To remove these, distillation is resorted to. Fig. 8 represents a common Laboratory still. This instrument frequently forms a part of the range of furnaces underneath the open chimney, but it may with equal or greater convenience be placed over a portable furnace, as in the Plate, and in this form its construction will be more obvious. A is the body of the furnace, B its door. C the top, or lid of the furnace, is removed; and in its place is the body of the still fitting in like a pan to come over the fire. H is the head of the still fitting well to the body, and continued immediately, or with the intervention of a water-bath. It consists of four pieces; A is the boiler which fits into the bottom of the vessel A, and is thus deeply immersed in the hot water. This part is only occasionally fitted in to distil such spirituous liquors as do not require the greater heat of the fire, and, in fact, would be injured by unprotected exposure to its action. C is the capital, or part in which the vapour is condensed; the form is conical, and a small channel runs round the bottom to internally collect the condensed fluid as it trickles down from the under surface of the cone. From this channel it is conveyed into any convenient vessel by a pipe terminating at F. The upper surface of the cone forms the bottom of the vessel D, which is kept constantly full of cold water for the condensation of the vapour, and hence is called the refrigeratory. This water is let off by the stopcock e, when it becomes warm, and a fresh supply is poured in at the top, which is left uncovered for the purpose. The whole may be made of tinned copper; and this alembic possesses a great advantage over the still before described, that all its parts may readily be cleaned; while, if the still with the spiral worm be employed for strongly scented waters, or volatile oils, it is extremely difficult to get it free from their contamination. Some trouble is caused by the necessity of frequently changing the water in the refrigeratory; and it is essential that the cone be made to taper upwards to a considerable height, as otherwise the drops are apt to fall back into the boiler, or body of the still. This form of the instrument is, probably, more ancient than the spiral condensing worm, as it is only an improvement upon the simple alembic of the Alchemists.

Fig. 9 is a representation of a very convenient little retort apparatus. The process of distillation consists of two parts, the cucurbit A, into which the substance for distillation is put; and B, the capital, or part wherein the vapour is condensed; the neck C of the cucurbit fits into the capital and round the rim of the latter at D D; there is a channel in which the liquor from the top of the capital is collected and carried by a pipe E into the vessel destined for its reception. Sometimes the whole is of one piece, and in this case there is a stopper at F for the admission of the liquor to be acted upon. Silver or glass are the materials of which this instrument is usually formed; and it may be conveniently used over a lamp, or in a sand-bath. The bottom of the cucurbit, if made thin, will bear a considerable heat.

The most simple, and, for Chemical purposes, the most common apparatus for distillation, is the retort and receiver.

The retort is either plain (fig. 11) or tubulated, (fig. 13.) and fitted with a ground stopper at the top. A is the body for the reception of the substance, B is the neck, and C the beak which is fitted into the neck of the receiver. In some cases, also, luting is applied to keep the vapours enclosed within the vessels. Retorts are made of different substances; as lead, porcelain, earthenware, and glass; the latter may conveniently be used over an Argand’s lamp; and will, if good, bear any heat below that at which glass fuses.

When the plain retort is used, a long funnel, called a retort funnel, is extremely convenient for pouring in a liquid without wetting the neck of the retort.

The receiver (fig. 12) is the vessel into which the distilled liquid drops from the beak of the retort; and in some cases to effect the entire condensation of the vapour, it is necessary to keep the receiver immersed in cold water, or even in a freezing mixture.

The adopter (fig. 14) is employed to prolong the distance between the retort and receiver. The beak of the retort is inserted at one end, and the beak, or small end of the adopter, in a similar manner, enters the mouth of the receiver. These vessels are usually made of glass.

Fig. 16 represents a very convenient little retort easily made from a piece of glass tube, and which may, if necessary, be called the tube retort.
**Dropping Bottle.** A common bottle of any sort with a tube passing through the cork, having a capillary orifice. This is a most useful little instrument; as it is obvious, that if the bottle be half full of distilled water, and held in the hand when inverted, the expansion of the air from the warmth of the hand will propel the liquid, drop by drop, from the orifice of the tube. See fig. 17.

**Dropping Tube.** This is represented in fig. 18. It is useful to add gradually any liquid reagent to a solution; for the lower orifice being extremely small, the tube may be filled by sucking the air out from the larger end, and the finger applied to the orifice from which the mouth is removed, prevents the escape of the liquid from the tube, until it is brought to the vessel for which it is designed; and when there, regulates to a drop the quantity suffered to descend from the tube.

**Drying Instrument for Precipitates in Filters.** A (fig. 19) is an Argand lamp, B is a vessel containing water to be boiled by the lamp, with a sort of chimney by the side for the escape of steam. C is a glass vessel, which, resting on a rim, sinks into the water; and within this conical glass the filter to be dried is placed.

**Eudiometer.** Of this instrument there are several kinds; the earliest was employed by Priestley, in consequence of his discovery that nitrous gas absorbed oxygen from atmospheric air, and produced a substance absorbable by water. This method will be described hereafter, but for the experiment itself a graduated glass tube is sufficient, with another smaller one of known capacity, by which to measure the quantities of the respective airs submitted to experiment. Fig. 20 represents Priestley's instrument.

**Folde's Eudiometer** consists of a very strong glass tube, about seven inches long, open at the lower end only, and graduated into hundredths of a cubic inch. (fig. 21.) Very near to the top of the tube a short piece of wire passes through, and is cemented into each side of the tube, leaving a distance of about ¼ of an inch in the middle of the cavity of the tube between their two ends. When a mixture of gases, that may be united by the electric spark, is confined in this tube, one of the wires is connected by a chain with the outer coating of a charged jar; then if the glass knob be brought into contact with the other wire, a discharge takes place, causing a strong spark to pass between the ends of the wires within the tube, and thus the union of the gases is effected. The French close the lower end of this Eudiometer with a stopcock, and give a more complicated form to the whole instrument; but it is thereby rendered more liable to be burst by the violence of the explosion. In England the Eudiometer generally stands over the mercurial trough at the time of an experiment, and is supported by an iron clamp, which by means of a spring allows of some elevation at the moment of the explosion, but not so much as to raise the tube above the surface of the mercury. It is an advantage to be able to sink the Eudiometer down into the fluid, so that the exterior portion may be on a level with that on the interior of the tube, otherwise a calculation is necessary.

To these instruments we must recur hereafter when a greater knowledge of Chemical agents may make their use more intelligible. Fig. 22 is Dr. Hope's Eudiometer; fig. 23 is Mr. Pepy's; figs. 24 and 25 Davy's; and fig. 26 is a graduated glass tube as employed by Berthollet.

**Evaporating Dishes, or Capsules,** are generally made of Wedgwood's ware, either in the form of shallow pans, (fig. 27,) or segments of a sphere, (fig. 28;) for some purposes dishes of copper, platinum, or silver, may be employed; and for minute experiments a watch-glass is a most convenient vessel.

Files. Of these different sorts are required, but especially the three-cornered file for cutting a small notch in glass tubes, after which they easily break in the place required. Also the kind called Rat's-tail, as with these perforations are readily made in corks, through which glass tubes have to be passed.

**Filtre.** The process of filtration is so generally known as to render all description unnecessary. For some purposes a vessel made of porous stone is employed, or even a jar with a stratum of sand at the bottom. Hair sieves, flannel bags, and muslin, or a piece of tow in a common tunnel. For all delicate purposes in the Laboratory a piece of unsized paper is preferable. If the filter is large it must be folded into a conical form, and placed within a glass tunnel, but in all cases it is advisable to avoid the use of filters as much as possible. The object of filtration is generally to obtain a precipitate, that it may be dried and its quantity ascertained; now it is scarcely possible to remove the whole of the filtered substance from the paper without loss, and if the precipitate be dried upon the filter, unless the paper be reduced to exactly the same state of dryness as at first, a fallacious weight is introduced. In most cases a precipitate will in a reasonable time sink down to the bottom of a fluid with which it is mixed, and the clear supernatant liquid may be drawn off by a sucking tube. (fig. 18;) but as a paper filter is sometimes necessarily employed, the following artifices are not without their utility.

From the same sheet of paper make a double filter, that is, one filter fitting within another. Use both together, and dry both together. Then take the one containing the precipitate out of the other, and by placing the empty one in the scale which contains the weights, a counterpoise is obtained, and all further calculation rendered unnecessary.

Sometimes the precipitate is to be dried at a red heat; and although the ashes remaining after the combustion of a small filter do not amount to more than ¼ th of a grain, and might easily be allowed for, yet frequently the precipitate is of such a nature that the carbonaceous matter would at a high temperature produce decomposition. Perhaps in such a case the following method is as short as is consistent with accuracy.

Use the double filter as before. Reduce the whole to such a state of dryness as may leave the precipitate state coherent, but not pasty. By separating the filters, and using one as a counterpoise to the other, the weight of the precipitate in this state is known. Let this weight = a. Detach some of the precipitate from the filter, and put it into a platinum crucible, carefully ascertaining the weight of the quantity so introduced. Let this = b. Subject the crucible and its contents to the required heat, and again ascertaining the weight of the precipitate now it is thoroughly dry, let this weight = m; then it is evident from proportion that the weight of the whole precipitate, supposing it so dried, = \( \frac{am}{b} \).
When the quantity of fluid to be filtered is very small, and the clear liquor is wanted for experiment, it is advisable to moisten the filter first with distilled water, to compensate for the moisture which it will absorb.

**Flasks.** Figs. 29, 30, and 31 are of the common form and of white glass; they are principally used for forming solutions in acids, water, &c. The common flasks in which Florence oil is sold are the best that can be procured; they will bear a heat approaching to redness without injury, and always form a serviceable and cheap resource for the experimental Chemist.

**Furnace.** In the construction of furnaces there is great variety; the following, however, are some of the most useful, in the processes of modern Chemistry.

- Large furnaces are much less called for than formerly.
- The maximum heat is advisable to moisten the filter first with distilled water, to compensate for the moisture which it will absorb.
- The Evaporating Furnace, or Sand-bath. Fig. 38 represents a front section of the furnace; A, the ash-bin; B, the grate; C, part of the flue; D, the sand-containing an evaporating dish at E; G, the place of the ascending flue. Fig. 39 represents a vertical section, perpendicular to the former. The other parts correspond; but it is to be observed, the flue C, after running along the front, returns again, and is carried along the back, as at D, before it rises to form the chimney G.

The Blast Furnace is variously made, but fig. 34 is on the whole the most convenient. "A is the internal cavity for containing the fuel and crucible, it is slightly bevelled downwards, as in the figure, to allow of the fuel sinking down as the lower part is consumed; B is the flue passing into a hot chamber; C, an appendage particularly useful for drying luted crucibles, or raising them gradually to a proper temperature for the furnace, for roasting ores, and various other purposes; D is the flue connecting it with the vertical chimney E, which, to produce a strong heat, should be 30 or 40 feet high; F & F are covers, consisting of twelve-inch Welch tiles, with handles; G, the stove-hole, through which no more of the fire is seen than what appears between the grate and the bearing bar H, this space is left for the purpose of raking the fire, or occasionally taking out the bars; K is the ash-pit, which is sunk below the level of the ground, and is covered, when it projects at L, by an iron grating."

Henry's Portable Blast Furnace is formed from the common black-lead crucibles used by the goldsmiths. In fig. 39, the lower piece C is the bottom of one cut off so as to leave a cavity of about one inch in depth. The middle piece or fire-place A is formed from another, and a third is inverted, and placed upon the centre piece at B; a hole is cut for the escape of smoke; the pipe of a pair of double bellows is inserted at F, and from the cavity in the piece C the air passes through six gimlet holes to the fire; on a stand, resting in the bottom of the furnace, a crucible is placed, as seen at X. This furnace, if supplied by the steady action of a good pair of double bellows, produces a prodigious heat, and is certainly one of the most economical and effectual furnaces in the Laboratory. By a slight alteration it may be adapted to the purposes of asaying. See Henry's Chemistry, vol. i. p. 446.

**Common Crucible.** The same kind of crucible, with a small kind of grate loosely fitted in, so as to give room for a sort of ash-bin beneath, and having a hole, as at A, fig. 40, for the pipe of a pair of bellows, will be found of constant and essential service.

**Gasometer.** An instrument for containing gases, and, as the name implies, for measuring their volume. Of the common gasometer, fig. 41 represents the vertical section. A is a hollow cylinder of sheet-tin, entirely open at the bottom, and sliding freely up and down between the sides of the fixed cylinder B and the exterior of the gasometer C. D and E are stopcocks at the mouths of the tubes, which run down the sides of the vessel, and, uniting in the centre, reascend to F, thus forming a communication with the interior of the instrument. Water is poured in at the top, and, by inspection of the figure, it is obvious that the water will rise from the bottom P Q, until it reaches the level of the dotted line D E, filling only the space between the cylinder B and the exterior surface of the gasometer; a circular ring of about one inch in breadth. Thus, all communication between the gas in A and the atmospheric air is cut off. By opening either or both the stopcocks, D and E, and pressing down the cylinder A, the air is driven out, and by the same apertures any other air may be introduced. The volume of air contained is shown by the graduated line on the side of the movable cylinder. G G are weights running on pulleys for counterpoise. F is a cavity, in which it is sometimes convenient to put solid substances capable of abstracting certain impurities from the gas contained in the vessel.

Peppy's Gasometer, or Gasholder, consists of a japanned iron or copper vessel, fig. 42. A is the part which contains the gas, and commonly holds six or eight gallons. B is a cistern for holding water, having two
The Graduating Tube is a taper glass tube, fig. 45, with a capillary orifice. Suppose that it is capable of graduating a glass measure into cubic inches, or tenths, or hundredths. The weight of such a given volume of mercury is easily obtained by calculation; this quantity is then carefully weighed into a glass capsule, and from thence either poured or sucked into the tube. The height M, at which it stands in the tube, is then marked with a file, and by successively filling the tube to this mark, and then transferring the contents to the tube to be graduated, marking it at each time, any number of the required degrees may be obtained.

In this process let s be the specific gravity of the mercury employed, and as at the temperature 68° F., a cubic inch of water weighs 252.458 grains, it follows that if our graduation required were \( \frac{1}{10} \) of a cubic inch, we must take a weight of mercury equal to \( 2,524.58 \times s \) grains, to form the standard division upon our graduating tube.

Jars. Of these Pneumatic Chemistry require an extensive assortment; they are of glass, and of different sizes; some are graduated, some are not: the method for graduating these, is identical with that employed for measures.

Knives. The common pallet knife of the painters, and other similar instruments made of horn or bone.

Lamp. The kinds employed in the Laboratory are the lamp in which spirit of wine is burned from a cotton wick, or from a wick made of a faggot of fine brass wire; figs. 46 and 47. The former is of glass, the latter of japanned tin. Fig. 48 represents Argand’s Oil Lamp in its most common form. In this well known and excellent lamp the wick has a circular form, and thus allows a current of air to pass up through the centre of the flame. The combustion is rendered so perfect, by proper management, as to allow of no deposit of lamp black on the vessels exposed to its flame. For effecting solutions in flasks, for distillations in small retorts, and, indeed, for every experiment to be conducted on a small scale, this is an invaluable instrument in the hands of the experimental Chemist.

Professor Daubeney, of Oxford, speaks highly of a portable gas lamp, and such we have seen; but, as yet, this sort of lamp is not in general use.

Lutes and Cements. Lutes are cementing substances applied to the joints of Chemical apparatus, especially retorts and receivers, to prevent the escape of volatile matters. It is sometimes necessary to smear or coat the surfaces of retorts or tubes with some such substance,
Chemistry.

Cements are of essential service in the Laboratory to join broken vessels, and to assist in constructing the endless variety of apparatus employed in Chemical research. A few, therefore, of the most useful kinds of each will be described.

**Fire Lute** is made of good clay, of which, perhaps, that used by the pipe-makers is the best: it should be well dried, but, according to Thenard, should not be calcined, finely powdered, and sifted. It is then to be gradually mixed, and beaten up with drying oil. The more beating it receives, the better its quality. The quantity of oil is to be such as to make the lute of the consistency of glazier's putty. It resists well the action of corrosive vapours, but, of course, does not bear much heat. In a closed earthenware vessel it will keep long uninjured, which greatly adds to its convenience.

**Linseed, or Almond Meal,** or any coarse farinaceous substance, if formed into a paste with water, or, what is still better, dissolved starch, or weak glue, will make an excellent lute: it should be bound round with slips of moistened plaster, or bits of rag. This is, perhaps, the most convenient lute of any, but its combustibility limits its application.

Lime forms the basis of some valuable lutes and cements. Let a lump of quick lime be partially slaked, by being once dipped in water, and then suffered to fall to powder: a thin paste formed of this with strong glue, or the white of eggs, is very tenacious, and sets with great rapidity, especially if some more of the powdered lime be strewed over it. For joining glass tubes, retorts, and receivers, and other such purposes, a rag may be dipped in the glue or white of egg, and wrapped round the vessel: the lime being applied afterwards.

Lime and fine brick-dust, formed into a paste with blood, will make a cement, having a considerable power of resisting moisture for coarse purposes.

A simple and excellent method for joining glass apparatus, is by soaking slips of bladder in warm water: the bladders then thicken, and if smeared with paste or white of egg, will closely adhere. Linen rag and paste may, sometimes, be similarly employed. The cements of lime have this advantage, that they may be applied instantly to any accidental crack: and thus, by careful management, the vexation and loss of beginning an operation are avoided. They bear also a considerable heat without injury.

Fire Lute is applied to retorts, or tubes, when it is necessary to subject them to a strong heat, by which they might otherwise fuse or fall together and lose their shape. It is prepared by heating clay with as much fine sand as can be employed, without destroying the tenacity of the mass: old crucibles powdered are better than the sand; and chopped hair, or straw, or tow, must be added in small quantity. Such a lute is applied to the interior of iron furnaces, to protect the metal from the action of the fire. The lids of crucibles are cemented on, when required, with this compound. One thing is important, that the coated vessel be suffered to dry thoroughly, before it is subjected to the action of the fire.

Fusible Lute is of service chiefly to counteract the porosity of earthen retorts, or to fill up the cracks by which they are too often impaired. The following is recommended for this purpose. (Repertory of Arts, &c. vol. I.)—Dissolve one ounce of borax in half a pint of boiling water, and add as much slaked lime as will make it into a thin paste. Spread it over the retort with a brush, and, when dry, apply over the whole a lute of slaked lime and linseed oil, beaten till it is perfectly plastic. This becomes dry in a day or two, and the vessel is then fit for use. Stoneware retorts may thus be used several times with safety, (always renewing the oil and lime lute,) whereas, in the common way, and even with the clay and hair lute, they generally crack when cooling, or on being heated a second time."

The following composition is recommended by Aikin for joining on the covers of crucibles, or other such purposes, where it is required to keep the vessels air-tight when hot. "Brick-dust and clay, in fine powder, are to be mixed with a tenth part of glass of borax: when wanted for use, a sufficient quantity is to be mixed with water, so as to be conveniently applicable to the vessels. The heat to which they are afterwards exposed, brings the luting to a state of semivitrification adhering firmly to the crucible."

**Parker's Cement,** made into a paste with water, soon sets; it will bear a red heat, and may be made air-tight by being brushed over with a melted mixture of equal parts of wax and oil.

**Plaster of Paris.** Put some water into a capsule, and keep sprinkling the powder into it. This cement may be made air-tight in the same manner as the former, and is still stronger if mixed up with weak glue. It will bear a low red heat.

**Fusible Fluxes,** for coating tubes, retorts, &c. so as to glaze them, may be made by mixing any clay with one-tenth of its weight of borax; a cream is to be formed with water, which is to be applied with a brush. Stourbridge Clay, ground to a fine powder, makes with water a lute, capable of bearing a higher temperature than any other English cement. A sufficient number of lutes have now been described for the Laboratory of the experimentalist: it remains then, under this head, only to mention some of the best cements.

**Hard Cement.** That which is most extensively employed, is easily prepared by melting together, in an iron ladle, five parts of resin, one of bees' wax, and adding one part of very fine brick-dust or bole earth, or red ochre, or Venetian red. The compound is to be well stirred together: it may be poured out of the ladle upon a greased stone slab, and, while warm, molded into sticks and kept for use. This cement is well adapted for joining glass vessels, or for stopping cracks. It resists moisture, but, of course, is unable to bear heat or the action of spirits and oils.

A still cheaper kind, for inferior purposes, is made of six pounds of resin, one of red ochre, half a pound of plaster of Paris, and a quarter of a pint of linseed oil. A heated iron rod is the most convenient mode of applying these cements, the first especially.

**Soft Cement.** Yellow wax two parts, turpentine one part, with a little Venetian red to give colour. This cement may be made plastic at any time, by working it a little in the hands, and is extremely convenient for rendering any apparatus air-tight, where heat is not likely to interfere; also for rendering the stoppers of bottles perfectly air-tight. Glass, or precious stones, may be very firmly united by merely heating them sufficiently to melt mastic, which is to be applied to the whole of the surface of fracture, and the two pieces pressed together so as to leave as little as possible of cement between.
Caoutchouc, or Gum Elastic, is a useful substance when formed into tubes, or it serves to join glass tubes together for the transfer of gases; for this purpose there is a convenient sort manufactured in sheets by Mr. Hancock, Goswell Mews, Goswell-street-road.

The labels are usually affixed to bottles by gum water, but for this purpose isinglass, dissolved in warm vinegar, is preferable.

Pasted Paper. This is a most convenient mode of affixing labels, and also for stopping cracks in apparatus. Mr. Faraday has given a good receipt for preparing it. Take equal parts of powdered gum and flour, and add a little alum, make this into a thin cream with water in an evaporating dish. Keep stirring this mixture over a lamp till it boils, and after it has boiled a few minutes it may be removed, and applied to the paper with a brush. The paper is then suffered to dry, and moistened for use as occasion may require.

Those cements, which are employed for uniting metals, are termed solders, and, concerning them, a more particular account will be found in another part of this Work: but as the Chemist must frequently become his own workman, he will have, at times, to experience the great difficulty of making a solder unite with the surfaces of the metals he wishes to join. In Galvanic experiments, few surfaces, which appear to touch, are, in reality, in such contact as to allow of the conveyance of the fluid: hence it is frequently necessary to unite the wires by soldering. Copper and brass wires are prepared for receiving and uniting with common solder, by dipping them into a solution of nitrate of mercury: by this method they are rendered perfectly free from grease, and an amalgam is formed at the surface which materially favours the operation.

Iron Cement, such as is used for joining iron pipes, is not often required in the Laboratory. It consists of sulphur one part, sal ammoniac two parts, iron eighty parts. The iron to be clean turnings in small bits, and the whole to be mixed up with a small quantity of water.

Matrass. See Flask.

Measures. The measures of capacity mentioned in the writings of English Chemists, are the wine gallon; its fourth part, the quart; and its eighth, the pint, equal to 28,875 cubic inches. Few modern writers, however, make use of any measure of capacity for gases, except the cubic inch, which forms, undoubtedly, the most Scientific unit.

The following relations are, however, important, as they form part of the Parliamentary regulations enacted in 1825.

The pound Troy contains 5760 Troy grains.

The pound Avoirdupois contains 7000 Troy grains.

The Imperial gallon contains 277,274 cubic inches, or 70000 grains of water. Hence the pint contains 34,66 cubic inches very nearly, or 8750 Troy grains of water.

The cubic inch of water = 252,458 Troy grains.

The cubic inch of mercury = 3425,35 Troy grains.

The standard temperature and pressure for the above being Thermometer F. 62, Barometer 30 inches.

It may be convenient to remember that to convert old measures to the Imperial standard,

Multiply by 0.08943 in corn measure.

Multiply by 0.88311 in wine measure.

Multiply by 1.01704 in ale measure.

And to convert the Imperial into the old measures,

Multiply by 1.03153 in corn measure.

Multiply by 1.20032 in wine measure.

Multiply by 0.98324 in ale measure.

The accurate graduation of measures for gases and liquids, is of great importance to the practical Chemist; and for this purpose a very convenient instrument has been already described. See Graduating Tube.

When a jar only partly filled with any air is standing over the pneumatic trough, it is evident that the air within is not under the full pressure of the atmosphere, and therefore has its volume enlarged. To know the actual volume under a mean pressure and temperature, a calculation is necessary; (see Barometer in Chemistry;) but supposing a jar to be immersed always to the same depth in the trough, say, for example, one inch; then, if it be first filled with water, and successive equal measures of air be admitted from a smaller vessel, the jar may be tolerably accurately graduated as far as pressure is concerned; and in this case, it is evident that the divisions will decrease in distance from each other, proceeding from the top of the jar. Had the jar been graduated by equal volumes, as a tube, it must have been sunk to such a depth in the fluid, that the fluid within and without might be on a level before any correct estimate of its contained air could have been obtained.

Mortars. Of this utensil there should be in the Laboratory several kinds. A large bell-metal one, of Wedgewood’s ware, several sizes, fig. 49. A small iron one with a turned cavity. These are so well known, as to require no further description. Fig. 50 represents what is called a diamond mortar. It is used to abrade substances, without allowing any particle to fly off in the operation. This mortar is made of hardened steel. The pestle is a, a solid cylinder turned so as to fit the tube b accurately, which tube is exactly fitted to the cavity c of the mortar.

Fig. 51 represents a section of the agate mortar and pestle, employed for reducing hard mineral substances to an impalpable powder, for analyses after they have been broken down in the diamond mortar.

Muffle. Fig. 52, a sort of small oven made of crucible clay, for the protection of cuppels when placed in a furnace.

Phials form, of course, a part of the furniture of the Laboratory. There is a kind with a glass cap fitting closely over the common stopper: very convenient for ether, acids, and other liquids producing volatile or noxious vapours.

Pneumatic Trough. A vessel calculated to contain water or mercury for the confinement of gases in Pneumatic Chemistry. The water trough may be thus constructed, (fig. 53.) A B is a rectangular vessel of tin or of tinned copper plate, in a wooden frame, and standing on four legs. At the part C the depth of the trough is not more than 2½ inches, and on this part the jars stand when in use. The part D, however, is 10 or 12 inches deep, with a shelf E whereon to rest the jars during the operation of filling; and to facilitate this purpose, there are small holes having inverted funnels beneath; under which the beak of one or more retorts may be placed.

The mercurial trough may be formed by hollowing out a piece of close-grained wood: but the most complete are made of cast iron, and sold at the shops of the Philosophical instrument makers.

Proof, a sort of small flask, into which a curved

CHEMISTRY. 605

Chemistry. tube is fitted by grinding. They are plain, fig. 54, or tubulated, fig. 55. For obtaining small quantities of gases, they form a convenient apparatus.

Receiver. See Distillatory Apparatus.

Retort. See Distillatory Apparatus.

Sand-bath. A vessel containing heated sand, into which retorts and flasks are immersed for evaporation or distillation. They thus receive an equable temperature, and are protected from the immediate action of the fire. The sand-bath may be fitted to the top of a portable furnace; or, if large, may be heated by a flue, and thus form a part of the range of furnaces in the Laboratory.

Scissors and Shears, of various sizes, for cutting wire, plates of metal, &c. &c.

Sieves of muslin and hair, of different degrees of fineness.

Soils. Davy's instrument for the examination of, fig. 56.

Syrphons: for drawing off the clear liquor from above precipitates.

Tubes of glass, porcelain, platinum, iron, caoutchouc, &c. &c.

Tubes graduated: are generally about half an inch in diameter, and about a foot long: they are used in delicate experiments on gases, and are commonly divided into parts of a cubic inch, by a method already explained under Measures.

Tube, dropping or sucking. This very useful little instrument has been already noticed, fig. 19. At the lower end is a very small orifice, which being introduced into the clear fluid from which a precipitate has subsided, by suction with the mouth at the upper orifice, the bulb of the tube may be filled with fluid, and on closing the orifice with the tongue, the tube may be removed without the loss of one drop of the fluid. Thus, by repeating the process if necessary, a precipitate may be obtained nearly free from all supernatant fluid, without occasioning any disturbance in it, and the objectionable use of a filter is avoided.

Tubes of Safety. To guard against the effects of absorption on the one hand, or expansion on the other, the tubes of safety are employed. Figs. 57 and 58 represent the two kinds. Suppose the tube, fig. 57, to be fitted by passing through a cork or cement into the tubulature of a retort or Woulfe's bottle; and that so great a pressure from the expansion of gaseous matter takes place, as to endanger the bursting of the vessel, in this case the bulb C is about one-third filled with mercury, and as the pressure takes place upwards, some portion of the gas will escape; but the mercury retaining its place, will suffer no return of atmospheric air to the vessel.

Next, suppose that in a retort to which the tube, fig. 58, is affixed, a condensation of the gaseous contents takes place, so that absorption may be commencing at the beak of the retort, the cold fluid entering would infallibly break the vessel. But the bulb containing mercury, as in the former case, though differently arranged, will suffer some of the atmospheric air to ascend through the tube, and thus restore the equilibrium.

Fig. 59 represents a Woulfe's bottle, having a tube of safety, formed of a small glass tube, passing through a cork, and dipping half an inch below the surface of the fluid in the bottle. Tube transferring: is not in very general use, but is, nevertheless, a convenient instrument, and is thus described by Dr. Thomson:

"It is often necessary to transfer determinate quantities of gas from the water trough to the mercurial trough. This must be done without introducing any water along with the gas, except what may exist in the gas in the state of vapour. This is done with the greatest facility, by means of the tube represented in fig. 60, which was first used, we believe, for the purpose in question, by Mr. Cavendish. This is a glass tube open at both ends: but one of the extremities is bent round, and is drawn out into a fine capillary bore. The tube is graduated into 100th parts of a cubic inch, and the degrees should be made as conspicuous as possible. A good method is to fill the lines after they have been cut in the glass with black or red sealing-wax. When we want to transfer a given bulk of gas from the water trough to the mercurial trough, we fill this tube with mercury, and shutting the end b with the finger, we introduce the end a into a glass jar standing over water, and filled with the gas to be transferred. On removing the finger from the extremity b, the mercury falls down, by its weight, into a vessel placed at the bottom of the trough to receive it, and the gas enters by the capillary extremity a to supply its place. When the gas admitted into the tube amounts to the quantity desired, (half a cubic inch for example,) we shut the end b with the finger again. We then withdraw the tube from the water trough and wipe it dry. The end b is now to be placed uppermost, and the end a introduced under the bottom of the glass jar (filled with mercury, and standing over the mercurial trough) destined to receive the gas. On removing the finger, the weight of the mercury in the tube forces out the gas. When it has all made its way into the destined test glass, we remove the tube; and we may, in the same way, introduce an additional quantity of any other gas, till we have made up the intended mixture."

Tunnels, of pewter, glass, and Wedgewood's ware. Glass tunnels employed for filtering, should have raised ribs of glass running from the top towards the lower orifice for the escape of the liquid. Without this contrivance, the moist paper adheres to the sides of the glass, and the process is very materially retarded. Sometimes glass rods, or bits of straw are placed between the paper and the glass to answer the same purpose.

Weights. See Measures.

Woulfe's Apparatus is represented in fig. 61. By an inspection of the figure, it will be evident that if A be a tube through which gas is passing from a retort, for the purpose of being absorbed by the same or different liquids in the two tubulated bottles: the vertical tube in the centre will prevent any liquid being forced from the second bottle into the first, in case of absorption; the gas which does not combine with the liquid in the first vessel, will pass into the second, and if not there absorbed, may pass into a third similarly disposed, or to a pneumatic trough by the tube B.

Introduction.

(1.) It may be reasonably expected, that something should here be premised with regard to the Arrangement that will be adopted in the following Synopsis of Chemical Science. The difficulties that immediately present themselves on commencing such a task are well known to every Chemist. We might, perhaps, safely shelter ourselves under the authority of some well-known writer, and adopt the system which he has made use of. This, however, is not our intention; but we shall lay before our readers an Arrangement which to us seems better adapted to the nature of this Work than any that we could thus select; not that we are confident of its being intrinsically better for all purposes, or that it ought to be generally adopted; for we are fully convinced, that as the Science itself is only in a progressive state, and by no means advanced to maturity, future discoveries must greatly change, and may indeed altogether overturn those fundamental positions upon which all our existing Systems rest. We possess among the English, German, and French writers, several excellent general Treatises on this subject: but the fact of no two of these writers having adopted a similar Arrangement, must show that great diversity of opinions exist upon the subject; and that the voice of universal consent has not called any one Scheme to the post of preeminence; and therefore cannot condemn a writer for arranging the Facts of this Science in whatsoever order may seem to him best fitted for explaining its Laws and Principles.

There is, however, a sort of presumption in favour of a Synthetic method of describing, first, all the Simple bodies, and then the Binary compounds, and next the Ternary, and so on; to be derived from the fact, that Thomson, Thenard, and Berzelius, the three best Systematists, have all, more or less, adopted it. Our reason for departing from a plan sanctioned by such high authorities is this; that as the properties of a Simple substance, which it is the Chemist's province to investigate, are, in fact, mainly developed in its power to enter into the combination of more complex bodies, the Principle of such an Arrangement is perpetually and necessarily violated. Thus, for instance, one of our most able writers professes to describe the Element Iodine; and, according to his System, Iodic Acid, a Binary compound, ought to appear in a different part of his Work; whereas he finds himself compelled to describe the Acid in treating of the properties of the Simple base. This is no solitary case; the properties of the more Complex substances are so constantly starting up before us as characteristics of their Elements, that the same evil pervades every portion of such a Classification. We admit that it has a less appearance of Philosophical arrangement to describe any one Elementary substance, and then to pursue it through all its more complex forms, for the production of Proximate Elements; but we think that by such a method the properties are more readily studied in connection with each other, leaving less probability of repetition or omission. All must have experienced the difficulty of hunting through the properties of one substance, described in several parts of the same Work.

Whatever be the truth in these particulars as referring to a complete Code of Chemical Science, we feel persuaded that the Plan which we have here adopted is better suited to a Synopsis like the present, which must be limited to a moderate magnitude, and having its peculiar characteristics as a Work of reference only. We profess to give a Summary of the properties of each known body; and it is of obvious importance that these should be arranged in such a manner as to be most ready of access; but to extend the utility of our pages we give also a series of references to direct the Student, who may wish to pursue any research more in detail, to all that is valuable on the subject.

(2.) As it happens with regard to some substances, that either subsequent discoveries or differences of opinion on points of theory have introduced more than one name for the same substance, we have in such cases affixed the Synonyms to the head of each subsection. The Chemical Symbols for the Simple, and also for many of the Compound bodies, will be found from the Tables in the Appendix; but may, in some cases, be conveniently introduced before.

Generally speaking, we refer the more complete description of any compound to its second appearance in this Treatise; thus if A and B unite to form a Proximate Element, we mention the combination under the Section describing A; but reserve the description of the substance to the Section on B, for the sake of becoming acquainted also with the ordinary properties of the Element B; but this rule is not quite invariable. At times we find ourselves compelled to speak of the action of a substance, to which the Scheme may hitherto not have conducted us. In extenuation of this apparent dereliction from the just laws of System, we would urge that no reader is in reality so little acquainted with the Chemical Elements as not to know them by name when the word may occur to him.

We have found it convenient also not to insert the Atomic Weights of bodies in the text, except for some specific purpose; but all these, as well as the Specific Gravities, will be given in a tabular form in the Appendix.

(3.) In pointing out to the Student those Works from Books, the perusal of which he will derive the greatest advantage, we may be frequently understood as making our acknowledgments to those Writers to whom we feel under the greatest obligation for the assistance they have afforded us in arranging this Treatise.

As the most Elementary Work, we recommend the Conversations on Chemistry, in two volumes 8vo.; a much larger and more Scientific Work also in two volumes, by Dr. Henry. There has also been recently published a very good Work in one volume 8vo., by Dr. Turner; and Nicholson's Chemical Dictionary, with additions by Dr. Ure, will be found to contain much useful matter.

The four great Systems of Thomson, Murray, Thenard, and Berzelius, are all Works of first-rate merit. The first abounds in valuable facts and extensive references; the second is a Work containing much of the Philosophy of Chemistry, written in a very continuous and pleasing style; M. Thenard has given extensive generalizations, which are of the greatest importance; and the last edition of the System of Berzelius, seems not unworthy of the reputation of that most distinguished and indefatigable Philosopher. The original is in Swedish; and we conclude that it is not yet completed, as we are in possession of only the first five half volumes of a German translation, which is published at

CHAPTER I.—IMPOUNDERABLE AGENTS.

INTRODUCTION

(5.) It has been usual in Systems of Chemistry to enter rather fully into the History and Effects of the four substances or properties, (be they which they may,) the names of which are comprised in our first Part. This was especially the case with the first and third; and was a necessary consequence of the method in which these Sciences had been studied. This necessity, however, no longer exists; each of the four, viz. Caloric, (Heat,) Light, Electricity, and Magnetism, having vindicated to itself a separate rank among the Sciences; and each has very properly formed the subject of a separate Treatise in this Encyclopædia. We name them here, not for the purpose of repetition; not with the design of entering at large upon the general doctrines of each of these Sciences; but only to mark their connection with Chemistry, and to describe the Chemical Effects produced upon the Elementary Molecules of Matter by their Influence; viewing them strictly in the light of Agents; means employed to effect Chemical purposes. Future researches may, it is true, show that some one or other of these forms the Spring and Principle of Chemical Affinity; or, on the other hand, it may appear that Chemical Affinity is the influential agent for the development of some of these Physical Properties; but, in the uncertainty that at present exists, we consider the arrangement we have adopted as best calculated to elucidate the principles of our Science.

§ 1. Chemical Agency of Caloric.

Caloric. (6.) Caloric is the term made use of to designate the cause of Heat; the comparative absence of Caloric, or its presence in a less degree, we call Cold: these are but terms of ordinary language, and not very precise in their meaning. The real nature of Caloric is at present unknown. By some it is supposed to be actually a fluid substance; by others, only a property of matter. Should the former supposition be correct, we need only observe, that its tenuity is such as to have hitherto eluded all efforts that have been made to prove that it possesses any gravitating power. Under either view, therefore, we are justified in calling it one of the Imponderable Agents. The numerous and highly important Physical Properties that it exerts upon all material Bodies have already been examined in our Treatise upon Heat. In Art. (108.) of that Treatise we have marked out what we conceive to be the just boundary between the effects of Caloric upon Physical and Chemical Science; or, in other words, we have separated its effects into those which take place upon the Integrand Molecules of Matter, from those which take place upon the Constituent ones. The latter alone fall within the scope of this Treatise.

It is obviously essential to the sort of action that we now suppose, that there should be present dissimilar elementary Molecules in the Chemical sense of the word; these we are to consider either as combined or uncombined. If the Molecules be combined, Caloric may produce Decomposition; if uncombined, and the Molecules be conveniently disposed for the operation to take place, Caloric may effect their union.

(7.) The cases of Chemical Decomposition effected by Heat alone, are, perhaps, neither very numerous nor very distinctly marked. The general operation of increased Heat upon all matter tends to convert it successively from the Solid to the Liquid, and from the Liquid to the Gaseous form. But should no extraneous matter be present, decomposition does not frequently take place. It is true, that where Molecules chemically dissimilar are in union, and these are very unequally affected physically by the action of Caloric, decomposition may readily ensue. To select a familiar instance, let any alloy of Mercury, with some metal of difficult volatility, be heated beyond the boiling point of Mercury; the Mercury will rise in vapour, and break from its Chemical combination with the less volatile metal. This is, however, in great measure a Physical operation; for in the commencement of our experiment the dissimilar Molecules of the two metals are united by their Chemical Affinity, with a force surpassing that by which the Molecules of the more volatile metal tend to separate, and to assume the Gaseous form. But, by further accession of Caloric, this latter force increases to such an extent as to overpower the former one, and decomposition ensues.

(8.) Nevertheless there are instances in which, as far as we can judge, the Physical effects upon the dissimilar Molecules of a compound body are equal; and yet, by increase of Temperature, decomposition is produced. For instance, the gas called Protoxide of Chlorine (Euchlorine) undergoes decomposition, and its Gaseous Elements separate, upon exposure to a very moderate increase of Temperature.

(9.) On the other hand Caloric, or its effect Heat, seems to be a powerful promoter of Chemical combination. It is well known that many Elementary bodies, when placed in contact, and heated, enter into Chemical union. But here also it is difficult to say precisely how much of this effect is truly Chemical and how much Physical; how much is due to the change of Molecular affinity produced by the Heat, and how much to the state favourable to union, arising from a change in the Physical constitution of the bodies acted upon.

(10.) Hitherto we have limited our remarks to the action of Caloric either upon two or more dissimilar bodies not in union, or upon one compound body. But the case which is of more frequent occurrence to
§ 2. Chemical Agency of Light.

(11.) The only part of the history of Light which we conceive to belong to the subject now before us, is its agency in promoting Chemical composition or decomposition. For its general properties see the Treatise on Light.

Scheele noticed some of the decompositions produced by Light, and examined the conditions necessary to the success of the experiment. Oxygen, when held by a light affinity, may be separated by this agent; and this extends to metallic oxides of that kind even when combined with an acid. Thus Scheele, having evaporated a solution of gold to dryness, again dissolved the salt in distilled water, and placed the solution in a glass-stopper bottle. The bottle was then exposed to the sun's rays, and in a fortnight the surface became covered with a pellicle of reduced gold. (a.) Mrs. Fulhame also, in her Essay on Combustion, states, that a piece of silk, which had been dipped in a solution of gold, was exposed to the sun's rays and kept rather moist; it was at first yellow, then became green, then purple, then showed spangles of gold; and at the expiration of an hour the whole piece of silk was covered with a film of metallic gold. Another piece of silk was similarly treated, and put into a dark place, in which it remained three months without undergoing any change save the acquisition of a brownish tint. Silver also in solution was reduced by the action of Light, while in the dark it underwent no alteration. Many very amusing experiments of this nature may be seen in Mrs. Fulhame's Essay. (b.)

Decomposing Power.

(12.) In nitric acid the oxygen is retained by a feeble degree of affinity. If a bottle containing this acid be exposed to the sun's Light, it first becomes yellow, then orange, by the separation of a part of its oxygen. But if the same bottle be quite full and closed with a glass stopper, no such decomposition can take place from the mechanical obstacle opposed to the escape of the oxygen. (c.) Berthollet found that a bottle so exposed to the sun's rays, and provided with a bent tube to convey the gas to a Pneumatic trough, produced a considerable quantity of oxygen in a very few days. (d.)

(13.) If a piece of paper moistened with a solution of nitrate of silver, or if a portion of the precipitated muriate of silver (which is a white powder) be exposed to the sun's rays, a very few minutes are sufficient to change the colour almost black. It is believed, that in these changes the acid is frequently removed, wholly or in part, as well as the oxygen from the metal. Berthollet contrived that this colorific process should take place under water; and he found that a portion of the acid had in fact separated from the oxide and remained in the water. (e.)

(14.) Scheele proved that it was to a true Chemical agency on the part of Light, and not to its heating power, that these effects were to be attributed. For this purpose he exposed the same substances which he had found to change so readily, but in phials covered with black paint. The phials became very hot, but even in several days' exposure no Chemical effect was produced upon the substances within. (f.) This fact was further confirmed by Berthollet. Rumford, however, adduced experiments in opposition to this doctrine, and endeavoured to show, that the effects produced were due to the Heat alone. He obtained a partial degree of reduction, by exposing pieces of silk, which had been dipped in metallic solutions, to the Light of a candle. He produced the same effect by placing small pieces of charcoal in a tube with some solution of gold or silver, and then exposing the whole to the Heat of boiling water, the metals were reduced on the surface of the charcoal. (g.) The first experiment we conceive proves only that the Light of the taper tended, in some degree, to produce the same effect which the sun's Light would have accomplished more speedily and completely. The second case also was proved to be fallacious by Berthollet, who showed, from the gas evolved, that the decomposition had been caused by the direct action of the charcoal. (h.)

(15.) Having thus adduced instances of Decomposition produced by the action of solar Light, we must now show that it possesses, in a very marked degree, the opposite property in certain cases of determining combination.

Mr. Dalton remarked when Chlorine and Hydrogen gases were mixed together, Light had a material effect upon the rate of the Chemical combination which resulted. Thus in a feeble Light the union took place but slowly, but if the mixed gases were exposed to the direct rays of the sun, the combination was so rapid as to be frequently attended with an explosion. (i.) MM. Gay Lussac and Thenard observed the same fact, and found that it even held good with the compound hydrogogenous gases when mixed with Chlorine. (k.)

Berthollet had previously shown that if a solution of Chlorine in water were exposed to the sun's Light in a flask, provided with a bent tube to collect the gaseous product, oxygen was evolved. (l.) The Chlorine decomposed the water, uniting with the hydrogen to form muriatic acid, and hence the escape of gaseous oxygen. Chlorine and carbonic oxide are not readily brought to combine, even under considerable elevation of temperature, but by exposing the mixture to solar Light the union is effected.

(16.) To solar Light then we must allow a considerable power of Chemical action, but we shall find that the different parts of the solar beam differ greatly in this power. Scheele first remarked that when the solar spectrum was cast upon a piece of paper, impregnated with muriate of silver, it became black much sooner in the violet than in the other coloured rays. (m.) Senebier repeated this experiment, and estimated the comparative powers thus. The same tint produced by the muriate of silver by 15 seconds' exposure to the violet ray, required for its production 23 seconds in the purple ray; 29' in the blue; 37' in the green; 55 minutes in the yellow; 12 minutes in the orange; and full 20 minutes in the red ray. (n.) Sir H. Engle-
field found that the blue ray had a greater power than the other rays in communicating the luminous property to Canton’s Phosphorus. Seebeck found that when a mixture of Chlorine and Hydrogen gases was exposed to the solar Light, under a red glass, the combination took place but slowly, but that under a blue glass the union was instantaneous; with several other similar facts. (p.)

(17.) The existence of calorific rays beyond the extreme limit of the visible red ray of the spectrum, suggested the possibility of a similar set of Chemical rays beyond the opposite, the violet end. This inquiry seems to have been pursued by Dr. Wollaston and M. Ritter simultaneously. They both found that there was a set of Chemical rays of greater refrangibility than those of Light and of Heat. Ritter came fully to the conclusion that, besides the visible rays of the spectrum, there were two other sets of invisible rays: one of which being less refrangible than any of the luminous rays, was found beyond the red end of the spectrum, having a greater calorific power than the colorific rays, and tending also to promote oxidation: the other set of invisible rays being more refrangible than the colorific rays, was found beyond the violet end of the spectrum, being inferior to the colorific rays in heating power, and tending to the separation of oxygen from its combinations. (p.) Dr. Wollaston made use of muriate of silver also, and arrived at a similar conclusion. He employed also guaiacum, which changes from a yellow to a green colour by exposure to Light; and this, from the absorption of oxygen, as is proved by the process succeeding better when the gum is placed in oxygen gas. There was, however, this peculiarity, that the change was promoted at the violet end of the spectrum, while in the red extremity the yellow colour might be restored. This fact, then, is hostile to the universality of Ritter’s law. (q.) Berard amply confirmed these experiments; he divided the spectrum into two portions, and then concentrated the rays of each portion with a lens. The part from the red to the green produced a brilliant Light, but the muriate of silver remained in it for more than two hours quite unaltered. The part from the green to the violet inclusive did not by its concentration produce a very vivid Light, but blackened the silver in less than ten minutes. Hence we learn that the deoxidating power of the rays decreases very rapidly in passing from the violet to the red end of the spectrum. (r.)

(18.) It would appear, also, that there is an analogous difference in the Chemical action of artificial Light produced from different sources; for Mr. Brande has stated that the Light produced by the combustion of oil gas, coal gas, or olefiant gas, even when concentrated so as to produce a considerable degree of Heat, effects no change on the muriate of silver, nor yet on a mixture of Chlorine and Hydrogen; but that the Light from charcoal, ignited by the voltaic battery, speedily colours the muriate and unites the gases. He could obtain no Chemical action from the Light of the moon. (s.)

Some other experiments of Ritter in the paper formerly mentioned are very curious, and the report of MM. Berthollet and Biot, upon Berard’s experiments, is well worthy of examination. (t.)

(19.) Some experiments of M. Chaptal tend to prove that the process of crystallization is influenced by the presence of Light. He found that when a number of capillary crystals were shooting up the sides of a vessel containing a saline solution, the effect took place only on that side of the vessel that was illuminated. He was thus able to cause the crystals to form on any one side, and by placing a screen against the vessel the line between Light and darkness was distinctly marked by the limit of the crystallization. This phenomenon was most easily observed in metallic salts. (u.)

(20.) "The operation of Bleaching affords another Bleaching example of the Chemical changes which Light is capable of producing. Colour in insect is taken away, and this depends equally on the transfer of oxygen, the colouring matter of the thread receiving that principle probably from the decomposition of the water with which the substance to be bleached must be supplied. This formed the old method of bleaching; and the substitution of the Chlorine in the new mode, establishes this theory of the changes of which the operation consists.

"Even the processes of animated nature are influenced by the Chemical agency of Light. Organization, sensation, spontaneous motion, and all the operations of life (says Lavoisier) exist only at the surface of the earth, and in places exposed to the influence of Light; and without it nature itself would be inanimate. Hooke, it seems, was the first to apply the principle of Light and of Heat to the adaptation of plants to particular climates. Those which grow under a clear sky, and an intense solar light, are in general more pungent, odorous, and aromatic, than those which are placed under the opposite circumstances; and plants which are the natives of a warm climate will not grow or produce their fruit in situations where they are less exposed to its genial influence. The artificial exclusion of Light from vegetables, giving rise to the process named Etiolation or Blanching, affords another proof of its action on vegetation. The plant always extends its branches towards any opening at which light may enter; and if this be closed, and another opened in a different situation, it changes the direction in which it was shooting, and still turns towards the Light; and in this way, as M. L’Abbé Tessier has shown, plants may be made to grow in any direction. If kept in perfect darkness, they become feeble, succulent, insipid, and of a white or yellowish colour, while, if transferred to a situation where they enjoy the solar rays, they regain their green colour, and become vigorous. These changes from the exclusion of Light appear to be owing to the accumulation of oxygen in the plant, as, under its influence, this principle is disengaged from their leaves, derived probably from the decomposition of water, and perhaps of other compounds subservient to vegetable nutrition. According to the experiments of Tessier and Decamale, the Light emitted by a lamp gives even a green colour to the leaves, though less deep than that from the light of day. The Light of the moon has a similar effect. (v.)

(21.) "Nor are animals exempt from the influence of this important agent. Deprived of it they suffer nearly the same changes as vegetables do, and the darkness of their colour is in general greater according to the intensity of the Light to which they are habitually exposed. Insects which live underground are usually of a light shade; the animals of the Arctic regions are almost all pale or white, while those belonging to the tropical countries are distinguished by the variety and brilliancy of their hues. Even in Man we trace a gradation of colour proportioned nearly to the climate in which he resides." (w.)
§ 3. Chemical Agency of Electricity.

Electricity. (22.) According to the Principles already proposed, this Section will be devoted to an account of the Chemical effects of Electricity; including those which are produced by the application of the Voltaic Pile, as well as those which proceed from the common Electrical Machine. That these two instruments only produce different modifications of the same great Physical Agent we have already explained; and therefore for the future, when we speak of the Electrical agency by which any Chemical change is to be effected, we would be understood to refer to an operation producible either by ordinary, or by Galvanic Electricity, though much difference may exist as to the actual fitness of these respective modifications of Physical force, with reference to the purpose intended.

Electricity existed for many years as a Science, previous to the discovery of its intimate relations to Chemical Affinity, and this discovery did not take place until Voltaic Electricity had become known to the Philosophers of the present Century. Galvani's discovery of what he termed Animal Electricity, which was in fact the Electricity of the contact of dissimilar Elements, took place accidentally in 1791. It was succeeded by about ten years of active research made by the Philosophers of all Europe; but as the great problem which they investigated with so much zeal, was the necessary conditions of the probable theory of muscular contraction produced by this species of Electricity, no immediate profit accrued to Chemical Science. At length, in 1800, Volta, by a fair system of reasoning upon the effects of Metallic contacts, was led to construct the Pile. His end was fully answered when he had obtained a series of most interesting Electrical effects highly important to the Theory which he was labouring to establish. The history of this discovery was communicated to Sir Joseph Banks, who laid the letter before Messrs. Nicholson and Carlisle. (a.) By these gentlemen the experiments of Volta were repeated and verified: they discovered the positive and negative Electricities of the opposite ends of the Pile; and accidentally stumbled upon the great discovery of the first Chemical decomposition effected by Electricity. They had formed a part of their circuit by water, and observing small bubbles of gas to be disengaged, apparently from the wires in the water, they found that this gas had the smell of Hydrogen. The important remark was not lost upon these experimentalists, who, pursuing the research, fully demonstrated the decomposing power of the Pile. They found that at one wire Hydrogen Gas was evolved, while the other wire became oxidated; and by employing wires of Platinum they obtained Oxygen and Hydrogen Gases from the two wires respectively, and in such proportions as to form water. Such was the origin of the most important series of discoveries. (b.)

Mr. Cruickshanks, an eminent Surgeon at Woolwich, immediately verified these discoveries, and added to them that of the reduction of metals from their solutions, and the decomposition of the Neutral Salts. Cruickshanks also invented the Trough. Dr. Henry of Manchester decomposed the Nitric and Sulphuric Acids; and also resolved Ammonia into its Elementary Constituents. At length Sir H. Davy commenced that splendid series of researches which have tended more than those of any other individual to explain the Electrochemical relations of the molecules of bodies; and have not been surpassed in acuteness of investigation, or brilliancy of result, by those of any individual that ever lived, if we except the sublime discoveries of the great author of the Principia. It were unjust not also to mention the valuable contemporary researches made in Paris by Humboldt, Gay Lussac, and Thenard; though we do not enter upon any minute historical description of them in this place, but refer our readers to the Treatise on Galvanism.

(23.) For the best proofs of the identity of ordinary and Galvanic Electricity we are mainly indebted to Dr. Wollaston. The question has been long agitated; and perhaps to some, may not even yet appear to have been satisfactorily decided. The sensation produced upon the human frame is substantially the same, whether from the Leyden Jar, or from the excited Voltaic Pile. The rapidity of communication is the same in both cases. The conducting powers of all bodies are identical to both fluids. The spark is in both cases visible when the discharge takes place through a thin stratum of air. The Pile in activity will charge a Leyden Jar either positively or negatively, according to the Pole with which the connection may be established. The Electrometer serves as a measure of Tension for both instruments. And the Chemical changes which may be produced by developing the Polarities of elementary or constituent molecules of bodies, are the same in kind, whichever agent be employed. (c.)

(24.) Before we proceed to the actual Chemical agencies of the Pile it may be well to mention those combinations which are best adapted to the purposes intended. This we say with reference chiefly to selection, for as the actual construction of Galvanic Apparatus more properly belongs to the general Treatise on that subject, to it we refer our readers.

(25.) The simple Galvanic circle consists of three more or less perfect conducting substances. It may be formed either of two perfect conductors and one imperfect conductor; or of two imperfect conductors with one perfect conductor. These terms were introduced by Sir H. Davy, in whose Work various arrangements of both sorts may be found (d.) But as the
effects produced by any simple Galvanic Circuit are feebly; especially with reference to Chemical action, it is usual to form compound Galvanic Circuits or Batteries. These consist simply of the reiteration of a number of simple alternations. The metals and the liquids are arranged in various forms, as Troughs, Piles, or Spirals. In practice Copper and Zinc are the metals usually employed; producing a combination of great energy at the least expense.

(26.) For igniting or fusing Metallic wires, or in other words, for producing great Heat by generating a very considerable quantity of Electricity, in a short time, so as to produce Heat in its passage through a conductor comparatively perfect, plates of large surface are required. But for producing Chemical Decomposition large plates are not necessary: the number of the plates is, however, of essential importance; they may be small, but they must be numerous. The Couronne de Tasses of Volta is an excellent arrangement for Chemical purposes: but on the whole the Battery we can most strongly recommend, should consist of plates from four to six inches square, arranged after Dr. Wollaston's plan in Wedgwood Troughs.

(27.) Though water and saline solutions are sufficient to excite the Chemical action of a Battery, yet weak acid liquids are most efficacious. For Chemical purposes the acid may be used in a highly dilute state: Mr. Singer, who made many experiments on this subject, recommends one part of Sulphuric Acid with two or three of Nitric Acid, and from forty to sixty parts of water, as an efficacious and enduring charge.

Where long-continued action is required, without great intensity, a solution of common salt, with the addition of a little Muriaetic Acid, forms an economical and sufficient charge. Those effects which are purely Electrical are best developed by a charge consisting of a weak saline solution; or even of spring water only.

(28.) We now arrive at that which is the legitimate object of this Section; viz. the Chemical action of the Pile. If any compound body, which is itself a conductor, or which can be made even partially so, be placed between two wires connected with the Poles of the Battery, so that the substance itself shall form a part of the Circuit, the Elementary molecules of that body will undergo certain changes in their forces of Polarity, and in many cases to such an extent as to overcome the Affinity which formerly bound them together in Chemical combination.

For example, let two Platinum wires from the opposite Poles of the Battery be placed at any distance from each other in the same vessel of water; bubbles of Gas will be disengaged at the extremities of each wire: the quantity issuing from that part of the water in contact with the wire proceeding from the Negative Pole of the Battery is, in volume, double of that issuing from the other wire which constitutes the Positive Pole: and if these gases be collected, as they easily may by inverting test tubes filled with water over them, the former is found to be Hydrogen; the latter Oxygen Gas. Now these are known to be the just constituents of water, and if the gases be again mixed and exploded by the Electric spark, water is reproduced without any residuary matter.

If the wire forming the Positive Pole be of copper, or any oxidable metal, the oxygen never assumes the gaseous form, but unites with the metal so as to produce a metallic oxide.

If in a similar manner the wires be introduced into a strong solution of Sulphuric or Phosphoric Acid, Oxygen Gas will rise from the Positive Pole and the inflammable Element will collect round the wire connected with the negative Pole.

(29.) The following is found to be the general Law of these decompositions, viz. that the non-metallic bodies, sometimes thence called Electronegative, Oxygen, Chlorine, Fluorine, Iodine, and Bromine, with all Acids, are found at the Positive Pole of the Voltaic Circuit, while the Electropositive non-metallic Bodies, (combustibles of some writers,) the Metals, Alkalies, Earths and Oxides, in short all bases, tend to the Negative Pole or surface.

(30.) The following singular extensions of these properties were discovered by Sir H. Davy in 1806 and 1807.

If the Polar Wires do not dip into the same mass of water, but into separate vessels of that fluid, having a connecting metallic wire between them, the decomposition still takes place.

If the wires be introduced into a strong solution of Sulphuric Acid, a weak solution of Phosphoric Acid, a solution of common Salt, with the addition of a little Muriatic Acid, forms an economical conductor comparatively perfect, plates of large surface are required; but on the whole the Battery we can most strongly recommend, should consist of plates from four to six inches square, arranged after Dr. Wollaston's plan in Wedgwood Troughs.

(27.) Though water and saline solutions are sufficient to excite the Chemical action of a Battery, yet weak acid liquids are most efficacious. For Chemical purposes the acid may be used in a highly dilute state: Mr. Singer, who made many experiments on this subject, recommends one part of Sulphuric Acid with two or three of Nitric Acid, and from forty to sixty parts of water, as an efficacious and enduring charge.

Where long-continued action is required, without great intensity, a solution of common salt, with the addition of a little Muriaetic Acid, forms an economical and sufficient charge. Those effects which are purely Electrical are best developed by a charge consisting of a weak saline solution; or even of spring water only.

(28.) We now arrive at that which is the legitimate object of this Section; viz. the Chemical action of the Pile. If any compound body, which is itself a conductor, or which can be made even partially so, be placed between two wires connected with the Poles of the Battery, so that the substance itself shall form a part of the Circuit, the Elementary molecules of that body will undergo certain changes in their forces of Polarity, and in many cases to such an extent as to overcome the Affinity which formerly bound them together in Chemical combination.

For example, let two Platinum wires from the opposite Poles of the Battery be placed at any distance from each other in the same vessel of water; bubbles of Gas will be disengaged at the extremities of each wire: the quantity issuing from that part of the water in contact with the wire proceeding from the Negative Pole of the Battery is, in volume, double of that issuing from the other wire which constitutes the Positive Pole: and if these gases be collected, as they easily may by inverting test tubes filled with water over them, the former is found to be Hydrogen; the latter Oxygen Gas. Now these are known to be the just constituents of water, and if the gases be again mixed and exploded by the Electric spark, water is reproduced without any residuary matter.

If the wire forming the Positive Pole be of copper, or any oxidable metal, the oxygen never assumes the gaseous form, but unites with the metal so as to produce a metallic oxide.

If in a similar manner the wires be introduced into a strong solution of Sulphuric or Phosphoric Acid, Oxygen Gas will rise from the Positive Pole and the inflammable Element will collect round the wire connected with the negative Pole.

(29.) The following is found to be the general Law of these decompositions, viz. that the non-metallic bodies, sometimes thence called Electronegative, Oxygen, Chlorine, Fluorine, Iodine, and Bromine, with all Acids, are found at the Positive Pole of the Voltaic Circuit, while the Electropositive non-metallic Bodies, (combustibles of some writers,) the Metals, Alkalies, Earths and Oxides, in short all bases, tend to the Negative Pole or surface.

(30.) The following singular extensions of these properties were discovered by Sir H. Davy in 1806 and 1807.

If the Polar Wires do not dip into the same mass of water, but into separate vessels of that fluid, having a connecting metallic wire between them, the decomposition still takes place: Hydrogen Gas is evolved from the one wire, and Oxygen from the other. The same takes place if the connection between the two vessels of water be made by moist fibres of Cotton, Ammianthus, or any other conducting substance.

To understand these interesting experiments of Sir H. Davy; suppose two Agate cups marked P and N to denote the Poles of the Battery with which they were connected; Positive and Negative respectively. Sulphate of Potash, or Soda, was placed in N and distilled water in P; the connection between the two cups was established by moist fibres of Ammianthus. The Acid passed over to the cup P, and the solution in the cup N, which was at first neutral, became alkaline. A converse experiment was made by placing the saline solution in P, and distilled water in N. In this case the water became alkaline, and pure Acid remained in the cup P.

In another experiment when Nitrate of Silver had been placed in the cup P, the Ammianthus leading to the cup N was coated with a film of metallic Silver; thus showing that an actual and substantial passage of the Element took place along the connecting substance.

The same results obtain if a third cup M, containing pure water, be placed between P and N, so as to form a part of the connecting circuit, while the water remains pure, though the Acid and the base have both been transmitted through it.

Again, let the three cups be arranged as before; having Sulphate of Potash in N, a weak solution of Ammonia in M, and pure water in P. In this case, to arrive at the cup P the Sulphuric Acid must pass through a free Alkali for which it has a very strong Affinity; yet in five minutes this was effected with a Battery of one hundred and fifty pairs of four-inch plates. Thus the ordinary forces of Affinity were suspended or overpowered by that of Electrical Polarity.

In the same way, strong Acids were made to pass through strongly alkaline solutions, and alcali through strongly acid liquids, without entering into combination.

It was by reasoning upon these facts, that Sir H. Davy contrived to apply the decomposing power of the Pile to the exhibition of the bases of the alcali and alkaline earths, and thus arrived at a series of results as novel as they were important. (c.)

(31.) Strictly speaking, there can be no Electro-
Burned.
Metals burned.

Chemical action upon a substance that is a nonconductor; and yet some adventitious circumstance may induce a sufficient degree of conducting power to bring the elementary molecules of the substance within the reach of the Electrical action, so that their Polarity may be affected and decomposition produced. For example, glass is a nonconductor, and yet where Electrochemical experiments are made in glass vessels, a slight decomposition of the surface will sometimes be manifested by the setting free of a portion of its alkali. In this case the water or liquid forms the mean of communication for a sufficient Electrical power to the molecules of glass immediately in contact with it.

Among the most usual Galvanic experiments are those in which metallic wires or leaves are either fused or burned by the discharge of a Battery. The metals are all comparatively perfect conductors; but the circumstance of their becoming heated at all by the Electrical discharge, seems to us a proof that they are not strictly so. By a perfect conductor we should understand a body which would instantaneously allow the passage of any quantity of Electricity without reference to the superficial magnitude of the conducting body itself. A perfect conductor in this sense is, however, unknown; the metals which are the best conductors, suffer certain effects, which bear some constant ratio to the quantity of Electricity transmitted, and to the quantity of metallic surface along which it passes. The first and most obvious of these effects, is the development of Caloric. Thus wires are heated, or even fused, by the Voltaic as by the Electric discharge. So far this is only a physical operation; but when the discharge is very powerful, the metals undergo combustion, and are oxidized. Now whether this Oxidation be simply the effect of their Elevation of Temperature in a medium affording Oxygen, so that the same effect in kind and quantity would be produced by an equal intensity of Heat however excited; or whether the Heat evolved during the Electrical Transit be at all more favourable to this Chemical combination, by adding a sort of determining force, no experiments have yet ascertained.

We might, therefore, at present, be justified in regarding the burning of metals by Galvanism, merely as a case of Chemical combustion arising out of the ordinary Physical application of Heat to a combustible body. The most powerful Battery that has ever been constructed for the fusion and combustion of metals, is that of Mr. Children, with which most splendid results were obtained. The description of this instrument and its powers may be seen in the Phil. Trans. (f)

The conditions upon which the ignition or combustion of metallic wires depends, are totally different from those which influence Chemical decompositions. It is generally understood that in the Voltaic Battery the Intensity of the Electricity depends upon the number of plates; and that the Quantity evolved depends upon the superficial magnitude of the plates. Chemical decompositions, as we have already remarked, depend upon Intensity of action, and, therefore, require a great number of plates which may be very small; but the Calorimotive effect upon metals, seems to arise from Quantity; and, therefore, for these last-mentioned purposes, the number of the plates is not so important as the intensity. And as it has been observed above that the Electricity should be evolved with great rapidity, the charge of dilute Acid may be advantageously employed of a greater strength than is required for Chemical purposes. All this is stated as fact deducible from experiment, without reference to any particular Theory of the action of the Battery.

(34.) It is a curious and important inquiry to ascertain the ratio which the number and superficial extent of the plates in a Battery, bear towards the effects of different kinds produced by that Battery. On this subject the following remarks by Sir H. Davy, are important. "MM. Gay Lussac and Thenard have announced that the power of Chemical decomposition increases only as the cube root of the number of plates; but their experiments were made with parts of Piles of a construction very unfavourable for gaining accurate results; and in various trials, made with great care in the Laboratory of the Royal Institution, the results were altogether different. The Batteries employed were parts of the great combination, carefully insulated, and similarly charged; arcs of Zinc and Silver presenting equal surfaces, and arranged in equal glasses filled with the same kind of fluid, were likewise used; and the tubes for collecting the Gases were precisely similar, and filled with the same solution of potassa. In these experiments, ten pairs of plates produced fifteen measures of Gas; twenty pairs in the same time produced forty-nine; again, ten pairs produced five measures; forty pairs, in the same time, produced seventy-eight measures. In experiments made with arcs, and which appeared unexceptionable, four pairs produced one measure of Gas; twelve pairs, in the same time, produced 9.7 of Gas; six pairs produced one measure of Gas; thirty pairs, under like circumstances, produced 24.5 measures; and these quantities are nearly as the squares of the numbers.

"It would appear from the experiments of Van Marum and Paff, confirmed by those of Messrs. Wilkinson, Cuthbertson, and Singer, that the increase of power of Batteries, the plates of which have equal surfaces, is as the number. I found that ten double plates, each having a surface of a hundred square inches, ignited two inches of Platinum in wire of one-eightieth of an inch; twenty plates, five inches; forty plates eleven inches; but the results of experiments on higher numbers were not satisfactory; for one hundred double plates, of thirty-two square inches each, ignited three inches of Platinum wire of one-seventieth, and one thousand only ignited thirteen inches, and the charges of dilute Acid were similar in both cases.

"The power of ignition for equal numbers of plates, seems to increase in a very high ratio with the increase of surface, probably higher than even the square; for twenty double plates, containing each two square feet, did not ignite one-sixteenth as much wire as twenty containing each eight square feet, the acid employed being of the same strength in both cases.

Numerous circumstances are opposed to the accuracy of experiments made with high numbers or very large surfaces; the activity of combinations rapidly diminishes, in consequence of the decomposition of the menstrum used; and this decomposition is much more violent, the greater the number and surface of the alternations; the vapour rising likewise, when the action is intense, interferes by its conducting power, and the Gas by its want of conducting power; and when series containing above five are ignited above these cases it is to be considered, that the insulation is very perfect, there is a considerable loss of Electricity; thus the great Battery of two thousand double plates belonging to the Royal Institution will
Theories.

scarcely act by its true Poles, when arranged on a floor of stone, and requires not merely the insulation of porous wood; and when arranged on a stone floor, it is hardly possible to walk near any of the approaching series without receiving shocks. In cases of the ignition of wire, the cooling influence of the substances in contact, and of that part of the chain not ignited, interferes most when small quantities of wire are employed, and with feeble powers; and hence the effect is at first in a lower, and then in a higher ratio than the number, when the whole range is small, as in the experiments above stated. If there is an imperfect connection in any of the series, a great diminution of power is the consequence. If one plate is corroded or covered with more oxide than the rest, there is a general loss of effect. If copper is substituted for Zinc, or Zinc for Copper, in a single series the result is similar; and I find that a Platinum wire, introduced in the place of an arc of Silver and Zinc, in a series of thirty, diminished its power of producing Gas so much, that it was equal only to that of four."

Theories.

(35) To examine the different Theories which have been proposed in order to account for the origin of those Phenomena which are termed Galvanic or Voltaic, falls not strictly within the scope of this Treatise. It may, however, be necessary for us to state in what manner it seems connected with Chemical Affinity, especially as some have supposed all Chemical Affinities to spring from Electrical action; whilst others, on the contrary, have asserted that all Electrical Phenomena are essentially accompanied by Chemical changes, thus referring those Phenomena to the mutations which take place among the Elementary molecules of Bodies. Whether the Electrical Polarities of the molecules of matter be or be not the cause of Chemical Affinity, is a question which the Chemist is deeply interested in resolving.

Volta, who laboured assiduously and successfully in this field, supposed that Electricity was developed solely by the contact of dissimilar metals. The fluid with which the Pile is charged, he regarded only in the light of a conductor. It seems true that the mere contact of two metals is sufficient for the evolution of Electricity; for if a plate of Copper and a plate of Zinc be made to touch each other, both being affixed to insulating handles, the Copper, after their separation, is found charged with resinous, and the Zinc with vitreous Electricity. The same, however, has been recently found to take place with two discs of the same metal when they are of different temperatures before their contact. In these cases no Chemical change is apparent; though it is possible, and even probable, that some oxidation may take place to a slight extent. In this Theory of Volta all the Chemical changes which manifestly attend the Electrical action, are, as causes, disregarded.

Dr. Wollaston became the most direct opponent of the views of Volta, and in an admirable Memoir, published in the Philosophical Transactions for 1801, he advanced numerous arguments in support of a contrary explanation of the case. The substance of Dr. Wollaston's Theory consists in supposing the Chemical change to be the primary action; as, for instance, the oxidation of the Zinc, where plates of Zinc and Copper are employed; and that the development of Electricity is a consequence resulting from thence.

The Theory of Sir H. Davy, which is now more generally received, acknowledges both sorts of action already noticed. It admits the disturbance of the natural Electricities upon the contact and subsequent separation of dissimilar bodies, and does not consider that a Chemical change is essential to the commencement of Electrical action. But it was proved by experiment, that for the continuance and accumulation of Electrical action, Chemical changes in the Elements of the Pile are indispensable. Sir H. Davy traces this mixed operation by supposing that by the contact of the Zinc and Copper plates in the Pile, all the former become Positive, and all the latter Negative; that by means of the conducting fluid interposed, all the vitreous Electricity is enabled to accumulate at one end of the Pile, and all the resinous fluid at the other. Such is the primary and momentary action; but to produce a repetition of these effects, so as to promote the continuance action of the Pile, he considers the Chemical change as perpetually tending to restore the Electric equilibrium that has been thus disturbed. This takes place by the Electronegative Elements, Oxygen, Acids, &c. passing to the Zinc plate, while the Electropositive Elements, the Bases, Hydrogen, &c. go to the Copper surface, restoring, momentarily, the Electric equilibrium in both cases, and thus preparing the metals for a new effort of the Electromotive force. On these points consult references (k).

(36) Whatever Theory be adopted with regard to the primary development of Electrical Action in the Pile, it becomes a matter of convenience to form some system which may unite in one view the effects as such; in order that we may employ it as a practical assistant in submitting bodies to Voltaic Electricity as a Chemical Agent. For this end it is quite immaterial which of the Theories already mentioned be admitted. In fact, the explanation which we are about to recite is to be considered not as an assertion of the actual laws which govern the molecular Affinities of substances, but only as a convenient mode of representation, a sort of illustration; it may be the true one in its most strict sense, or it may not; but in either case we may safely employ it as a law by which to regulate the methods, and foretell the results of our experiments.

Of such explanations the most clear was given by Grothus, and first published in Italy. We subjoin the substance of it, as given in M. Thenard's Work, though it is almost verbatim the same with that of the original author as republished in the Annales de Chimie, (k.) because it gains an additional authority from having passed through the hands of that able Systematist. (k.)

If we place between the two Polar wires of a Pile in activity, any substance which is capable of undergoing decomposition by that Pile, immediately all the Elementary molecules in each compound atom placed between the Positive and Negative Poles, undergo Polarization; that is to say, their natural Electric fluid is decomposed, and some of the Elementary molecules becoming Positive, tend towards the Negative Pole; while others becoming Negative, tend towards the Positive Pole. Suppose there to be only five compound Atoms between the two Poles, and that each Atom should be composed of two Elementary molecules; let A represent the Positive molecule and B the Negative molecule in the first Compound Atom, and A' be the Positive molecule, and B' the Negative molecule in the second Compound Atom, and so on: the arrangement which will then result is shown in the following diagram:

(37.) The agencies of Magnetic influence in aiding or in impeding Chemical Affinities have as yet been recognised to only a very slight extent. And yet these two species of action are not quite independent of each other; some substances are sensible of Magnetic power, others not so. Among the metals some are capable of permanent Magnetism, others are only capable of a temporary Magnetic state induced by Electricity. Iron when present even in a small proportion renders the mass containing it attractive by the Magnet. The same property is continued to it even in its lowest degree of oxidation, but in the higher stages of oxidation it loses this property. Pure metallic Nickel, Cobalt, Manganese, and Chromium, are all attracted by the Magnet. But with these a small admixture of Arsenic is fatal to the property.

(38.) The permanency of Magnetism is also sometimes greatly affected by the Chemical constitution of the body; thus, pure soft Iron soon loses any Magnetic power that may be communicated to it: but the presence of that small proportion of carbon which converts Iron into Steel, renders it capable of retaining permanent Magnetism even for many years.

(39.) Berzelius relates (m.) that Hansteen and Maschmann placed a solution of Silver in a Syphon-shaped tube that the Silver might be reduced by Metallic Mercury; and that they always found that when the two legs of the tube stood in the Magnetic meridian, the Silver was reduced, but as soon as a Magnet was placed near it the reduction commenced. He also found the reduction most considerable at the North Pole of the wire, which is in accord with the experiments of Hansteen and Maschmann.

10. Lüdecke placed over the two Poles of a horse-shoe Magnet a glass vessel containing saline solutions of such concentration as to crystallize in a few hours' time. He employed Acetate of Lead, Muriate of Ammonia, or Proto-Sulphate of Iron. When crystallization had taken place, it appeared that there was a clear round space left vacant between the two Poles where the Magnetic force was strongest; though the rest of

Part H.

its conducting power is much increased, we may perceive the methods pointed out in our Treatise on Galvanism.

...
CHAPTER I.—General Physical Properties of Ponderable Matter.

(41.) The Properties of Matter which we profess to examine in this Treatise are those that are strictly Chemical. But it must not thence be inferred that we have no business with the Physical Properties of bodies, for several of those marks by which a Chemist distinguishes one substance from another are, strictly speaking, Physical Properties. Such as Hardness, Specific Gravity, Elasticity, Colour, &c. To investigate all these fully is a part of the province of General Physics, and several of these properties form the basis of all Mechanical Science. In this preliminary introduction we shall as briefly as possible mention those Properties which are essential to the understanding of future Sections, entering at the same time rather more fully upon such details as form a portion of the operations of practical Chemistry.

(42.) Magnitude is a Property belonging to all substances, and need not be made more intelligible by verbal definitions: let it only be remembered that it refers to space alone. Magnitude may be Linear, Superficial, or Solid; in which latter case it is usually spoken of under the term Volume. Divisibility is a Property of Matter having reference to Magnitude. Mathematically speaking, Matter is divisible ad infinitum, but the practical or mechanical divisibility of Matter is limited by our powers of handling or viewing minute objects. Hence it is that the Chemical divisibility of Matter greatly exceeds that which can be effected mechanically: for by dissolving a solid substance in any appropriate menstruum we may very greatly dilute the solution, and still be able to prove by reagents that every portion of the solution, however minute, contains also some portion of the original Solid. The limit to this also seems to be fixed by the powers of our organs of vision, &c. But in this case the extreme minuteness of that portion of solid matter which has been separated from the original mass, and thus indirectly again recognised, almost surpasses our conception.

That Property of Matter about which much has been written under the name of Impenetrability of parts, is, in fact, the same thing as the Property of being touched and felt, by which we are convinced of the existence of substances. Generally speaking, two substances cannot exist in the same space, and this is all that is meant by the property of Impenetrability; but the existence of the Property itself, speaking with mathematical rigour of Matter in its natural state, seems to be at least doubtful. It is supposed that no substance is absolutely solid, and the experiments with metallic alloys, in which great condensation frequently takes place, as well as the solution of solid masses of metals or salts in liquid menstrua, without proportionally adding to the volume of the mass, goes far to support the mathematical view of the case. Impenetrability exists if we speak of any one given substance only, and it must exist with reference to all Matter if we possessed it in an absolutely solid state; but as this is never the case, we cannot assert it of all heterogeneous bodies with reference to each other.

It would appear that all substances are Compressible; some to a great extent, as the Aeriform Fluids; some scarcely at all, as the Liquids and Solids.

Elasticity is also a term of frequent occurrence among the Physical Properties of bodies: it is defined to be that Property by which bodies that undergo compression return to their former state upon the removal of that pressure. It has not been so done, but some limitation ought to be made, as to the manner in which...
State of Aggregation.

(43.) The State of Aggregation in which all bodies exist, is either Solid, Liquid, or Aeriform: the two latter are both comprised under the general term Fluid. As these states are Physically different, so are the effects produced upon them by the operations of various Physical agents.

Solids may be defined to be those substances the integral molecules of which adhere together with such tenacity, that between them no relative motion nor separation takes place without the operation of some considerable extrinsic force impressed. The extreme measure of this intrinsic adhesion is the limit which is sufficient for the substance's preserving its solid form when left to itself, be that form what it may.

Fluids, on the contrary, have so slight a cohesive force existing between their particles that they easily move relatively to each other, and cannot, if left to themselves, preserve any form, but are contained in vessels formed of solid matter for their support.

It is obvious that these two states, the Solid and the Fluid, may pass gradually into each other; and the freedom of motion among the particles is the limit at which the solid state ends and the fluid one commences. For example, if a mass of Lead be taken, it is at first a solid, but, if it be sufficiently heated, the particles acquire the power of moving among themselves with such facility upon the impression of any slight force, that the fluid state commences and the Lead becomes a liquid.

The aeriform substances agree in all the Properties hitherto attributed to liquids: they are strictly fluid, and enjoy this property in a higher degree than the Liquids; but they possess also this remarkable one in addition; viz. that their molecules are repulsive of each other, to any extent at which they have hitherto been tried. The aeriform fluids require to be confined in vessels of solid matter; but whatever be the magnitude of the vessel, the idiorepulsive forces of the molecules enable them to extend themselves equally throughout all the space contained within the vessel.

(44.) We are able, by various means, to make many substances pass through each of these states, the Solid, the Liquid, and the Fluid, in succession. Thus Ice, by the application of Heat, passes from the solid to the fluid state, and by an increased action of the same Physical agent, the water passes to the aeriform state, becoming Steam. Reasoning upon Analogy we may conclude that all substances in Nature are capable of existing in each of these three forms, but there are few substances in which our means are sufficiently powerful for us so to exhibit. Some Solids we are unable to fuse, that is, to reduce to the form of Liquids; but as the means of producing intense Heat have been increased, this number has been gradually diminished. Many of these, however, our means do not enable us to volatile, though we have just reason for supposing that the defect lies in our powers, and not in the natural capacities of the bodies.

Heat is the principal Physical Agent by which these changes are effected, but it is not the only one, for Chemical Affinity can produce an analogous operation. Thus when two substances, existing in different mechanical states, combine together, the resulting body is of the one state or the other; in which case one of the two yields up its original condition, the laws which regulate the existence of the other substance. For example, Silica, which in its pure state is a solid, unites with Fluoric Acid, and becomes an invisible constituent part of a Gas; a term given by Van Helmont to aeriform fluids and still much employed by Chemists to designate all such that are not vapours, Atmospheric Air excepted. Oxygen Gas unites with Metals, and thus becomes a Solid. In other cases both substances change their condition; thus Oxygen Gas and Hydrogen Gas unite, and form the Liquid, Water; Ammoniacal Gas and Muriatic Acid Gas unite to form a solid substance, the Muriate of Ammonia.

(45.) It has been supposed by many Philosophers, that the state of aggregation of bodies depends upon the resultant of two opposite forces, the one an attractive one, inherent in the molecules of matter, the other a repulsive one, due to the operation of combined caloric. And, further, that a body is solid when the attractive force surpasses the repulsive one, liquid when both are in equilibrium, and aeriform when the repulsive one is the more powerful of the two.

(46.) We find in all bodies a tendency to fall to the ground, or, in fact, towards the centre of the Earth; the measure of this tendency, or force, is called the Weight of the body. In various masses taken from the same substance, the Weight is in direct proportion to the volume of the body. But as it is obvious to all, that in masses taken from different substances, the Weight of a given volume of one differs greatly from the Weight of an equal volume of another, it is convenient to have some mode of expressing this difference.

For this purpose let it be supposed, that we had a Table exhibiting the Weights of some given volume of all substances known; and, further, let the number expressing the Weight of any one of these be made the unit of the scale; then calling this one, and reducing all the other numbers, so that they bear the same proportion to unity, which their true Weights for the given volume bear to the true Weight of the given volume of the substance adopted for the standard, we arrive at what is called the Table of Specific Gravity: that is to say, a Table of the proportionate tendencies of substances to the Earth without reference to their quantity or magnitude. Solid Bodies and Liquids are usually referred to water as the unit of their Specific Gravity, but to this subject we shall return hereafter.

(47.) It must be obvious that, as this tendency of bodies to the Centre of the Earth is a part of the universal law of Attraction, the Weight of a given mass of any substance must change if estimated at different distances from the centre of force. Thus in consequence of the spheroidal figure of the Earth, bodies weigh less at the Equator than they do at the Poles;
and of course less on the summits of high mountains
than in the plains below.

(48.) In matters of great delicacy when Solids are
concerned, and in all cases when aeriiform matter is
in question, the Specific Gravities of bodies are supposed
to be taken in vacuo; and at some given temperature;
as, otherwise, the dilatations or contractions produced
by Heat would greatly interfere with uniformity of result.

Proceeding upon these principles; if W be the
Weight of any mass of matter, S its Specific Gravity,
g the force of Gravity at the latitude in which the expe-
riments are made, and W' the Weight of an equal
volume of water, at the standard temperature which in
England is usually taken at 60° Fahrenheit, or some-
times 62° Fahrenheit,

\[ W = g W' S. \]

Here it is to be remarked, that W, W', S, and g, are
not absolute quantities, but abstract numbers, each
referring to some assumed unit.

In France, it is usual to adopt for the standard Tem-
perature that at which water has its maximum density;
and from the constitution of the French System of
Weights and Measures, the Gramme Weight consists of
one cubic Centimetre of Distilled Water at that tem-
perature. If therefore V be the number of cubic Centi-
mètres in the mass, V is also the Weight in grammes
of the volume of water equal to that of the sub-
stance. And V S becomes the actual Weight of the
same volume of any other substance whose Specific
Gravity is S.

Should it be required to find the value of W' for any
given volume of water; W' = 252,458 V Troy Grains;
Thermometer 62° Fahrenheit; Barometer 30 inches;
where V refers to English Cubic Inches: because at
that Temperature and Pressure, one Cubic Inch of Dis-
tilled Water weighs 252,458 Troy Grains, according to
the latest examination.

(49.) The following General Theorems are of con-
stant service to the practical Chemist.

Let W be Weight, V Volume, and S Specific Gra-
phy.

Then, generally,

\[ W \propto V S, \]
\[ S \propto \frac{W}{V}, \quad \text{and} \quad V \propto \frac{W}{S}. \]

Let there be two substances mixed, or combined,
providing only that no condensation take place.

Let W_a, W_b, and W, be the Weights of the mixture,
the denser, and the lighter bodies respectively.

Also let S_a, S_b, and S, be their Specific Gravities
respectively.

And V_a, V_b, and V, their volumes respectively.

(50.) Then \[ S = \frac{W_a + W_b}{V_a + V_b}. \]

(51.) Or \[ S = \frac{W_a + W_b}{W_a S_a + W_b S_b} \quad S_a S_b, \]

which is the usual formula, but in practice it is more
conveniently represented thus

\[ S = \left( \frac{W_a + W_b}{S_a + S_b} \right). \]

(52.) Also \[ V_a = \frac{S_a}{S_a - S_b} \cdot V_b. \]

(53.) And \[ V_a = \frac{S_a}{S_a - S_b} \cdot V_b. \]

(54.) Also \[ S = \frac{V_a V_b}{V_a - V_b}. \]

(55.) And \[ S = \frac{V_a V_b - S_a V_b}{V_a - V_b}. \]

(56.) If these formula be applied to the case of
Atmospheric Air, S_a becomes = 1, because in all ques-
tions relating to aeriiform bodies, the Specific Gravity
of Atmospheric Air is made the unit of the scale to
which S_a and S_b are referred. From all the above for-
mula g has disappeared, because it is usual to consider
the force of Gravity unity.

(57.) These things being premised, we need only
General

advert to one other Property of Matter which also is from Heat,
general in its effects, or operations. It is this, that
whether matter exist in the solid, the liquid, or the
gaseous form, it dilates by the application of Heat,
and contracts when Caloric is abstracted. By this pro-
PERTY the Solids are least affected, the Liquids rather
more so, and the aeriiform substances possess this Pro-
PERTY to a very great extent. From their Physical con-
stitution it is obvious that this must be the case; for
since the molecules of all Gases and vapours are in so
active a state of mutual repulsion, that their volume at
time depends upon the pressure to which they are
subject, if we suppose an equilibrium between that
pressure and the elastic force of the Gas, any accession
of Caloric, which, as is well known, increases the re-
pulsive force, will enable the aeriiform Fluid to expand
itself, and to occupy a larger volume.

The case of water, which has its maximum density at
40° Fahrenheit, and of those metals which expand
during the act of solidification, does not justly form an
exception, for all these effects are dependant upon a
new arrangement of the molecules which takes place
during the process of crystallization.

(58.) It may be convenient to note the general for-
General

mula for the expansions of all bodies by accessions of
formula.

Let V be the volume at any temperature t; and V'
be the volume at temperature t'; where t and t' are
counted from the point of melting ice. Also let K be the
true cubic dilatation for each unit of volume, (in terms of V)
and for each degree of the thermometer to which t
refers.

Thus, generally, \( (\text{HEAT, 35.}) V'' = V \left( 1 + K t'' \right) \)
\( \left( 1 + K t' \right), \]

which formula applies to Solids, Liquids, or Gases.

(59.) But since in some Tables of dilatations the linear
dilatations only are given, let this = k, then in this case,

\[ V'' = V \cdot \frac{1 + 3 k t'' + 3 k t'^{1/2} + k t'^{3/2}}{1 + 3 k t' + 3 k t^{1/2} + k t^{3/2}}. \]

(60.) And it has been shown (HEAT, 35.) that in
Solids where at a distance from their fusing points the
dilatation is very small, we may make \( K = 3 k, \) and
employ the formula in Art. (56.) or as a still more
simple, though less rigorous, expression, we may use this

\[ V'' = V \left\{ 1 + K (t'' - t') \right\}. \]
CHEMISTRY.

Properties that belong to Solids exclusively.

(61.) There are several of the Physical properties of Solid Bodies, which, though not strictly Chemical, afford valuable assistance to the Chemist: such are Britteness, a property too well known to need description: Ductility, or the power of being drawn out into wires; Malleability, the capacity for being beaten out into thin Laminæ. Gold is the most malleable of metals, and it is also extremely ductile, but these properties only uniformly accompany each other, for Iron is tolerably ductile, but malleable only to a very slight extent. Tenacity depends upon the cohesive force with which the molecules of a solid adhere together. Many experiments have been made on this subject chiefly referring to the metals. Their Tenacity has been estimated, by ascertaining what is the utmost weight that a wire of given diameter will be able to sustain without being broken. The Hardness of Solids differs greatly, and is frequently used as a test, especially in Mineralogical researches. The Fusibility of those Solids that we are able to melt by heat differs considerably, Vide Treatise on Heat, Art. (65.) and Table IV. Appendix. The Volatility of substances frequently serves as an auxiliary property for separating one substance from another in Chemical Processes, as this property differs in extent for different substances. The Compressibility of Solids exists, though it is scarcely used as a mark of recognition: for the Specific Gravity of metals is increased by their being hammered. Elasticity and Sonorousness are other existing Properties that need only to be named. The Texture of Solids, or the mode in which their Elementary Molecules are united to each other, is a subject of great intricacy, but is one which at times falls under the Chemist's examination; as, for instance, in the experiments made by Messrs. Stodart and Faraday upon the metallic alloys, by submitting them to the action of dilute acids. The Structure of Solids refers more particularly to Crystalline Bodies, and may be described as that species of texture which results from the aggregation of the variously formed Integrand molecules of the Crystal. Crystalline Form is also an important feature in the description of many Solids, such as the Metals, Salts, and native Minerals, but its study forms an independent branch of Mathematical Science. The Specific Gravity is, of all others, that property which affords the readiest, and frequently the most decisive, Physical indication of the nature of a solid substance.

(62.) From the explanation already given of the nature of Specific Gravity, Art. (46.) the rationale of the means employed for ascertaining the Specific Gravity of Solid Bodies will be very apparent. The substance is first weighed in air, and then in water. The apparent loss of weight by the latter process is equal to the weight of the volume of water displaced by the presence of the solid.

Let \( W_a \) be the weight in air, and \( W_w \) the decrement of weight from the immersion; i.e. the weight lost.

Then the Specific Gravity \( S = \frac{W_a}{W_w} \).

Strictly speaking, the first weighing should take place in vacuo, and the temperature of the Bodies, especially the water, should be 62° Fahrenheit, the Barometer standing at 30 inches. The instruments employed are either the Hydrostatic Balance of Nicholson, or a delicate Balance of the common construction; in which case the substance to be weighed is suspended by a hair from one of the arms, and thus immersed in the water.

(63.) When it is required to find the Specific Gravity of a Salt or other substance that is soluble in water, the usual process may be followed by using instead of water, oil or alcohol, or any Liquid of known Specific Gravity, in which the substance is not soluble. In this case the process affords the Specific Gravity of the substance, referred to that of the Liquid in which it has been weighed, and as the Specific Gravity of this Liquid is known with reference to water, the Specific Gravity of the Solid is easily calculated from these ratios.

(64.) Various methods have been devised for obtaining the Specific Gravity of Substances in the state of Powder; of these the following is much the best. It was originally proposed by M. Say in the Annales de Chimie, tom. xxiii. p. 1; but the following description is given of the instrument as employed by Professor Leslie, in the Annales of Philosophy for April 1826.

"The instrument consists of a glass tube, \( a e \), about three feet long, open at both ends. The wide part, \( ab \), is about 4 inches in diameter, the part \( be \) about \( \frac{1}{6} \). The two parts communicate at \( b \) by an extremely fine slit, which suffers air to pass, but retains sand or powder. The mouth at \( a \) is ground smooth, and can be shut so as to be air-tight by a small glass plate shown a little above it in the figure. The substance whose Specific Gravity we wish to find, suppose it to be sand, is put into the wide part of the tube, \( ab \), which may either be filled to the top or not. The tube being then held in a vertical position, the narrow part is immersed in an open tube or vessel, \( x \), filled with mercury, till the mercury rises to the gorge at \( b \). The lid is then fitted on air-tight at \( a \). In this state it is evident that there is no air in the tube except what is mixed with the sand in the cavity \( ab \). Now suppose the Barometer at the time to stand at 30 inches, and that the tube be lifted perpendicularly upwards till the mercury stands in the inside of \( b e \) at a point \( c \), 15 inches above its surface in the open vessel \( x \). Had the Barometer stood at 29 inches, the height must have been 1½ inches, and so on; which may be regulated by a scale.

It is evident, then, that the air in the inside of the tube is subjected to a pressure of exactly half an atmosphere, and of course it dilates and fills precisely twice the space it originally occupied. It follows, too, that since the air is dilated to twice its bulk, the cavity \( ab \) contains just half of what it did at first, and the cavity \( bc \) now containing the other half, the quantity of air in each of these parts of the tube is equal. In other words, the quantity of air in \( bc \) is exactly equal to what is mixed with the sand in \( ab \), and occupies precisely the same space which the whole occupied before its dilation. Let us now suppose the sand to be taken out, and the same experiment repeated, but with this difference, that the cavity \( ab \) is filled with air only. It is obvious, that, as the quantity of air is greater than it was when part of the cavity was filled with sand, it will, when dilated to double the bulk, under a pressure
C H E M I S T R Y.

Tenacity. Of 15 inches, occupy a larger space than in the other experiment, and the mercury will only rise, let us suppose to d. But let it be remembered that the attenuated air in the narrow tube always occupies exactly the space which the whole occupied under the ordinary atmospheric pressure. Now this space is in the one case the cavity b c, and in the other b d. Hence it clearly follows, that the cavity c d, which is the difference between these, is equal to the bulk of the solid matter in the sand. Now by marking the number of grains of water held by the narrow tube b c on a graduated scale attached to, we can find once what is the weight of a quantity of water equal in bulk to the solid matter in the sand, and by comparing this with the weight of the sand in air, we have its true Specific Gravity.

As some porous bodies, such as Charcoal, hold much condensed air within their pores, and may, probably, retain this property in some degree even when in powder, the chance of error arising from this source is obviated by comparing the dilatation which takes place under different degrees of pressure—under 10 inches and 20, for instance, or under \( \frac{7}{4} \) and 15.

The Specific Gravity of Charcoal is generally estimated as under 5, but by this process the powder of Charcoal exceeds that of the Diamond. The Specific Gravities of Mahogany is 1.06, but of Mahogany saw dust 1.68. That of Wheat flour 1.56, and of pounded Sugar 1.52. Of Salt 2.15, agreeing with the common estimate. Volcanic ashes 4.4, being equal to that of some metallic ores.

Corrections. (65.) Should it be necessary to introduce these very minute corrections, which depend upon the temperature of the substances or liquids employed, the formula for this purpose may be seen in M. Biot's *Physique*, vol. i. p. 426, though we cannot devote the space requisite for their introduction into this Treatise.

(66.) Substances which are usually called Solid, but which like Charcoal contain numerous pores, are capable of condensing within those pores very considerable quantities of Gases: but to this property we shall advert when we have entered more fully upon the description of aeriform fluids.

Properties that belong to Liquids.

Liquids. (67.) Of the extensive catalogue of Properties that has been recited as belonging to Solid Bodies, few only will be found to apply to those Substances which exist in the Fluid State.

Tenacity. In Tenacity the Fluids may be said to differ slightly, as there is a difference in the magnitude of the drop that may be formed by each when falling from the mouth of a Phial: and the quantities which will issue from small orifices under given pressures are found to be variable. This circumstance, however, may also be explained by attributing to each different degrees of their characteristic Property Fluidity.

Volatility. Some Fluids are of easy Volatility; others are not volatile at all under any processes to which we can submit them; though analogy and experiment would unite in leading us to suppose that all substances in nature are capable of being rendered fluid, and of being also volatilized by the application of a sufficient degree of heat. *Vide Treatise on Heat*, Art. (65.) &c. And it is to be remembered, that in practice some substances, such as the fat oils, take fire, and are consumed upon a sufficient elevation of temperature: so that the universal of the law seems here to be interfered with by the presence of another phenomenon. The exception, however, only apparent, for the fat oils are capable of regular distillation in vacuo.

Circumstances connected with the evolution of Ebullition, vapour, and its passage through the fluid, produce the phenomenon of *Ebullition*. *Vide Treatise on Heat*, Art. (73.) &c. The temperature at which fluids boil, or pass into the state of vapour, frequently forms a part of the Chemist's researches, and ought always to be stated among the physical properties of every fluid.

(68.) For a long time it has been questioned whether liquids were compressible, and water was the substance upon which experiments were made. The Florentine Academicians were the first to devise a process which by its result seemed to prove that water was compressible to a slight extent: the researches of Professor Gerst and of Mr. Perkins have decided this point satisfactorily. By a pressure of 2000 atmospheres, Mr. Perkins reduced a mass of water to \( \frac{3}{5} \) of its original volume.

(69.) As might be expected, the Specific Gravity of Specific Liquids forms an important feature in their Physical History. Water is made the unit of the scale to which they are referred as in the case of solids. The mode usually employed for obtaining equal volumes of the two substances to be compared is very simple: the weight of the water, which is contained by a small bottle capable of being accurately closed, is compared with the weight of an equal volume of liquid obtained by filling and weighing the same bottle.

Let \( W_a \) and \( W_b \) be the weights of the water and of the liquid respectively, then the Specific Gravity

\[
S = \frac{W_b}{W_a}
\]

And for greater simplicity, the small bottle or flask is sometimes made to hold exactly 1000 Grains of Distilled Water, and a constant counterpoise is provided for the empty bottle; so that when it is filled with any other liquid, the weight that is required in addition to the counterpoise to produce an equilibrium, represents at once the ratio borne by the liquid to 1000 grains of distilled water; or, in other words, the Specific Gravity of the Fluid.

(70.) It is evident, however, that the rule above given produces only an approximative result. For, in the first place, both the water and the fluid must be referred to some fixed standard of temperature, to obviate the effects of dilatation. In France, this standard point has been judiciously placed at the maximum density of water, which is about 40° Fahrenheit, but in this country 62° Fahrenheit is usually considered the standard point. In the next place, the dilatation of the bottle should be allowed for by calculation. The experiments also should be made in vacuo; or else reduced by calculation so as to obviate the errors arising from their being made in air and moisture. And lastly, the Barometric Pressure should not be overlooked.

It would be easy to insert formula which afford these corrections, but in practice they are seldom resorted to, and the limits to which we must here confine ourselves, only permit our referring those who may wish for further information on the subject to M. Biot's *Physique*, tom. i. p. 399.

(71.) We have already adduced in Art. (58.), a general formula applicable to the Dilatations of Liquids by the Effect of Caloric; but since, it always happens...
that Liquids are contained in vessels formed from some material which is also affected by heat, though it may be in a greater or less degree, it becomes necessary that we should be able to compute the value of the apparent inaccuracy thus introduced. On this subject consult the Treatise on Heat, Art. (42.), whence we learn that if \( V \) be the volume of a fluid contained in any vessel at 32° Fahrenheit; \( V' \) the apparent volume that the Fluid in the same vessel assumes by being heated \( t' \) above 32° Fahrenheit; \( \delta \) the true cubic dilatation due to \( t' \) upon each unit of which \( V \) is a multiple; and \( K \) the cubic dilatation of the substance of the vessel for each degree to which \( t \) refers, expressed also in terms of that unit to which \( V \) and \( V' \) refer; that

\[
\delta = \frac{V' - V}{V} + \frac{V'Kt}{V},
\]

where \( \frac{V' - V}{V} \) is the true dilatation of the fluid, and \( \frac{V'Kt}{V} \) is the correction to be applied in consequence of the dilatation of the vessel.

Now let \( \theta \) be the true cubic dilatation of the contained fluid for each degree of the scale to which \( t \) refers, and the same being true for any other temperature \( t' \), (above 32° Fahrenheit,) we have

\[
\delta = \theta \frac{V' - V}{V} + \frac{V'Kt}{V},
\]

where \( \theta = \frac{1 - t'\theta}{1 + t'\theta} \)

and similarly \( V'' = V. \frac{1 + t''\theta}{1 + t''K} \)

\( V'' = V. \frac{1 + t''\theta}{1 + t''K} \)

which is independent of the volume at 32° Fahrenheit, and is true for any Liquid or Gas contained in any expansive vessel.

(72.) Liquids absorb the power of absorbing Gases, and under the head of aeriform Fluids that property will be noticed.

Physical Properties of Aeriform Bodies.

(73.) The properties which we have to record as belonging to aeriform fluids are, as might be anticipated, more nearly similar to those of liquids, than to those of solids. They are Tenuity, Weight, Compressibility, and Elasticity.

Aeriform bodies have frequently been divided into two classes: permanently elastic gases and vapours: the former comprising atmospheric air, and those gases which under all our ordinary operations at common temperatures are permanently elastic. The latter consisting of vapours produced from solids or liquids by the influence of caloric. It would seem, however, from the analogies presented by certain recent experiments, that the distinction between these two classes is rather formal than real. In short, that the difference, though confessedly well marked, depends solely upon those temperatures and pressures under which we live and make our experiments. For by the skill of Mr. Faraday, many of those gases which formerly were considered as permanently elastic have been exhibited under the liquid form.

There is, however, so great a practical difference between the vapour of water, and of other fluids, which rises at so low a temperature as to be continually present in our experiments, and the vapour of pure carbon, which has only been undesignedly produced during the most intense heats, employed on a large scale, that for convenience we shall, in some degree, adhere to the old arrangement, and thus speak first of pure and dry gases, proceeding afterwards to the vapours.

To speak with strict precision, as far as our present knowledge permits, we may define both gases and vapours to be solid bases, united with such a portion of caloric as that the combination resulting exists in the aeriform state.

Pure dry Gases.

(74.) It would appear that a difference exists in the molecular constitution of gases, both from the difference of their specific gravities, their difference of Tenuity proved by the times that given volumes of each gas require for passing through orifices of given magnitude, and also from certain Chemical views arising out of the theory of Atoms. Mr. Faraday ascertained the times requisite for the escape of different gases from a vessel whence they issued through capillary tubes. The pressure at the outset of the experiment was the same in each case for all the gases, viz. 1 1/4 atmosphere.

<table>

<tr>
<td>Coal Gas</td>
<td>100.0</td>
</tr>
<tr>
<td>Hydrogen</td>
<td>57.0</td>
</tr>
</tbody>
</table>

Under low pressures the differences are not so great; for in one such case a certain volume of olefiant gas, and an equal one of hydrogen gas, issued in the same interval of time, the pressure being inconsiderable. Hydrogen gas, under the pressure of a small column of mercury, escaped through some very small orifices in one-third of the time that an equal volume of olefiant gas did. The differences between the results of these experiments increased in proportion to the resistances opposed to the issuing of the fluids, whether these resistances arose from diminishing the diameter of the tubes, or from increasing their lengths. The proportionate times of escape did not vary in any ratio with the specific gravities of the gases. And the ratios expressing the issuing powers of different gases under the same pressure, did not bear any direct proportion to another corresponding set of numbers resulting from a similar experiment under a different pressure. (a.)

M. Girard subsequently made some experiments of a similar nature, on a large scale, from one of the gasometers for lighting Paris.

The comparison refers to common air and carburetted hydrogen, issuing from equal orifices, at equal distances from the gasometer, under the same pressure, and during a given time. The lengths of the pipes through which the airs passed were as the numbers 1288, 3758, and 6228; the quantities of atmospheric air issuing were as the numbers 902, 541, and 394, and of carburetted hydrogen as the numbers 1281, 710, and 541. M. Girard's paper is well worthy of attention. (b.)

(75.) The gases differ considerably from each other in weight, that is in specific gravity. Thus we find our attention called to two problems, which frequently occur to the practical Chemist for solution. The one the determination of the absolute weight of a given volume of any gas under a given temperature and
pressure; and the other, the ratio of such weights for all the different gases, that is their specific gravities, referred to the weight of any one among them as a unit. For this purpose Atmospheric Air has been employed, calling its weight unity in the Series.

On the general principles of Specific Gravities, if we have the weight of a volume of dry gas and of an equal volume of dry atmospheric air, at a given temperature and pressure, the specific gravity of the gas equals the weight of the gas divided by the weight of the air. But before we enter upon the practical processes for obtaining the Specific Gravity of a Gas, we must become better acquainted with certain other properties of aeriform Fluids.

For the Specific Gravities of the gases see Table No. 1, and consult References (c.), (d.), (e.), (f.), (g.) (76.) A pure and dry gas is capable of being mechanically compressed when confined in a close vessel, and upon the removal of the pressure, the aeriform fluid returns to its original volume. And when air is confined in a bent tube and loaded with different weights of mercury, the spaces into which it is compressed are found to be inversely as those weights. But the weights are the measures of the elasticity, therefore the elasticity always varies directly as the space occupied by the air.

The density varies inversely as the space, and therefore the elasticity of air varies directly as its density. (Mariotte’s law.)

Volume.

(77.) Hence if \( V \) be the original volume of a gas under a pressure \( p \), (usually expressed in inches of mercury in the Barometer,) and \( V' \) its volume under a pressure \( p' \),

\[
\frac{V}{V'} = \frac{p'}{p}, \quad \text{or} \quad V = V' \frac{p'}{p}.
\]

This formula is employed whenever we have the volume of a gas \( V' \) under a known pressure \( p' \), and wish to ascertain its volume under some other pressure \( p \); in this case \( V \) is obtained from the above equation.

Example. Having 100 cubic inches of gas at Barometer 28, what is this equivalent to under the standard pressure of 30 inches?

Here \( V' = 100 \), \( p' = 28 \) and \( p = 30 \),

\[
\therefore V = 100 \times \frac{28}{30} = 93.333.
\]

(78.) If the air or gas be confined in a tall jar or tube standing over mercury, so that the pressure cannot be naturally equal within and without the jar, and thence the air becomes dilated.

Let the length of the column of gas in the tube = \( x \); let the total height of the column of mercury and gas above the surface of the fluid in the trough = \( h \); the altitude of the Barometer = \( p' \); then the true volume at that pressure,

\[
V = \frac{x}{p'} \cdot \left\{ p' - (h - x) \right\}.
\]

and \( V' \) may be reduced to \( V \), if required, by formula in (77.)

(79.) And should a similar reduction be required for gas standing over water, since \( p' \) refers to a pressure made by mercury, the preceding formula will become

\[
V' = \frac{x}{p'} \cdot \left\{ p' - \frac{h}{13.5} - x \right\}.
\]

and this also may be reduced to the standard pressure \( p \) as the preceding.

(80.) The weight of a given volume of any gas (at Barometer 30, Thermometer 60° Fahrenheit) = \( W \) (in cubic inches) \times Specific Gravity \times .305 grains Troy, (the weight of a cubic inch of dry atmospheric air.)

(81.) The weight of a given volume of air or gas varies as its density (49.), and therefore as the pressure to which it is submitted. Hence if we have the weight of a given volume of air at a given pressure, it is easy to ascertain, by proportion, the weight of a similar volume under any other pressure.

Generally, \[
\frac{W}{W'} = \left( \frac{p}{p'} \right)^{m} \quad \text{and} \quad W = W' \cdot \left( \frac{p}{p'} \right)^{m}.
\]

Example. If 100 cubic inches of atmospheric air, at Barometer 28 inches, weigh 28.466 grains Troy, what will a similar volume weigh when the Barometer is at the standard altitude?

Here \( W' = 28.466 \), \( p = 30 \), \( p' = 28 \),

\[
\therefore W = 28.466 \times \frac{30}{28} = 30.5 \text{ nearly}.
\]

30.5 grains being the weight actually admitted at present on the experiments of Sir G. Shuckburgh.

(82.) But it is also known that all substances undergo a change of volume by Heat, and that this operates upon gases to a very considerable extent. It has been shown (HEAT, 34.) that if \( V \) be the volume of any substance at 32° Fahrenheit, and \( V' \) its new volume when heated, \( t \) the degrees that it is heated above 32°, and \( K \) the cubic dilatation of the unit of mass for each degree of Fahrenheit,

\[
V' = V \times \left( 1 + \frac{K}{480} \right) \cdot \text{Fahrenheit}.
\]

Hence if we know the volume of a gas \( V \) at 32° Fahrenheit, we can learn its volume \( V' \) upon its being heated any number of degrees; for it has been proved by Dalton and Gay Lussac, that \( K \), the cubic dilatation of all gases, is \( \frac{1}{33} \) of the original volume, at 32° Fahrenheit, for each degree that they are heated.

Example. Let it be required to know what will 100 cubic inches of gas, at 32° Fahrenheit, become in volume when heated to 60° Fahrenheit.

Here \( V = 100 \), \( t = 28 \) and \( K = \frac{1}{480} \).

\[
V' = 100 \left( 1 + \frac{28}{480} \right) = 105.83 \text{ cubic in.}
\]

(83.) But it has also been shown (HEAT, 35.) that the volume at any other temperature may be introduced into the formula without having recourse to the volume at 30° Fahrenheit; and this is a case of more frequent occurrence than the former.

For if \( V \) be the volume at 32° Fahrenheit, \( V' \) that at temperature \( t' \), and \( V'' \) that at temperature \( t'' \), we have from the general theorem, calling \( K \) the cubic dilatation as before,

\[
V'' = V \left( 1 + \frac{K}{480} \right) \left( 1 + \frac{K}{480} \right).
\]

Hence by division we have generally, \[
V'' = V' \left( 1 + \frac{K}{480} \right) \left( 1 + \frac{K}{480} \right) = \frac{458 + t''}{480 + t'} \quad \text{for Fahrenheit only}.
\]

Example. Let it be required to calculate what 100 cubic inches of gas, at temperature 50° Fahrenheit, would become, if heated to 60° Fahrenheit,

Here \( V' = 100 \), \( t' = 18 \), \( t'' = 28 \) and \( K = \frac{1}{480} \).
Generally, \( V'' = V \cdot \frac{1 + K t'}{1 + K t} \)

\[ \frac{508}{498} = 102.008 \text{ cubic inches.} \]

Dilatation of vessel.

(84.) And since air, or gas, is frequently confined in vessels of glass or metal, which also change their absolute capacity by change of temperature, it is desirable to be able to compute the variations arising from this cause. For this we may employ the general formula given in Art. (71.)

(85.) Let it be required also to introduce into the formula last referred to an expression which may provide for simultaneously correcting the volume for any change of barometric pressure from \( p' \) to \( p'' \) during the experiment.

Let \( p' \) and \( p'' \) be the barometric pressures at the temperatures \( t' \) and \( t'' \) respectively; then, by Art. (77.)

\[ V'' = V \cdot \frac{p'}{p''} \cdot \left( \frac{1 + t'' K}{1 + t' K} \right) \]

which gives us the true volume due to the pressure \( p'' \).

(86.) And if further we wish to reduce this to the standard altitude of 30 inches, we have from (77.)

\[ V (\text{the volume at standard altitude}) = V'' \cdot \frac{p'}{30} \]

Weight.

(87.) Let us next consider how the weight of a gas is made to vary by change of pressure, i.e.

Having the weight of a given volume of gas at a given temperature, required the weight of the same volume at some other temperature.

Generally, if \( V' \) and \( V'' \) be any two volumes of gas, at temperatures \( t' \) and \( t'' \) above 32° Fahrenheit, which volumes are both \( V \) at 32° Fahrenheit; the weights of any given volume of the gas being \( W' \) and \( W'' \) at the temperatures \( t' \) and \( t'' \) respectively.

Then, by (82.)

\[ V' = V (1 + K t'), \]

and \( V'' = V (1 + K t'') \).

\[ \therefore V' : V'' :: 1 + K t' : 1 + K t'' \]

But the weights \( \propto \) the densities which \( \propto \) inversely as the volumes.

Hence \( W' : W'' :: 1 + K t' : 1 + K t'' \);

and \( W'' = W' \cdot \frac{1 + K t'}{1 + K t''} \).

Example. If 100 cubic inches of gas, at temperature 50° Fahrenheit, weigh 50 grains, what will an equal volume of the same gas weigh at 60° Fahrenheit?

Generally, \( W'' = W' \cdot \frac{1 + K t'}{1 + K t''} \)

Here \( W' = 50 \), \( t' = 18 \), \( t'' = 28 \);

\[ \frac{1 + 18}{480} = 49.015 \text{ grains.} \]

\[ \frac{1 + 28}{480} = 50.498 \text{ grains.} \]

(88.) It is frequently required to apply both the last corrections to a quantity of gas obtained in some experiment; hence

Having a given volume of gas under a given pressure and temperature; required the new volume when both pressure and temperature are changed.

This Problem may be solved at two steps: first ascertaining the change from temperature by (83.), and then the change by pressure by (77.); but it is nearer to embody both in one formula.

For this purpose call the original volume, temperature above 32° Fahrenheit; and pressure; \( V', t', \) and \( p' \), respectively.

And let \( t'' \) and \( p'' \) be the new excess of temperature above 32° Fahrenheit and the new pressure; while \( V'' \) is the new corrected volume. Also let \( Q \) be the new volume corrected for temperature but not for pressure.

Then by (83.) \( Q = V' \cdot \frac{1 + k t''}{1 + k t'} \) which corrects temperature only;

and by (77.) \( \frac{Q}{p} = \frac{p'}{p''} \), which corrects for pressure,

\[ \therefore \frac{Q}{p'} = \frac{p'}{p''} \cdot \frac{1 + k t'}{1 + k t''} \]

Example. Having 100 cubic inches of gas at 50° Fahrenheit and Barometer 29 inches; required the volume of this at 60° Fahrenheit and Barometer 30 inches.

Generally (85.) \( V'' = V' \cdot \frac{p'}{p''} \cdot \frac{1 + k t'}{1 + k t''} \).

Here \( V' = 100 \), \( p' = 29 \), \( p'' = 30 \), \( t' = 50 - 32 = 18 \), \( t'' = 29 \);

\[ \therefore V'' = 100 \cdot \frac{29}{30} \cdot \frac{508}{498} = 98.6 \text{ cubic inches.} \]

(89.) Similarly. Having the weight, pressure, and temperature of a given volume of gas; required the weight of an equal volume when pressure and temperature both vary.

The same notation remaining, let \( Q \) represent the new weight produced, supposing the temperature alone had varied.

Then by (87.) \( Q = W' \cdot \frac{1 + k t'}{1 + k t''} \).

But weight \( \propto \) density \( \propto \) pressure,

\[ \frac{W''}{Q} = \frac{p''}{p'}, \text{ and } W'' = Q \cdot \frac{p''}{p'} \]

and by substituting the value of \( Q \) before obtained

\[ W'' = W' \cdot \frac{p'}{p''} \cdot \frac{1 + k t'}{1 + k t''} \]

Example. If 100 cubic inches of gas, Thermometer 50° Fahrenheit, Barometer 29 inches, weigh 50 grains; what will 100 cubic inches weigh, Thermometer 60° Fahrenheit, Barometer 30 inches?

Generally, \( W'' = W' \cdot \frac{p'}{p''} \cdot \frac{1 + k t'}{1 + k t''} \).

Here \( W' = 50 \), \( p' = 29 \), \( p'' = 30 \), \( t' = 50 - 32 = 18 \) and \( t'' = 28 \);

\[ \therefore W'' = 50 \cdot \frac{29}{30} \cdot \frac{498}{508} = 50.706 \text{ grains.} \]

(90.) All that has hitherto been said respecting the True for all properties of a pure and dry gas applies equally to dry gases, atmospheric air, or to a mixture of gases, provided
only that no moisture be present, since it is proved by the experiments of Gay Lussac that all gases undergo the same dilatations by the same increments of temperature. And that the actual cubic dilatation of gas, in being heated from 32° Fahrenheit to 212° Fahrenheit, is .375 of the original volume; so that (Heat, 52.) the cubic dilatation due to one degree

\[
\frac{1}{480} = 0.002083 \text{ of the volume at melting ice.}
\]

**Moist Gases.**

The general principles which regulate the effects of moisture when present in gases have been already noticed in the Treatise on Heat, (79.) et seq., we would offer, therefore, in as concise a form as possible, the practical results which demand the Chemist's remembrance and attention.

Let \( V_d \) be the volume of a dry gas and \( V_m \) the volume to which the former increases upon being saturated with moisture.

Let \( p \) = the atmospheric pressure, or the tension of the dry gas.

Let \( f \) = the tension of the vapour due to the temperature and to be found from tables.

Then since the elasticity of a gas varies inversely as its volume.

\[
\text{Elasticity of dry gas } (p) : \text{elasticity of moist} :: V_d : V_m.
\]

But (Heat, 91.) \( p = p \cdot \frac{V_d}{V_m} + f \).

Hence

\[
V_d = p \cdot \frac{V_m - f}{p - f},
\]

and

\[
V_m = p \cdot \frac{V_d}{p - f}.
\]

**Example.** Having 100 cubic inches of gas saturated with moisture at Barometer 30 and Thermometer 60° Fahrenheit. Required the volume of this gas when dry.

Here \( f = .524 \) by Dalton's tables \( p = 30 \) \( V_m = 100 \);

\[
V_d = \frac{30 - .524}{30} \cdot 100 = 98.253 \text{ cubic inches.}
\]

And if \( V_v \) represent a virtual volume due to the vapour, or, in other words, the quantity by which \( V_d \) is increased by the moisture,

\[
V_m = V_d + V_v = \frac{p}{p - f} V_v,
\]

and

\[
V_v = \frac{f}{p} V_m^2,
\]

or,

\[
\frac{f}{p - f} V_v.
\]

(93.) Supposing that we had a given volume of a moist gas at some given temperature and pressure, it is easy to reduce this volume to that which is due to the standard temperature and pressure by (88.): but we only speak of such a change as shall not condense the moisture.

Thence having the volume of moist gas we obtain the volume of dry gas therein contained by (91.)

(94.) But suppose that we had obtained the specific gravity of a gas in a state of saturation; and that it was required to calculate the specific gravity of the same gas when dry.

Let \( p \) = the barometric pressure.

Let \( f \) = the elasticity of the vapour due to the temperature found from Tables, Heat, Encyclopædia Metropolitana, Appendix, Table V. and Art. (79.) of that Treatise, and let \( S_d, S_v, \) and \( S_m \) be the specific gravities of the dry gas, the vapour diffused throughout the volume of gas, and of the moist gas respectively.

Then

\[
V_m S_m a = V_v S_d a + V_v S_v,
\]

and if we suppose that the specific gravity which we have taken from the Table is the one belonging to a volume of vapour equal to the entire original volume of moist gas,

\[
V_v = V_m,
\]

so that

\[
S_m = \frac{p - f}{p} S_v + S_d,
\]

or

\[
S_d = \frac{p - f}{p} (S_m - S_v).
\]

But if, on the other hand, we conceive that the volume of vapour is to be estimated on the supposition that its volume is reduced to the volume of the dry gas, then \( V_v \) becomes \( V_d \).

and we have

\[
S_m = \frac{p - f}{p} (S_d + S_v),
\]

or

\[
S_d = \frac{p - f}{p} S_m - S_v.
\]

which is the view taken by Professor Thomson, in his interesting experiments, First Principles, vol. i. p. 66.

(95.) Formula for obtaining \( f \) immediately may be seen in the Treatise on Heat, (79.)–(82.): or its value may be found from the Table V., Appendix to the same Treatise.

(96.) In these calculations we frequently require the specific gravity of vapours, especially that of the vapour of water at different temperatures. Now, as far as we at present know, the specific gravity of vapour in contact with the fluid from which it is formed varies directly as the elastic force of that vapour. Heat, Encyclopædia Metropolitana. (77.)

Hence

\[
S_v = \frac{f_v}{f_t} \times S_t,
\]

where \( S_v \) and \( S_t \) represent the specific gravities at \( n^\circ \) Fahrenheit and 212° Fahrenheit respectively, \( f_v \) and
On taking the Specific Gravity of Gases.

(99.) Being now competent to introduce the necessary corrections, we may proceed to the practical processes for ascertaining the specific gravity of gases. For this purpose we require a good air-pump; a large flask with a stop-cock; and an air-jar graduated into cubic inches and provided also with a stop-cock.

To obtain then the weight of a known volume of any gas, the flask is to be exhausted, then most accurately weighed, then filled with the gas by screwing it to the stop-cock of the air-jar containing the gas: the weight is to be then again taken, and it is evident that the increase of weight is the weight due to the number of cubic inches that have entered the flask, as shown by the air-jar.

The specific gravity of dry atmospheric air is always made unity, and the weight of one cubic inch of dry atmospheric air is 0.00353 grains Troy at Barometer 30, Thermometer 60° Fahrenheit. Therefore at any pressure $p$ and any temperature $t$ Fahrenheit, let $V$ cubic inches of a dry or moist gas weigh $W$ grains; and let $a$ be the weight of a cubic inch of dry atmospheric air at the pressure $p$ and temperature $t$ Fahrenheit: so that the weight of a volume $V$ of dry common air at $p$ and $t$ would be $aV$, then

$$S = \frac{W}{aV}$$

and from hence, if moist the specific gravity of the same gas when dry may be found from Art. (94.)

(100.) Professor Thomson has proposed and employed a method still more simple for taking the specific gravity of gases, with this advantage, that it is more independent of a very accurate exhaustion of the flask.

Let $W$, $W'$, and $W''$, be the weights of the flask before exhaustion, after exhaustion, and when filled with the gas respectively.

Then $W - W'$ is the weight of the atmospheric air removed from the flask: and $W'' - W'$ is the weight of the gas admitted; and since the volumes are in both cases the same, the specific gravities are as the weights directly.

Hence $S$ (the specific gravity of the gas) = \[ \frac{W'' - W'}{W - W'} \]

which gives the specific gravity of the gas dry or moist, as it may happen to be, and is so far independent of the atmospheric pressure and temperature.

Specific Gravity of Vapours.

(101.) By far the best method for ascertaining the specific gravity of vapours is that contrived by M. Gay Lussac, and well described in Biot's Physique, vol. i. vapours, p. 291. The principle employed is that of ascertaining the relative volumes of a body in the liquid state, and of the same body when converted into vapour at a known temperature. We fear that it would occupy too much space, or the process is well worthy of insertion in this place.

Power of Conducting Heat.

(102.) A heated body, if placed under similar circumstances, will cool with different velocities in different gases. We are of opinion that this can scarcely be said to depend solely upon a difference in the conducting power of these bodies; in some degree this may be the case, but probably the effect produced depends chiefly upon the motion of the gaseous molecules by which currents are produced, and thus the heat is successively carried off rather than truly conducted. These views are favoured by the circumstance that the powers of different gases in favouring the escape of caloric from a heated body, seem to be in some inverse ratio of their density. It was found by Dulong and Petit that the nature of the surface of the heated body did not affect the results; but it has been shown by Count Rumford's experiments, that moisture in all gases materially aids their power to abstract caloric from the heated body.

This subject has engaged the attention of Mr. Dalton and Sir H. Davy; the latter suffered the bulb of a Thermometer, which had been heated to 160° Fahrenheit, to cool in 21 cubic inches of each gas, at temperature 52° Fahrenheit.

The thermometer cooled down to 106° Fahrenheit in the different gases, in the following times:

(104.) It has been already stated (66.) and (72.) that certain Solids and Liquids absorb Gases. On this subject we cannot do better than offer the following excellent statement by Dr. Henry.

"All solid bodies, that possess a certain degree of Solids, porosity, are capable of absorbing gases.
"This was first observed in charcoal. It has been found also by Saussure, jun. to belong to a stone called meerschaum, to adhesive slate, asbestos, rock cork, and other minerals; and to raw silk and wool. The following general principles are deducible from the experiments of Saussure, (A.)

1. It is necessary to drive the solid of the air which it naturally contains. When of a nature not to be injured by heat, this is most effectually done by igniting the solid, and quenching it under mercury, where it is to be kept, till admitted to a given volume of the gas to be absorbed. Solids that are decomposable by heat, may be deprived, though less effectually, of air, by placing them under a receiver, which must then be exhausted by the air-pump.

2. "The same solid absorbs different quantities of different gases. Charcoal, for instance, condenses 90 times its bulk of ammoniacal gas, and not twice its bulk of hydrogen.

3. "Solids, chemically the same, absorb different quantities of the same gas, according to their state of mechanical aggregation. Thus the dense charcoal of box-wood absorbed 7.4 volumes of air, while a light charcoal, prepared from cork, did not absorb a sensible quantity.

4. "Different solids absorb different quantities of the same gas; the quantity of carbonic acid absorbed by charcoal being about seven times greater than that absorbed by meerschaum.

5. "When the solid exerts no chemical action on the gas, the absorption is terminated in 24 or 36 hours.

6. "The effect of moistening the solid is to retard the absorption, and to diminish its amount; and when a gas has actually been absorbed, it is again driven out unchanged, partly by water of the ordinary temperature, and entirely by exposure to a boiling heat.

7. "During the absorption of a gas by a solid, the temperature of the latter rises several degrees, and bears a proportion to the absorbability of the gas, and the rapidity with which it is condensed.

8. "Solids condense a greater number of volumes of the more absorbable gases, under a rare than under a dense atmosphere; but if the absorption be reckoned by weight, it is most considerable under the latter state.

9. "When a solid, saturated with any one gas, is introduced into an atmosphere of any other gas, a portion of the first is expelled, and a part of the second takes its place.

"Gases are absorbed by liquids."

On this subject the following general principles may be laid down.

1. "The same liquid absorbs different quantities of different gases. Thus water takes up its own bulk of carbonic acid, and not one-fifth of its bulk of hydrogen gas.

2. "Different liquids absorb different quantities of the same gas. Alcohol, for instance, absorbs almost twice as much carbonic acid as is taken up by an equal volume of water.

3. "The absorption is promoted by first freeing the liquid from air, either by long-continued boiling in a vessel with a narrow neck, or by the air-pump. It requires also brisk and long-continued agitation, especially with the less absorbable gases.

4. "It does not appear that the gases are absorbed by all liquids, in the same order. For example, of four gases, naphtha absorbs most olefant gas; oil of lavender most nitrous oxide; olive oil most carbonic acid; and solution of muriate of potash most carbonic oxide.

5. "The viscosity of liquids, though it does not much influence the amount absorbed, occasions a longer time to be spent in effecting the absorption. On the other hand, the amount of any gas which is absorbed by water, is diminished by first dissolving in the water any saline substance.

6. "In general the lightest liquids possess the greatest power of absorbing gases; whereas, when there is no evident Chemical action, the heaviest gases are absorbed most copiously, and rapidly, by the same liquid.

7. "The temperature of a liquid is raised by the absorption of a gas, in proportion to the amount and the rapidity of the absorption.

8. "In all liquids the quantity of gases absorbed are directly as the pressure. For example, a liquid which absorbs its own bulk of gas under the pressure of the atmosphere, will still absorb its own bulk of the same gas under double, triple, &c. pressure; but its own bulk of gas, twice compressed, is equal to double its bulk of gas ordinarily compressed, and so on. The proofs of this law I have given at length in the Philosophical Transactions for 1803.

9. "When water, or, probably, any other liquid, is agitated with a limited quantity of any mixture of two gases, it does not absorb one gas to the exclusion of the other, but absorbs a portion of both. In this case, the density of each gas, in the water or liquid, has a constant relation to that without, for the same gas. Thus in carbonic acid gas, the density is the same within and without the water; in olefant gas and phosphuretted hydrogen, the density within is 1.27th of that without; in azote and hydrogen, it is about 1.50th, according to Dalton, though he originally stated it to be 1.64th, under the impression that the distances of the particles within were always some multiple of those without. This concise enunciation of the general law, deduced by Mr. Dalton from his experimental inquiries, will be better understood by the illustrations contained in a Paper published in the Annals of Philosophy, vol. vii. p. 216, where the reader will find a formula for ascertaining the quantities of mixed gases absorbed by water.

"The principle on which gases are absorbed and retained by liquids is still a subject of controversy. By Berthollet, Thomson, Saussure, and the generality of Chemists, it is ascribed, in all cases, to the exertion of a Chemical affinity between the gas and the liquid; but it is contended by Mr. Dalton and myself, that the effect in most cases is chiefly, if not wholly, mechanical. The discussion would lead me into details of too great a length; and I refer, therefore, for a statement of the argument, to two Papers which I have published in the eighth and ninth volume of Nicholson's Journal; to Mr. Dalton's New System of Chemical Philosophy; and to his Essay in the seventh volume of Dr. Thomson's Annals, which contains a reply to the objections advanced against the mechanical theory by Saussure, in the sixth volume of the same work. This reply seems to have unaccountably escaped the notice of several writers, who continue to urge the objections of Saussure, after they have been fully and satisfactorily answered by Mr. Dalton." (f.)
The term Alkali is derived from the Arabic name of the plant (*Salvia Kali*), from which one of these substances has long been extracted. The general properties of the Alkalis, especially as developed in the stronger ones, are as follows:—They change blue vegetable colours to green; and if such colours have been changed to purple or to a more vivid red by acids, they destroy that sort of action, and when used in sufficient quantity turn them absolutely to green. The same powers they possess even when saturated with Carbonic Acid—a property which the Alkaline Earths are without. Their taste is acid, possibly in great degree arising from their power of dissolving all animal matter with an energy proportionate to their state of concentration. They readily combine with oils or fatty matters, so as to form soaps. Their carbonates are soluble in water, but the carbonates of the Alkaline Earths are not so. Three of the Alkalis consist of Metallic Bases, united with Oxygen: viz. Potassa, Soda, and Lithia. One, viz. Ammonia, consists of two Gases, Hydrogen and Nitrogen; and the vegetable Alkalis, which are rather numerous, consist of various combinations of Oxygen, Hydrogen, and Carbon.

The term Acid is in familiar use, and is generally understood by all: its Chemical sense accords with, or is in fact adopted from ordinary language. Acids are substances having a sour taste; they are frequently highly corrosive of animal and vegetable bodies, and they change purple vegetable colours to a brighter red. Their most distinctive Chemical property is that they unite with other substances called bases, such as the Alkalis, the Earths, and Metallic oxides, and form a new class of bodies called Sulphites, in which the antagonist properties of both Acid and base undergo great modifications, or are absolutely annihilated.

We are in the habit of saying that one Acid is stronger than another, but the measure of the strength of the Acids respectively is not without some uncertainty. Various propositions have been made as to the scale to be adopted for this purpose, but none of these are quite free from objections. That which is most employed was proposed by Berthollet, and is taken from the relative quantities of different Acids required to saturate a given quantity of some base, but the plan is not free from objections.

The theory of Acidification, that is the effective cause producing acid properties, has engaged the attention of several Chemists; but as at this time there cannot be said to be any prevailing belief on the subject, we content ourselves with pointing out, by a reference, where the student may find any information that he may require on this subject. (k.)

(107.) The Etymology of the word Oxygen perpetuates the memory of a belief that once existed of that substance forming the element essential to the development of acid properties. This was, however, an error, as it will be seen from the following lists that the presence of Oxygen is not necessary to the formation of an Acid; and also that Hydrogen, which in many cases the antagonist of Oxygen, is capable of becoming the acidifying principle: while in some Acids neither the one nor the other exists.

### Class 1. Acids with Oxygen, and a nonmetallic radical:

We now proceed to the nomenclature of Greek system of derivation, and as it is liable to be divided. These are marked classes into which all substances are frequently divided. These are Inorganic and Organic. By the former we understand all such substances, whether simple or compound, as seem not to be capable of forming the chief constituents of bodies endowed with the functions of animal or vegetable life; although in such bodies they frequently exist as ultimate elements. In this division are comprehended the Metals, Earths, fixed Alkalis, the stronger Acids, and what were formerly called the simple non-metallic elements.

On the other hand, that which is called the Chemistry of Organic bodies, induces an examination of the various substances which form the existent elements, or the educts and products of animal and vegetable Organization. This branch of our Science chiefly refers to proximate elements, of which the number is very considerable. The properties of these bodies are well and distincitively marked; though in numerous cases the ultimate elements into which they may be resolved are precisely the same. Thus the Vegetable Acids and Alkalis may all be resolved into Oxygen, Hydrogen, and Carbon; and it is the various proportions in which these elements exist in the different substances which form the sole distinction discoverable upon their ultimate analysis.

We now proceed to the nomenclature of Chemical Compounds, and to the laws which regulate them, viz. the doctrines of Affinity, Definite Proportion, and the Theory of Atoms. After a careful examination of the systematic Treatises of our own and other Countries, and even after having prepared the greater part of what we deemed advisable to insert upon the subject, we have not hesitated to reject it, in favour of the Essay of a contemporary writer. In the main, we consider Dr. Turner's analysis of this part of our subject as the most clear that can be presented in the present state of our knowledge. We, therefore, shall make a considerable abstract from his Elements of Chemistry, taking only the liberty of making some slight alterations or additions which appear to us, or which have been pointed out by his reviewers, to be necessary. In some degree we shall also have to bring forward and discuss Professor Thomson's additions to our nomenclature, as developed and employed in his valuable Work on the First or Fundamental Principles of Chemistry.

(109.) "Chemistry is indebted for its nomenclature to the labours of four celebrated Chemists, Lavoisier, Berthollet, Guyton Morveau, and Fourcroy. The principles which guided them in its construction are exceedingly simple and ingenious. The known elementary substances, and the more familiar common ones, were allowed to retain the appellations which general usage had assigned to them. The newly discovered elements were named from some striking property. Thus, as it was supposed that acidity was always owing to the presence of the vital air discovered by Priestley and Scheele, they gave it the name of Oxygen, derived from two Greek words signifying generator of Acid; and they called inflammable air Hydrogen, from the circumstance of its entering into the composition of water."

"Compounds in which Oxygen forms a part were called Acids or Oxides, according as they do or do not possess acidity. An oxide of iron or copper signifies a combination of those metals with Oxygen, which has no acid properties. The name of an Acid was derived from the substance acidified by the Oxygen, to which was added the termination ic. Thus Sulphuric and Carbonic Acids signify acid compounds of Sulphur and Carbon with Oxygen Gas. If sulphur or any other body should form two Acids, that which contains the least quantity of Oxygen is made to terminate in ous, as Sulphurous Acid. The termination ured was intended to denote combinations of the simple non-metallic substances either with one another, with a metal, or with a metallic-oxide." This plan is still adhered to in France in the words Chloruret, Ioduret, &c., but in our own Country the analogy of the word oxide has been followed in the case of the five electro-negative bodies; thus we say chloride, iodide, fluoride, &c. "Sulphuret and carburet of iron, for example, signify compounds of sulphur or carbon with iron. The different oxides or sulphures of the same substance were distinguished from one another by some epithet, which was commonly derived from the colour of the compound, such as the black and red oxides of iron, the black and red sulphures of mercury. Though this practice is still continued occasionally, it is now more customary to distinguish degrees of oxidation by the use of derivatives from the Greek. Protoxide signifies the first degree of oxidation, Deutoxide the second, Tritoxide the third, and Peroxide the highest." The last term is rather objectionable, as being a departure from the Greek system of derivation, and as it is liable to be changed from new discoveries in the extent of oxidation. "The sulphures, carburetes, &c. of the same substance are designated in a similar way. The combination of Acids with Alkalis, Earths, or Metallic oxides, were termed Salts, the names of which were so contrived as to indicate the substances contained in them. If the acidified substance contains a maximum of oxygen, the name of the Salt terminates in ate, if a minimum, the termination in ate is employed. Thus the sulphate, phosphate, and arseniate of potash, are Salts of sulphuric, phosphoric, and arsenic Acids; while the terms sulphite, phosphite, and arsenite of potash denote combinations of that Alkali with the sulphurous, phosphorous, and arsenious Acids." This method, however, is found insufficient for its purpose, as it only provides for two degrees of oxygenation; hence the intermediate terms of hypo and hyper have been subsequently introduced.

"The advantage of a nomenclature which dispose
Chemistry, the different parts of a Science in so systematic an order, and gives such powerful assistance to the memory, is incalculable. The principle has been acknowledged in all Countries where Chemical Science is cultivated, and the minutest details of it have been adopted in Britain. It must be admitted, indeed, that some parts of it are defective. The erroneous idea of oxygen being the general acidifying principle has exercised an injurious influence over the whole structure. It would have been convenient also to have had a different name for hydrogen; but it is now too late to attempt a change, for the confusion attending such an innovation would more than counterbalance its advantages. The original nomenclature has therefore been preserved, and such additions made to it as the progress of the Science rendered necessary. The most essential improvement has been suggested by the discovery of the laws of Chemical combination. The different Salts formed of the same constituents were formerly divided into neutral, super, and subsalts. They were called neutral, if the Acid and Alkali are in the proportion for neutralizing one another; supersalts, if the Acid prevails; and subsalts, if the Alkali is in excess. The name is now regulated by the atomic constitution of the Salt. If it be a compound of one atom of the Acid to one atom of the Alkali, the generic name of the Salt is employed without any other addition; but if two or more atoms of the Acid be attached to one of the base, or two or more atoms of the base to one of the Acid, a numeral is prefixed so as to indicate its composition. The two Salts of sulphuric Acid and potash are called sulphate and bisulphate; the first containing one atom of the Acid to one atom of the Alkali; and the latter two of the former to one of the latter. The three Salts of oxalic Acid and potash are termed the oxalate, binoalate, and quadr-oxalate of potash; because one atom of the Alkali is united with one atom of the Acid in the first, with two in the second, and with four in the third Salt. As the numerals which denote the atoms of the Acid in a super-salt are derived from the Latin language, Dr. Thomson proposes to employ the Greek numerals, dis, tris, tetrakis, &c. to signify the atoms of Alkali in a subsalt."

"This method is in the true spirit of the original framers of our nomenclature. Chemists have already begun to apply the same principle to other compounds besides Salts; and there can be no doubt that it will be applied universally whenever our knowledge shall be in a state to admit of it." (l.)

(111.) The following paradigm will, perhaps, render the system of nomenclature more intelligible to the Chemical student.

For the sake of brevity, S. M. is put for sulphate of mercury.

The preceding scheme is only the rigid development of a plan proposed by Professor Thomson, in the Introduction to his *First Principles*, published in 1825.
The degrees of oxidation are marked by prefixes derived from the Greek, which, to be consistent, run Proto-, Deuto-, Trito-, Tetarto-, &c. First, Second, Third, Fourth, &c. The only deviation from this plan occurs in the word Sub, which should have been drawn Greco-Fonte, but being already in use, any alteration might prove inconvenient.

Upon each degree of oxidation a series of saline combinations may be produced; and it is necessary that words should be found to express atoms of Acid or of base so many times taken. Where the atom of base remains unity, and the atom of acid is once, twice, thrice, four times, &c., taken into combination, an ascending series of Latin numerals is employed. These obviously must be Bis, Ter, Quater, &c. And where, on the contrary, the atom of acid remains unity, and the atoms of base multiply, a series of numerals derived from the Greek are employed upon Dr. Thomson’s plan. These, of course, must be from the words δις, τρις, τετράς, &c. as in the paradigm.

The first part, therefore, of the name of a Salt so compounded informs us in what state of oxidation the metal exists; the second part gives us the proportion between the number of atoms of Acid and of base. If this second part be of Latin derivation, we know that our compound is a Sulphate; if of Greek derivation, we learn that it is a Subsalt.

For example, Deuto-ter-sulphate of mercury represents a Salt having for its base the oxide composed of 2 atoms of oxygen + 1 atom of mercury; and containing 3 atoms of Acid + 1 atom of base. But by Deuto-tri-sulphate of mercury we should understand the same base and the same Acid united in the proportion of 1 atom of Acid + 3 atoms of base.

In compounds of 1 atom of Acid + 1 atom of base we frequently leave out the prefix Prot-, in common usage, without inconvenience; but in those cases where numerous combinations exist, it is necessary always to make use of it; otherwise cases like this might occur, viz. a confusion between Trioxide of mercury and Tri-sulphate of mercury; which only become sufficiently distinct by adhering to the canon of nomenclature that gives Trioxide of mercury and Proto-tri-sulphate of mercury.

The definite proportions of all combinations between simple substances are expressed by Prot-, Deut-, Trit-, &c. as in the case of the oxides. Thus we say Protochloride, Deutiodide, Trioiodide, etc.

Some regard must be had to euphony, and the ordinary usages of compound words in constructing such names; thus we say Proto-bin-acetate, and not Protobi-acetate; Deuto-tri-oxalate, and not Deuto-trioxalate.

(112.) There are, however, several metallic oxides which the above system does not enable us clearly to express. Such are those which we at present describe in terms of half-atoms, saying that there are 1½ atoms of oxygen + 1 atom of base. It is probable that future researches will dispel this apparent anomaly, but for the present we are under the necessity of speaking of such combinations, and it would be convenient if our nomenclature could truly represent them to the mind.

At present the oxide of lead containing 1 atom of oxygen + 1 atom of base is called the Proxide; that containing 1½ atom of oxygen + 1 atom of base is called the Deutoxide; and that containing 2 atoms of oxygen + 1 atom of base is called the Tritoxide. But upon the common principles of our nomenclature, we should understand by these three words, three different oxides, containing 1, 2, and 3 atoms of oxygen respectively. It is with great difficulty, and with a full sense of the evils arising from any change made upon established names, that we venture to propose a plan for obviating this inconvenience. To obtain our end, we must borrow a custom from the German language. Ask a German what o’clock it is, and he will answer you halb sieben, for half-past six; and as we must keep to the Greek language for expressing the degrees of oxidation, we might use the prefix hemis, (ἡμισ, a half). Thus we should have in the case of Lead

1 Oxygen + 1 Metal = Protoxide of Lead.
1½ ditto + 1 ditto = Hemi-deutoxide of Lead.
2 ditto + 1 ditto = Deutoxide of Lead.

In the case of Manganese

1 Oxygen + 2 Metal = Sub-oxide.
1 ditto + 1 ditto = Protoxide.
1½ ditto + 1 ditto = Hemideutoxide.
2 ditto + 1 ditto = Deutoxide.
3 ditto + 1 ditto = Trioxide.

In this manner we could express any known combination, so that the name should fully express the relative atomic proportions of its constituents. We would also adopt the practice of many Chemists in banishing for ever the prefix Per, which has been used to express the highest degree of oxidation, partly because it is a Latin word, and therefore should not occur in the Greek ascending series: and partly, because we are never certain that we have arrived at the extreme degree of oxidation; and are, therefore, liable to have many of our names of Salts overturned by the discovery of a new degree of oxidation beyond the one with which we were previously acquainted.

At first sight this system of nomenclature may appear to present a formidable array of inharmonious words, but it is to be remembered that only a small proportion of the compounds so described are at present known to exist; and the advantages are not inconsiderable in a system which provides for the discovery of new substances, without requiring any change in names that may previously exist; and which always serves as a scheme of memoria technica for the atomic constitutions of the bodies named. We must admit that the plan now proposed may be liable to this objection, that in the strict meaning of the words, Protoxide, Deutoxide, &c., the first, second, &c., oxides are expressed; so that if what we call a Hemideutoxide exists, the Deutoxide is not the second but the third oxide. To us it seems that the choice lies between various methods, which all have their imperfections; but that the advantage of that system which, together with the name of the oxide or Salt, gives us its atomic constitution, outweighs all other considerations. It is also a serious affair to change terms which usage has established, but the plan proposed can scarcely be said to do so.

Affinity.

(113.) “All Chemical phenomena are owing to Affinity. Affinity or Chemical attraction. It is the basis on which the Science of Chemistry is founded. It is the ruling power with reference to which all the operations of the
Chemist are conducted, and hence it forms the first and leading object of his study.

"Affinity is exerted between the minutest particles of different kinds of Matter, causing them to combine so as to form new bodies, endowed with new properties. It acts only at insensible distances; in other words, apparent contact, or the closest proximity, is necessary to its action. Everything which prevents such contiguity is an obstacle to combination, and any force which increases the distance between particles already combined, tends to separate them permanently from each other. In the first case they do not come within the sphere of their mutual attraction; in the second they are removed out of it. It follows, therefore, that though Affinity is regarded as a specific power, distinct from the other forces which act on matter, its action may be promoted, modified, or counteracted, by several circumstances; and, consequently, in studying the phenomena produced by Affinity, it is necessary to begin by inquiring into the conditions that influence its operation.

The most simple instance of the exercise of Chemical attraction is afforded by the mixture of two substances with one another. Water and sulphuric acid, or water and alcohol, combine readily. On the contrary, water shows little disposition to unite with sulphuric ether, and still less with oil; nor, however intimately their particles may be mixed together, they are no sooner left at rest, than the ether separates almost entirely from the water, and a total separation takes place between that fluid and the oil. Sugar dissolves very sparingly in alcohol, but to any extent in water; while camphor is dissolved in very small quantity by water, but abundantly by alcohol. It appears from these examples, that Chemical attraction is exerted between different bodies with different degrees of force. There is sometimes no proof of its existence at all; between some substances it acts very feebly, and between others with great energy.

Simple combination of two principles is a common occurrence. The solution of Salts in water, the combustion of phosphorus in oxygen gas, and the neutralization of a pure Alkali by an Acid, are instances of the kind. The phenomena are, however, often more complex. It frequently happens that the formation of a new compound is attended by the destruction of an existing one. The only condition necessary for this effect is the presence of some third body, which has a greater Affinity for one of the elements of a compound, than they have for one another. Thus oil has an affinity for the volatile Alkali, ammonia, and will unite with it, forming a soapy substance called a liniment. But the ammonia has a still greater attraction for sulphuric Acid; and hence, if the Acid be added to the liniment, the Alkali will quit the oil, and unite by preference with the Acid. If a solution of camphor in alcohol be poured into water, the camphor will be set free, because the alcohol combines with the water. Sulphuric Acid, in like manner, separates baryta from Muriatic Acid. Combination and decomposition occur in each of these cases; combination of the Sulphuric Acid with the ammonia, of the water with the alcohol, and of the baryta with the sulphuric Acid; decomposition of the compounds formed of the oil and ammonia, of the alcohol and camphor, and of the Muriatic Acid and baryta. These are examples of what Bergmann calls single elective Affinity; elective, because a substance manifests, as it were, a choice for one of two others, uniting with it by preference, and to the exclusion of the other. Many of the decompositions that occur in Chemistry, are instances of single elective Affinity.

The order in which these decompositions take place has been expressed in Tables; of which the following, drawn up by Geoffroy, is an example:

**Sulphuric Acid.**

"This Table signifies, first, that Sulphuric Acid has an Affinity for the substances placed below the horizontal line, and can, therefore, unite separately with each of them; and, secondly, that the base of the Salts so formed will be separated from the Acid by adding any of the Alkalis or Earths which stand above it in the column. Thus ammonia will separate magnesia, lime, ammonia, and potash lime; but none of them can withdraw baryta from Sulphuric Acid, nor can ammonia or magnesia decompose the sulphate of lime, though stronitia or baryta will do it. Bergmann conceived that these decompositions were solely determined by Chemical attraction, and that, consequently, the order of decomposition represented the comparative forces of Affinity: and this view, from the simple and natural explanation it afforded of the phenomenon, was for a time very generally adopted. But Bergmann was in error. It does not necessarily follow, because lime can separate ammonia from Sulphuric Acid, that the lime has a greater attraction for the Acid than the volatile Alkali. Other causes are in operation which modify the action of Affinity to such a degree, that it is impossible to discover how much of the effect is owing to that power. It is conceivable that the ammonia may in reality have a stronger attraction for Sulphuric Acid than lime, and yet the lime, from the great influence of disturbing causes, might succeed in decomposing sulphate of ammonia.

The justice of the foregoing remark will be made obvious by the following example: when a stream of hydrogen gas is passed over the oxide of iron heated to redness, it deprives the iron of its oxygen entirely, combing with it so as to form water. On the contrary, when watery vapour is brought into contact with red hot metallic iron, the oxygen of the water quits the hydrogen, and combines with the iron. It follows from the result of the first experiment, according to Bergmann, that hydrogen has a stronger attraction for oxygen than iron has; and from the second, that iron has a greater Affinity for oxygen than hydrogen has. But these inferences are incompatible with each other. The Affinity of hydrogen for oxygen must either be equal to that of iron, or greater or less. If the first is the case, then the result of both experiments was determined by modifying circumstances; since neither of these substances ought on this supposition to take oxygen from the other. If the second, then the decomposition in one of the experiments must have been determined by extraneous causes in direct opposition to the tendency of Affinity.

"To Berthollet is due the honour of pointing out the fallacy of Bergmann's opinion. He was the first to show that the relative forces of Chemical attraction
Affinity is the cause of still more complicated changes than those which have been just considered. In a case of single elective affinity, three substances only are present, and two affinities are in play. But it frequently happens that two compounds are mixed together, and four different affinities brought into action. The changes that may or do occur under these circumstances are most conveniently studied by aid of a diagram, a method that was, I believe, first employed by Dr. Black, and has since been generally practised. Thus in mixing together a solution of the carbonate of ammonia and muriate of lime, their mutual action may be represented in the following manner:

\[
\text{Carbonic Acid} \quad \text{Ammonia} \\
\text{Muriatic Acid} \quad \text{Lime}
\]

Each of the acids has an attraction for both the bases, and hence it is possible either that the two salts should continue as they are, or that an interchange of principles should ensue, giving rise to two new compounds, the carbonate of lime, and muriate of ammonia. According to the views of Bergmann, the result is solely dependent on the comparative strength of affinities. If the affinity of the carbonic acid for the ammonia, and of the muriatic acid for the lime, exceed that of the carbonic acid for lime, added to that of the muriatic acid for ammonia, then will the two salts experience no change whatever; but if the latter affinities preponderate, then, as does actually happen in the present example, both the original salts will be decomposed, and two new ones generated. Two decompositions and two combinations take place, being an instance of what is called double elective affinity. Mr. Kirwan applied the terms quiescent and divellent, to denote the tendency of the opposing affinities, the action of the former being to prevent a change, that of the latter to produce it.

The doctrine of double elective affinity was assailed by Berthollet on the same ground, and with the same success as in the case of single elective attraction. He succeeded in proving that the effect cannot always be ascribed to the sole influence of affinity. For, to take the example already adduced, if the carbonate of ammonia decompose the muriate of lime by the mere force of a superior attraction, it is manifest that the carbonate of lime ought never to decompose the muriate of ammonia. But if these two salts are mixed in a dry state, and exposed to heat, double decomposition does take place, carbonate of ammonia and muriate of lime being formed; and, therefore, if the change in the first example was produced by chemical attraction alone, that in the second must have occurred in direct opposition to that power. It does not follow, however, because the result is sometimes determined by modifying conditions, that it must always be so. I apprehend that the decomposition of chlorine and cyanuret of mercury by sulphuretted hydrogen gas, which takes place even at a low temperature, cannot be ascribed to any other cause than a preponderance of the divellent over the quiescent affinities.

On the Changes that accompany Chemical Action.

The leading circumstance that characterizes chemical action is the loss of properties, experienced by the combining substances, and the acquisition of new ones by the product of their combination. The change of property is sometimes inconsiderable. In a solution of sugar or salt in water, and in mixtures of water with alcohol or sulphuric acid, the compound retains so much of the character of its constituents, that there is no difficulty in recognising their presence. But more generally the properties of one or both of the combining bodies disappear entirely. No ingenuity could guess a priori that water is a compound body, much less that it is composed of two gases, oxygen and hydrogen, neither of which, when uncombined, has ever been compressed into a liquid. Hydrogen is one of the most inflammable substances in nature, and yet water cannot be set on fire; oxygen, on the contrary, enables bodies to burn with great brilliancy, and yet water extinguishes combustion. The alkalis and earths were regarded as similar kind are afforded by the action of acids and alkalis on one another. Sulphuric acid and potash, for example, are highly caustic. The former is intensely sour, reddens the blue colour of vegetables, and has a strong affinity for alkaline substances; the latter has a pungent taste, converts the blue colour of vegetables to green, and combines readily with acids.
Density.

It is observed that two bodies rarely occupy the same space after combination which they did separately. In general their bulk is diminished, so that the specific gravity of the new body is greater than the mean of its components. Thus a mixture of 100 measures of water, and an equal quantity of Sulphuric Acid, does not occupy the space of 200 measures, but considerably less. A similar contraction frequently attends the combination of Solids. Gases often experience a remarkable diminution in the bulk of the combining substances, without a change of form, or when a Gas is condensed into a liquid, or when a Liquid becomes solid. The heat caused by mixing Sulphuric Acid with water is an instance of the former; and the common process of slaking lime, during which water loses its liquid form, in combining with that Earth, is an example of the second. The rise of temperature in these cases is obviously referable to a diminution in the capacity of the new compound for caloric; but an intense degree of heat sometimes accompanies Chemical action under circumstances in which an explanation founded on a change of specific caloric is quite inadmissible. At present it is enough to have stated the fact; the theory belongs to a different branch of our Science. The production of cold seldom or never takes place during combination, except when the specific caloric is suddenly increased by the conversion of a Solid into a Liquid, or a Liquid into a Gas. All the frigorific mixtures act in this way.

Form.

The changes of form that attend Chemical action are exceedingly various. The combination of Gases may give rise to a Liquid or a Solid; Solids sometimes become Liquids, or Liquids solid. Several familiar Chemical phenomena, such as explosions, effervescence, and precipitations, are owing to these changes. The sudden evolution of a large quantity of Gaseous matter occasions an explosion, as when gunpowder detonates. The slower disengagement of a Gas causes effervescence, as occurs when marble is put into Muriatic Acid. A precipitate is owing to the formation of a new body, which happens to be insoluble in the Liquid in which its elements were dissolved.

Colour.

The colour of a compound is frequently quite different from that of the substances which form it. There does not appear to be any uniform relation between the colour of a compound and that of its elements, so that it is not possible to anticipate the colour of any particular compound, by knowing the principles which enter into its composition. Iodine, whose vapour is of a violet hue, forms a beautiful red compound with mercury, and a yellow one with lead. The brown oxide of copper generally gives rise to green and blue coloured Salts; while the Salts of the oxide of lead, which is itself colourless, are for the most part colourless. The colour of precipitates is a very important study, as it often enables the Chemist to distinguish bodies from one another when in solution.
Crystallization appears to be only a modification of the ordinary cohesion of Solids; it probably depends on molecular polarity. A Fluid may contain a certain quantity of a Solid in solution; but let a portion of the Liquid be evaporated, so that the quantity of the Solid remains, while the quantity of Fluid is diminished. At a certain period in this process the Affinity of the Liquid for the Solid, is in equilibrium with the force of cohesion between the molecules of the Solid; but let the evaporation be continued, the latter force will preponderate, and then the particles of the Solid will cohere. In some cases the resulting Solid will present a crystalline form; but in others it will be only a powder. This difference in result arises from the nature of the attraction with which its molecules are endowed; but as far as Affinity is concerned, the cohesive force opposed to it differs not in kind, though it may possibly differ in intensity. With the measure of such difference we are at present unacquainted. Generally speaking, crystalline bodies are more soluble than those that are not so, but this rule is not invariable, and in many cases the increase of solubility depends greatly upon water of crystallization.

Elasticity. 

"From the obstacle which cohesion puts in the way of Affinity, the Gaseous state, in which the cohesive power is wholly wanting, might be expected to be peculiarly favourable to Chemical action. The reverse, however, is the fact. Bodies evince little disposition to unite when presented to each other in the elastic form. Combination does indeed sometimes take place, in consequence of a very energetic attraction; but examples of an opposite kind are much more common. Oxygen and hydrogen, and chlorine and hydrogen, though their mutual Affinity is very powerful, may be preserved together for any length of time without combining. The cause of this is obviously the distance between the particles preventing that close approximation which is so necessary to the successful exercise of Affinity. Hence many Gases cannot be made to unite directly, which nevertheless combine readily while in their nascent state; that is while in the act of assuming the Gaseous form by the decomposition of some of their solid or fluid combinations."

"Elasticity operates likewise as a decomposing agent. If two Gases whose reciprocal attraction is feeble, suffer considerable condensation when they unite, the compound will be decomposed by very slight causes. The chloride of nitrogen, which is an oil-like Liquid, composed of the two Gases chlorine and nitrogen, answers this description completely, and it is remarkable for being the most explosive substance hitherto discovered. A slight elevation of temperature, by increasing the natural elasticity of the Gases, or the contact of substances which have an Affinity for either of them, produces an immediate explosion."

"Many familiar phenomena of decomposition are owing to Elasticity. All compounds that contain a volatile and a fixed principle are liable to be decomposed by a high temperature." This statement has been objected to (m), and with reason, if by "liable to" we are to understand "certain to;" but, probably, the meaning is only that a tendency thence results, which in some cases may produce decomposition, but in others does not so. In the Review by which the objection is advanced the following opposite cases are cited, viz.

Chemistry. 

conceive are applicable to the case of four or more ingredients. It may be just to state that these opinions are not those of Dr. Turner, to whose Work we are on these points so much indebted, and to which we shall shortly return.

Crystallization. 

"From the obstacle which cohesion puts in the way of Affinity, the Gaseous state, in which the cohesive power is wholly wanting, might be expected to be peculiarly favourable to Chemical action. The reverse, however, is the fact. Bodies evince little disposition to unite when presented to each other in the elastic form. Combination does indeed sometimes take place, in consequence of a very energetic attraction; but examples of an opposite kind are much more common. Oxygen and hydrogen, and chlorine and hydrogen, though their mutual Affinity is very powerful, may be preserved together for any length of time without combining. The cause of this is obviously the distance between the particles preventing that close approximation which is so necessary to the successful exercise of Affinity. Hence many Gases cannot be made to unite directly, which nevertheless combine readily while in their nascent state; that is while in the act of assuming the Gaseous form by the decomposition of some of their solid or fluid combinations."

"Elasticity operates likewise as a decomposing agent. If two Gases whose reciprocal attraction is feeble, suffer considerable condensation when they unite, the compound will be decomposed by very slight causes. The chloride of nitrogen, which is an oil-like Liquid, composed of the two Gases chlorine and nitrogen, answers this description completely, and it is remarkable for being the most explosive substance hitherto discovered. A slight elevation of temperature, by increasing the natural elasticity of the Gases, or the contact of substances which have an Affinity for either of them, produces an immediate explosion."

"Many familiar phenomena of decomposition are owing to Elasticity. All compounds that contain a volatile and a fixed principle are liable to be decomposed by a high temperature." This statement has been objected to (m), and with reason, if by "liable to" we are to understand "certain to;" but, probably, the meaning is only that a tendency thence results, which in some cases may produce decomposition, but in others does not so. In the Review by which the objection is advanced the following opposite cases are cited, viz.

Chemistry.

that hydrate of copper is decomposed by a red heat, while hydrate of potash is not so. The compound of chloride of phosphorus and ammonia, which contains three elementary Gases, and a very volatile Solid, is not only very difficult of decomposition, but is not volatile at a red heat. Where, however, decomposition does occur we may return to Dr. Turner's explanation of the process. "The expansion occasioned by caloric removes the elements of the compound to a greater distance from one another, and thus, by diminishing the force of Chemical attraction, favours the tendency of the volatile principle to assume the form which is natural to it. Many solid substances which contain water in a state of intimate combination, part with it in a strong heat, in consequence of the volatile nature of that Liquid. The separation of oxygen from some metals by heat alone, is explicable on the same principle.

It appears from these and some preceding remarks, that the influence of caloric over Affinity is variable; for at one time it promotes Chemical union, and opposes it at another. Its action, however, is always consistent. Whenever the cohesive power is an obstacle to combination, caloric favours Affinity, as by diminishing the cohesion of a Solid, or by converting a Solid into a Liquid. As the cause of the Gaseous state, on the contrary, it keeps particles at a distance which would otherwise unite; or by producing expansion, it tends to separate substances from one another, which are already combined. There is one effect of caloric which seems somewhat anomalous; namely, the combination of Gases on the approach of flame. The explanation given of it by Berthollet is, probably, correct,—that the sudden dilatation of the Gases in the immediate vicinity of the flame, acts as a violent compressing power to the contiguous portions, and thus brings them within the sphere of their attraction.

"The influence of quantity of Matter over Affinity is universally admitted. If one body A unites with another body B in several proportions, that compound will be most difficult of decomposition which contains the smallest quantity of B. Of the three oxides of lead, for instance, the peroxide parts most easily with its oxygen by the action of caloric; a higher temperature is required to decompose the deutoxide, and the protoxide will bear the strongest heat of our furnaces without losing a particle of its oxygen.

"The influence of quantity over Chemical attraction may be further illustrated by the phenomena of solution. When equal weights of a soluble Salt are added in succession to a given quantity of water, which is capable of dissolving almost the whole of the Salt employed, the first portion of the Salt will disappear more readily than the second, the second than the third, the third than the fourth, and so on. The affinity of the water for the saline substance diminishes with each addition, till at last it is weakened to such a degree as to be unable to overcome the cohesion of the Salt. The process then ceases, and a saturated solution is obtained.

"Quantity of Matter is employed advantageously in many Chemical operations. If, for instance, a Chemist is desirous of separating an Acid from a metallic oxide by means of the superior Affinity of potash for the former, he frequently uses rather more of the Alkali than is sufficient for neutralizing the Acid. He takes the precaution of employing an excess of Alkali, in order the
more effectually to bring every particle of the substance to be decomposed in contact with the decomposing agent.

But Berthollet has attributed a much greater influence to quantity of Matter. It was the basis of his doctrine, developed in the Staticque Chimique, that bodies cannot be wholly separated from each other by the affinity of a third substance for one element of a compound; and to explain why a superior Chemical attraction does not produce the effect which might be expected from it, he contended that quantity of Matter compensated for a weaker affinity. From the cooperation of several disturbing causes, Berthollet perceived that the force of Affinity cannot be estimated with certainty by observing the order of decomposition; and he, therefore, had recourse to another method. He set out by supposing that the Affinity of different Acids for the same alkali is in the inverse ratio of the ponderable quantity of each, which is necessary for neutralizing equal quantities of the alkali. Thus, if two parts of one Acid A, and one part of another Acid B, are required to neutralize equal quantities of the alkali C, it was inferred that the Affinity of B for C was twice as great as that of A. He conceived further, that as two parts of A produce the same neutralizing effect as one part of B, the attraction exerted by any alkali towards the two parts of A ought to be precisely the same as for the one part of B; and he hence concluded that there is no reason why the alkali should prefer the small quantity of one to the large quantity of the other. On this he founded the principle that quantity of Matter compensates for force of attraction.

Berthollet has here obviously confounded two things, namely, force of attraction and neutralizing power, which are really different, and ought to be held distinct. The relative weights of muriatic and sulphuric Acids required to neutralize an equal quantity of any alkali, or, in other words, their capacities of saturation, are as 37 to 40, a ratio which remains constant with respect to all other alkalis. The Affinity of these Acids will, according to Berthollet’s rule, be expressed by the same numbers. But in taking this estimate we have to make three assumptions, all of which are disputable. There is no proof, in the first place, that muriatic Acid has a greater Affinity for an alkali, such as potash, than sulphuric Acid. Such an inference would be directly opposed to the general opinion founded on the order of decomposition; and though that order is by no means a satisfactory test of the strength of Affinity, it would be improper to adopt an opposite conclusion without having good reasons for doing so. Secondly, were it established that muriatic Acid has the greater Affinity, it does not follow that the attraction of these Acids for potash is in the ratio of 37 to 40. And, thirdly, supposing this point settled, it is very improbable that the ratio of their Affinity for one alkali will apply to all others; analogy would lead us to anticipate the reverse. Independently of these objections, M. Dulong has found that the principle of Berthollet is not in accord with the results of experiment.

Though this mode of determining the relative forces of Affinity cannot be admitted, it is possible that quantity of Matter may, some how or other, compensate for a weaker Affinity, and Berthollet attempts to prove it by experiment. On boiling the sulphate of baryta with an equal weight of pure potash, the alkali is found to have deprived the baryta of a small portion of its Acid; and on treating oxalate of lime with nitric Acid, some nitrate of lime is generated. As these partial decompositions are contrary to the supposed order of elective Affinity, it was conceived that they were produced by quantity of Matter acting in opposition to force of attraction. But they by no means justify such a conclusion. In the decomposition of sulphate of baryta by potash, no care was taken to exclude the atmospheric air during the operation; the alkali must consequently have absorbed carbonic Acid; and it is an established fact, that carbonate of potash decomposes partially the sulphate of baryta. A similar omission appears to have been made in the other experiments, where decomposition was attempted by pure potash or soda. In many cases the result may fairly be attributed to other causes.

A circumstance that influences the result of such experiments, and which Berthollet left out of view entirely, is the affinity of Salts for one another. On the whole therefore, we may infer that Berthollet has given no satisfactory case in which quantity of Matter is proved to compensate for a weaker Affinity. Saline substances indeed seem ill adapted to such researches. For it is impossible in many, if not in most cases, to decide upon the relative strength of attraction of two Acids for an alkali, or of two alkalis for an Acid, which, nevertheless, is an important element in the inquiry; and even did we possess such knowledge, the influence of modifying circumstances is such, that it is difficult to appreciate the share they may have in producing a given effect.

The influence of Gravity is perceptible when it is Gravity, wished to make two substances unite, the densities of which are different. In a case of simple solution, a larger quantity of saline matter is found at the bottom than at the top of the Liquid, unless the solution shall have been well mixed subsequently to its formation. In making an alloy of two metals which differ from one another in density, a larger quantity of the heavier metal will be found at the lower than in the upper part of the compound, unless great care be taken to counteract the tendency of Gravity by agitation. This force obviously acts, like the cohesive power, in preventing a sufficient degree of approximation.

(114.) The agency of Caloric, Light, Electricity Imponderable and Magnetism upon Chemical Affinity has been already generally adverted to. See (3.)—(40.)

On the Measure of Affinity.

As foregoing observations prove that the order of decomposition is not always a satisfactory measure of Affinity, it becomes a question whether there are any means of determining the comparative forces of Chemical attraction. When no disturbing causes operate, the phenomena of decomposition afford a sure criterion; but when the conclusions obtained in this way are doubtful, assistance may be frequently derived from other sources. The surest indications are procured by observing the tendency of different substances to unite with the same principle, under the same circumstances, and subsequently by marking the comparative facility of decomposition when the compounds so formed are exposed to the same decomposing agent. Thus on exposing gold, lead, and iron to air and moisture, the iron rusts with great rapidity, the lead is only tarnished, and the silver retains its lustre. It is hence inferred that iron has the greatest Affinity for oxygen, lead next,
and silver least. This conclusion is supported by concurring observations of a like nature, and confirmed by the circumstances under which the oxides of those metals part with their oxygen. The oxide of silver is reduced by heat alone; and the oxide of lead is decomposed by charcoal at a lower temperature than the oxide of iron.

It is inferred from the action of caloric on the carbonates of potash, baryta, lime, and the oxide of lead, that potash has a stronger attraction for carbonic Acid than baryta, baryta than lime, and lime than the oxide of lead. The Affinity of different substances for water may be determined in a similar manner.

Of all Chemical substances our knowledge of the relative degrees of attraction of the Acids and alkalis for each other is the most uncertain. Their action on one another is affected by so many circumstances, that it is in most cases impossible, with certainty, to refer any effect to its real cause. The only methods that have been hitherto devised for remedying this defect are those of Berthollet and Kirwan. Both of them are founded on the capacities of saturation; and the objections which have been urged to the rule suggested by the first Philosopher, apply equally to that proposed by the second. But this uncertainty is of no great consequence in practice. We know perfectly the order of decomposition, whatever may be the actual forces by which it is effected.

On the Proportions in which bodies unite, and on the Laws of Combination.

(115.) "The study of the proportions in which bodies unite naturally resolves itself into two parts. The first includes compounds whose elements appear to unite in a great many proportions; the second comprehends those, the elements of which combine in a few proportions only.

I. "The compounds contained in the first division are of two kinds. In one, combination takes place unlimited in all proportions; in the other, it occurs in every proportion within a certain limit. The union of water with alcohol and the liquid Acids, such as the sulphuric, muriatic, and nitric Acids, are instances of the first sort. Of Combination; and the solutions of Salts in water are examples of the second. One drop of sulphuric Acid may be diffused through a gallon of water, or a drop of water through a gallon of the Acid; or they may be mixed together in any intermediate proportions, and in each case they appear to unite perfectly with one another. A hundred grains of water, on the contrary, will dissolve any quantity of sea salt which does not exceed forty grains. Its dissolving power then ceases, because the cohesion of the Solid becomes comparatively too powerful for the force of affinity. The limit to Combination is, in such instances, owing to the cohesive power; and but for the obstacle which it occasions, the salt would, most probably, unite with the water in every proportion.

All the substances that unite in many proportions, give rise to compounds which have this common character, that their elements are united by a feeble affinity, and preserve when combined more or less of the properties which they possess in a separate state. In a Scientific point of view, these Combinations are of minor importance; but they are exceedingly useful as instruments of research. They enable the Chemist to present bodies to one another, under the most favourable circumstances possible for acting with effect; the liquid form is thus communicated to them, while the affinity of the solvent or menstruum, which holds them in solution, is not sufficiently powerful to interfere with their attraction for one another.

II. "The most interesting series of compounds is produced by substances which unite in a few proportions only; and which, in combining, lose more or less completely the properties that distinguished them when separate. Of these bodies, some form but one Combination. Thus there is only one compound of zinc and oxygen, or of chlorine and hydrogen. Others combine in two proportions. For example, two compounds are formed by copper and oxygen, or by hydrogen and oxygen. Other bodies again unite in three, four, five, or even six proportions, which is the greatest number of compounds that any two substances are known to produce, excepting those which belong to the first division.

"The Combination of substances that unite in a few proportions only, is regulated by three remarkable laws. The first of these laws is, that the composition of bodies is fixed and invariable; that a compound substance, so long as it retains its characteristic properties, must always consist of the same elements united together in the same proportion. Sulphuric Acid, for example, is always composed of sulphur and oxygen, in the ratio of 16 parts (by weight) of the former to 24 of the latter: no other element can form it, neither can its own elements in any other proportion form it. Water, in like manner, is formed of 1 part of hydrogen and 8 of oxygen; and were these two elements to unite in any other proportion, some new compound different from water would be the product. The same observation applies to all other substances, however complicated, and at whatever period they were produced. Thus sulphate of baryta, whether formed Ages ago by the hand of nature, or quite recently by the operations of the Chemist, is always composed of 40 parts of sulphuric Acid and 78 parts of baryta. This law, in fact, is universal and permanent. Its importance is equally manifest. It is the essential basis of Chemistry, without which the Science itself could have no existence.

Two views have been proposed for accounting for this law. The explanation now universally given of it is confined to a mere statement, that substances are disposed to combine in those proportions to which they are so strictly limited, in preference to any others; it is regarded as an ultimate fact, because the phenomena are explicable on no other known principle. A different doctrine was advanced by the celebrated Berthollet, in his Statique Chimique, published in 1803. Having observed the influence of cohesion and elasticity in modifying the action of affinity, as already described, he thought he could trace the operation of the same causes in producing the effect at present under consideration. Finding that the solubility of a Salt and of a Gas in water was limited in the first by cohesion, and in the second by elasticity, he conceived that the same forces would account for the unchangeable composition of certain compounds. He maintained, therefore, that within certain limits, bodies have a tendency to unite in every proportion; and that Combination is never definite and invariable, except when rendered so by the operation of modifying causes, such as cohesion, insolubility, elasticity, quantity of Matter, and the like.
Thus, according to Berthollet, sulphate of baryta is composed of 40 parts of sulphuric Acid and 78 of baryta, not because these substances are disposed to unite in that ratio rather than in any other, but because the compound so constituted has a great cohesive power.

These opinions, which, if true, would shake the whole Science of Chemistry to its foundation, were founded on observation and experiments, supported by all the ingenuity of that highly gifted Philosopher. They were ably and successfully combated by Proust, in several Papers published in the Journal de Physique, wherein he proved that the metals are disposed to combine with oxygen and with sulphur only in one or two proportions, which are definite and invariable. The controversy which ensued between these eminent Chemists on that occasion, is remarkable for the moderation with which it was conducted on both sides, and has been properly quoted by Berzelius as a model for all future controversialists. How much more sober opinion may have been divided upon this important question at that period, the dispute is now at an end. The infinite variety of new facts, similar to those observed by Proust, which have since been established, has proved beyond a doubt that the leading principle of Berthollet is quite erroneous. The tendency of bodies to unite in definite proportions only, is indeed so great as to excite a suspicion that all substances combine in this way; and that the exceptions thought to be afforded by the phenomena of solution, are rather apparent than real; for it is conceivable that the apparent variety of proportion noticed in such cases may arise from the mixture of a few definite compounds with each other.

The second law of Combination is still more remarkable than the first. It has given plausibility to an ingenious hypothesis concerning the ultimate particles of matter, called the Atomic Theory. The law itself, however, contains nothing hypothetical, being the pure expression of a fact first established by Mr. Dalton, and subsequently by many other Chemists. The nature of it will be at once understood by a simple perusal of the following table:

<table>

Now it will be perceived that in all these compounds, the numbers denoting the oxygen, which is attached to a given weight of the same base, bear a very simple ratio to one another. The deutoxide of hydrogen contains just twice as much oxygen as water does. The oxygen in carbonic acid is double that of carbonic oxide. The oxygen in the compounds of nitrogen and oxygen is in the ratio of 2 to 3, 4, and 5. So obvious, indeed, is this law, that it is observed at once when we compare the result of a few accurate analyses together; and the only subject of surprise is, that it was not discovered before. It is by no means confined to the compounds of combustibles with oxygen. Thus the sulphur in the two sulphurets of mercury, the chlorine in the two chlorides of mercury, is as 1 to 2. It extends also to the Salts. The bicarbonate of potassa, for example, contains twice as much carbonic Acid as the carbonate; and the oxalic Acid of the three oxalates of potassa is in the ratio of 1, 2, and 4. We must regard it, therefore, as a general law, the enunciation of which may be stated in the following terms. When two substances, A and B, unite chemically, the quantities of the two bodies must either be equal, or in the ratio of multiples or submultiples of each other. It is often called the law of multiples, or of Combination in multiple proportion.

Every one who hears this singular law announced for the first time, will naturally inquire if it really holds good in all cases. It may be stated in reply, that the examination of numerous compound bodies leaves no room to question the universality of the law; but that it is impossible from the present condition of the Science that every instance should be in accord with it. Two causes are in operation which tend to prevent such perfect coincidence. In the first place, we are not yet acquainted with all possible combinations; and secondly, our knowledge of the composition of known substances is not always precise; circumstances which will not excite surprise when it is considered, that the Science of Chemistry itself, and especially the Art of making accurate analyses, is of very recent origin. The mode in which the first cause operates is obvious: the effect of the second may be illustrated by a few examples. A few years ago Chemists were acquainted with only two compounds of sulphur and oxygen, the sulphurous and sulphuric Acids; the former of which is composed of 16 sulphur and 16 oxygen, and the latter of 16 sulphur and 24 oxygen. The quantity of oxygen combined with the same weight of sulphur in these compounds is in the ratio of 2 to 3. But this exception to the law of multiples was only apparent, arising from our ignorance of the hyposulphurous Acid, a compound which was first noticed by Gay Lussac in the year 1813. It is composed of 16 parts of sulphur and 8 of oxygen, so that the oxygen in the three compounds is as 1, 2, and 3. Arsenic affords an example of the same kind, in which, however, the anomaly is not yet explained. We know only two combinations of arsenic and oxygen which are thus constituted:

<table>
<thead>
<tr>
<th>Arsenic Acid</th>
<th>Oxygen</th>

<td>Arsenious Acid</td>
<td>39 + 16</td>
</tr>
<tr>
<td>Arsenic Acid</td>
<td>38 + 24</td>
</tr>
</tbody>
</table>

in which the oxygen is as 2 to 3. But we may confidently expect, on two grounds, that an oxide of arsenic will hereafter be discovered: first, because there is the analogous case of sulphur to justify such a supposition; and, secondly, because arsenic may be expected to form, like the other metals, a salifiable base with oxygen. The three compounds of oxygen and lead are composed of

<table>
<thead>
<tr>
<th>Lead</th>
<th>Oxygen</th>

</tr>
<tr>
<td>Peroxide (deutoxide, E. M.)</td>
<td>104 + 16</td>
</tr>
</tbody>
</table>

and the proportion of oxygen, therefore, is as 1, 1½, and 2. But it is manifest that the discovery of an oxide formed of 104 to 4 of oxygen, would at once make these compounds harmonize with Mr. Dalton's law.
The third law of Combinations is as fully as remarkable as the preceding, and is intimately connected with it. Water and hyposulphurous Acid may be adduced by way of illustration. The former is composed of 8 oxygen + 1 hydrogen; the latter of 8 oxygen + 16 sulphur. Now it is singular, that the well-known substance, sulphuretted hydrogen, is constituted of 1 hydrogen + 16 sulphur; that is, the quantities of hydrogen and of sulphur, which combine with the same quantity of oxygen, combine with one another. Again, 40 parts of selenium with 8 of oxygen form the oxide of selenium, and with 1 of hydrogen, selenium-hydroselenious Acid; 36 parts of chlorine with 8 of oxygen constitute the oxide of chlorine, and with 1 of hydrogen form muriatic Acid Gas; 16 parts of sulphur combine with 36 of chlorine to form the chloride of sulphur.

It is manifest from these examples, that bodies unite according to proportionable numbers; and hence has arisen the use of certain terms, as proportion, combining proportion, or equivalent, to express them. Thus the combining proportions of the substances just alluded to are

<table>
<thead>
<tr>
<th>Substance</th>

<tr>
<td>Selenium</td>
<td>40</td>
</tr>
</tbody>
</table>

When one body combines with another in more than one proportion, then the law of multiples already explained comes into action. Thus,

Hyposulphur. Oxygen.

Hyposulphurous Acid is composed of 16 or 1 pr. + 8 or 1 pr.
Sulphurous Acid .......... 16 or 1 pr. + 16 or 2 pr.
Sulphuric Acid .......... 16 or 1 pr. + 24 or 3 pr.

The most common kind of combination is one proportion of one body either with one or with two proportions of another. Combinations of 1 + 3, or 1 + 4, are very uncommon, unless the more simple compounds likewise exist. Ammonia, however, is a singular instance of the reverse. It is composed of nitrogen 14 parts + hydrogen 3 parts. Now, 14 is the precise quantity of nitrogen which unites with 8 of oxygen; and, therefore, 14 is considered as one proportion of nitrogen, which is consequently combined with three proportions of hydrogen. It is probable that compounds of 1 + 1 and 1 + 2 will hereafter be discovered, but they are quite unknown at present.

But this law does not apply to elementary substances only, since compound bodies have their combining proportions, which may likewise be expressed in numbers. Thus, since water is composed of one proportion, or 8 of oxygen, and one proportion, or 1 of hydrogen, its combining proportion is 9. The proportion of sulphuric Acid is 40, because it is a compound of one proportion, or 16 of sulphur, and three proportions, or 24 of oxygen; and in like manner the combining proportion of muriatic Acid is 37, because it is a compound of one proportion, or 36 of chlorine, and one proportion, or 1 of hydrogen. The proportional number of potassium is 40, and as that quantity combines with 8 of oxygen to form potash, the combining proportion of potash is 48. Now when these compounds unite, one proportion of the one combines with one, two, three, or more proportions of the other, precisely as the simple substances do. The hydrate of potash, for example, is constituted of 48 potash and 9 of water, and its combining proportion is consequently 48 + 9 = 57. The sulphate of potash is composed of 40 sulphuric Acid + 48 potash; and the muriate of the same alkali of 37 muriatic Acid + 48 potash. The combining proportion of the former Salt is, therefore, 88, and of the latter 85.

The composition of the Salts affords a very neat illustration of this subject; and to exemplify it still further, a list is subjoined of the proportional numbers of a few Acids and alkaline bases.

<table>
<thead>
<tr>
<th>Acid</th>
<th>Proportion</th>
</tr>
</thead>
<tbody>
<tr>
<td>Fluoric Acid</td>
<td>10</td>
</tr>
<tr>
<td>Lithia</td>
<td>18</td>
</tr>
<tr>
<td>Magnesia</td>
<td>20</td>
</tr>
<tr>
<td>Lime</td>
<td>28</td>
</tr>
<tr>
<td>Muriatic Acid</td>
<td>37</td>
</tr>
<tr>
<td>Potash</td>
<td>48</td>
</tr>
<tr>
<td>Arsenic Acid</td>
<td>52</td>
</tr>
<tr>
<td>Strontia</td>
<td>72</td>
</tr>
<tr>
<td>Baryta</td>
<td>78</td>
</tr>
</tbody>
</table>

It will be seen at a glance, that the neutralizing power of the different alkalis is very different; for the proportion of each base expresses the precise quantity required to neutralize a fixed quantity of each of the Acids. Thus, 18 of lithia, 32 of soda, and 78 of baryta, combine with 10 of fluoric Acid, forming the neutral fluates of lithia, soda, and baryta. The same fact is obvious with respect to the Acids; for 28 of phosphoric, 40 of sulphuric, and 62 of arsenic Acid, unite with 28 of lime, forming a neutral phosphate, sulphate, and arsenate of lime.

These circumstances afford a ready explanation of a curious fact, first noticed by the Saxon Chemist Wenzel; that when two neutral Salts mutually decompose each other the resulting compounds are likewise neutral. The cause of this fact is now obvious. If 88 parts of neutral sulphate of potash are mixed with 132 of the nitrate of baryta, the 78 baryta unite with the 40 sulphuric Acid, and the 54 nitric Acid of the nitrate combine with the 48 potash of the sulphate, not a particle of the Acid or alkali remaining in an uncombined condition.

<table>
<thead>
<tr>
<th>Compound</th>
<th>Proportion</th>
</tr>
</thead>
<tbody>
<tr>
<td>Sulphate of potash</td>
<td>88</td>
</tr>
<tr>
<td>Nitrate of baryta</td>
<td>132</td>
</tr>
</tbody>
</table>

It matters not whether more or less than 88 parts of sulphate of potash are added; if more, a smaller quantity of sulphate of potash will remain in solution; if less, nitrate of baryta will be in excess; but in either case the neutrality will not be affected.

The utility of being acquainted with these important laws is almost too evident to require mention. Through their aid, and by remembering the proportional numbers of a few elementary substances, the composition of an extensive range of compound bodies may be calculated with facility. By knowing that 6 is the combining proportion of carbon and 8 of oxygen, it is easy to recollect the composition of carbonic oxide and carbonic Acid; the first being 6 carbon + 8 oxygen; and the second 6 carbon + 16 oxygen. Forty is the number of potassium, and potash being its protoxide, is composed of 4 potash + 8 oxygen. From these few data we know at once the composition of the carbonate and bicarbonate of potash. The first is 22 carbonic Acid + 48 potash; the second, 44 carbonic Acid + 48 potash. This is done with very little effort of the memory; and the assistance derived from the
Some compounds are next examined, which contain the smallest proportion of oxygen or hydrogen, in combination with some other substance, the quantities of each being the smallest that can unite together. Carbonic oxide, with respect to carbon, and sulphuretted hydrogen, with respect to sulphur, answer this description perfectly. The former consists of 8 oxygen and 6 carbon; the latter of 1 hydrogen + 16 sulphur. The proportional number of carbon is, consequently, 6, and of sulphur 16. The proportions of all other bodies may be determined in the same manner.

"Since the proportional numbers merely express the relative quantities of different substances which combine together, it is in itself immaterial what figures are employed to express them. The only essential point is, that the relation should be strictly observed. Thus we may make the combining proportion of hydrogen 10, if we please: but then oxygen must be 80, carbon 60, and sulphur 160. We may call hydrogen 100 or 1000, or, if it were desirable to perplex the subject as much as possible, some high uneven number might be selected, provided the due relation between the different numbers is faithfully preserved. But a high, or such a practice would effectually do away with the advantage ascribed to the use of the proportional numbers, and hence it is the object of every one to employ such simple ones, that their relation may be perceived by mere inspection.

As the opinion of different Chemists concerning the simplicity of numbers is somewhat at variance, we possess several series of them. Dr. Thomson, for example, makes oxygen 1, so that hydrogen is one-eighth of unity, or 0.125, carbon 0.75, and sulphur 2. Dr. Wollaston, in his scale of Chemical equivalents, fixes oxygen at 10, by which hydrogen is 1.25, carbon 7.5, and so on. According to Berzelius, oxygen is 100. And, lastly, several other Chemists, such as Dalton, Davy, Henry, and others, call hydrogen 1, and, therefore, oxygen 8. One of these series may easily be reduced to any of the others, by an obvious and simple Arithmetical process; and, excepting that of Berzelius, whose numbers are inconveniently high for practice, it is not very material to which of them the preference is given. In this Work the last method is adopted, in consequence of its containing no fractional parts.

On the Atomic Theory of Mr. Dalton.

(116.) "The brief sketch which has been given of the laws of combination, will serve to set the importance of this department of Chemical Science in its true light. It is founded, as will have been seen, on experiment alone, and the laws which have been stated are the pure expression of fact. It is not necessarily connected with any speculation, and may be kept wholly free from it.

"The reason why persons, partially acquainted with the subject, have supposed it to be of an hypothetical nature, is sufficiently obvious. It was impossible to reflect on the regularity and constancy with which bodies obey the laws of proportion, without speculating about the cause of that regularity; and consequently, the facts themselves were no sooner noticed, than an attempt was made to explain them. Accordingly, when Mr. Dalton published his discovery of these laws, he at once incorporated the description of them with his notion of their Physical cause; and even..."
Sincethat period, though several British Chemists of eminence, and in particular, Dr. Wollaston and Sir H. Davy, have recommended and practised an opposite course, both subjects have been but too commonly comprised under the name of Atomic Theory; and hence it has often happened, that beginners have rejected the whole as hypothetical, because they could not satisfactorily distinguish between what was founded on fact, and what was conjectural. All such perplexity would have been avoided, and this department of the Science have been far better understood, as its value more justly appreciated, had the discussion concerning the atomic constitution of bodies been always kept distinct from what it was intended to explain. When employed in this limited sense, the Atomic Theory may be discussed in a few words.

Two opposite opinions have long existed concerning the ultimate elements of Matter. It is supposed, according to one party, that every particle of Matter, however small, may be divided into smaller portions, provided our instruments and organs were adapted to the operation. Their opponents contend, on the other hand, that Matter is composed of certain atoms, which are of such a nature as not to admit of further division. These opposite opinions have, from time to time, been keenly contested, and with variable success, according to the acuteness or ingenuity of their respective champions. But it was at last perceived that no positive data existed capable of deciding the question, and its interest, therefore, gradually declined. The progress of modern Chemistry has revived the general attention to this controversy, by affording a far stronger argument in favour of the atomic constitution of bodies than was ever advanced before, and which seems almost irresistible. We have only, in fact, to assume, with Mr. Dalton, that all bodies are composed of ultimate atoms, the weight of which is different in different kinds of Matter, and we explain at once the foregoing laws of Chemical union.

According to this view, every compound is formed by a combination of the atoms of its constituents. An atom of A may combine with 1, 2, 3, or more atoms of B, an arrangement on which depends the law of multiples. If water, for example, is composed of an atom of hydrogen and an atom of oxygen, it follows that every compound of hydrogen with an additional quantity of oxygen must contain 2, 3, or more atoms of oxygen; some multiple in a word by a whole number of the quantity of oxygen contained in water. It is equally clear, from this view of the composition of water, that the weight of an atom of oxygen is eight times heavier than an atom of hydrogen. The relative weight of the atoms of other substances may be determined in a similar manner. Thus an atom of carbon is 6 times, an atom of sulphur 16 times, and an atom of chlorine 36 times heavier than an atom of hydrogen; and this explains why they unite with one another in the proportions expressed by those numbers. What are called the proportional numbers are, in fact, nothing else but the relative weights of atoms.

No one can suppose that the laws of Chemical union are the effect of chance: there must be some cause for them in the nature of the ultimate particles of Matter. This cause, as we have just seen, is completely supplied by the supposed atomic constitution of bodies, which accounts for the phenomena in the most beautiful and consistent manner. So perfect, indeed, is the explanation, that the existence of these laws might have been predicted by the aid of the atomic hypothesis long before they were actually discovered by analysis. But these are not the only arguments which we at present possess in favour of the existence of ultimate indivisible particles of Matter. Dr. Wollaston, in his Paper on the Finite Extent of the Atmosphere, (Philosophical Transactions, 1822,) has defended this side of the question on a new and independent principle, and the proof he has given of the atomic constitution of bodies appears decisive.

Some Chemists, even without expressly adopting the Atomic Theory itself, have followed Mr. Dalton in the use of the terms atom and atomic weight, in preference to proportion, combining proportion, equivalent, and others of a like kind. All these appellations, however, have the same signification; and, in using the word atom, instead of the others, it should be held in mind that it merely denotes the proportions in which bodies unite: that it is the expression of a fact which will remain the same, whether the atomic hypothesis which suggested the employment of the term be true or false.

There is one circumstance which, at the first view, seems hostile to the supposed atomic constitution of Matter. In describing the law of multiples, it was mentioned that the oxygen in the three oxides of lead is the ratio of 1: 1 ½ : 2: so that if we regard the protoxide as composed of one combining proportion of lead to one proportion of oxygen, the second will contain one proportion and a half, or, according to the atomic theory, one atom and a half of oxygen. Now, though the half of a combining proportion may be admitted, the existence of half an indivisible particle of Matter is inconceivable: and this circumstance would be fatal to the Atomic Theory, were there not some satisfactory mode of accounting for it. Several explanations might be brought forward. One of them, as has already been mentioned, rests on the supposition that what is called the protoxide, is, in reality, composed of one atom of lead to two atoms of oxygen; and that the real protoxide has not yet been discovered. Another mode of accounting for the anomaly is, by regarding the present deutoxide as composed of the protoxide and peroxide combined with each other. A third method is, by doubling both elements of the anomalous compound, by which the exact ratio is preserved, and the idea of the fraction of an atom is avoided. Thus the protoxide and peroxide of iron are composed, the first, of one proportion, or 28 of metal + 8 of oxygen, and the second, of 28 of metal + an atom and a half, or 12 of oxygen; or what amounts to the same thing, of 56, or two atoms of iron, to 24, or three atoms of oxygen. These observations prove, that the occurrence of half proportions is not inconsistent with the atomic constitution of bodies; they show that the difficulty is explicable, and probably will, in the progress of discovery, be entirely removed. In the mean time, however, it would be inconvenient to allow any speculative notions in the subject to interfere with actual practice; and, therefore, it is best at once to admit the occurrence of half proportions: and, if any one prefer the term atom to equivalent or proportion, he must submit to the somewhat jarring expression of half an atom.

Mr. Dalton supposes that the atoms of bodies are spherical, and has invented certain symbols to represent the mode in which he conceives they may combine
There are several questions relative to the nature of atoms, most of which will, perhaps, never be decided. Of this nature are the questions which relate to the actual form, size, and weight of atoms, and to the circumstances in which they mutually differ. All that we know with any certainty is, that their weights do differ, and by exact analysis the ratios between them may be determined. The numbers which indicate the combining proportions of bodies, are, in fact, the relative weights of their atoms.

It is but justice to the memory of the late Mr. Higgins, of Dublin, to state, that he first made use of the atomic hypothesis in Chemical reasonings. In his Comparative View of the Phlogistic and Antiphlogistic Theories, published in 1789, he observes, (pp. 36 and 37.) that "in volatile vitriolic Acid a single ultimate particle of sulphur is intimately united only to a single particle of dephegisticated air; and that in perfect vitriolic Acid, every single particle of sulphur is united to two of dephegisticated air, being the quantity necessary to saturation:" and he reasons in the same way concerning the constitution of water and the compounds of nitrogen and oxygen. These remarks of Mr. Higgins do not diminish Mr. Dalton's claim of originality. They appear to have been quite unknown to him at the time he published his New System of Chemical Philosophy: and indeed they were made in so casual a manner, as not only to escape observation, but to prove that Mr. Higgins himself attached no particular interest to them. Mr. Dalton's real merit lies in the discovery of the laws of combination, a discovery which is solely and indisputably his; but in which he would have been anticipated by Mr. Higgins, had that Chemist perceived the importance of his own opinions. The merit of applying the atomic hypothesis to account for these laws likewise belongs to Mr. Dalton; nor is his ingenuity in the least affected by the circumstance that another person had previously explained insulated Chemical facts on the same principle.

On the Theory of Volumes.

(117.) "Soon after the publication of the New System of Chemical Philosophy in 1808, in which Work Mr. Dalton explained his views of the atomic constitution of bodies, a Paper appeared in the second volume of the Mémoires d'Arcueil, by M. Gay Lussac, on the Combination of Gaseous Substances with each other. There he proves that Gases unite together by volume in very simple and definite proportions. In the combined researches of himself and M. Humboldt, those gentlemen found that water is composed precisely of 100 measures of oxygen and 200 measures of hydrogen; and M. Gay Lussac, being struck by this peculiarly simple proportion, was induced to examine the combinations of other Gases, with the view of ascertaining if any thing similar occurred in other instances. The first compounds which he examined were those of ammoniacal Gas with muriatic, carbonic, and fluoboric Acid Gases. 100 volumes of the alkali combined with precisely 100 volumes of muriatic Acid Gas, and they could be made to unite in no other ratio. With both the other Acids, on the contrary, two distinct combinations were possible. These are:

100 Fluoboric Acid Gas with 100 ammoniacal Gas.
100 Ditto 200 ditto.
100 Carbolic Acid Gas with 100 ditto.
100 Ditto 300 ditto.

Various other examples were quoted, both from his own experiments and from others of those, all demonstrating the same fact. Thus ammonia was found by M. A. Berthollet to consist of 100 volumes of nitrogen + 300 volumes of hydrogen. 100 volumes of sulphurous Acid and 50 volumes of oxygen produced sulphuric Acid. Carbolic Acid is composed of 50 volumes of oxygen and 100 volumes of carbolic oxide.

From these and other instances M. Gay Lussac established the fact, that Gaseous substances unite in the simple ratio of 1 to 1, 1 to 2, 1 to 3, &c.; and this original observation has been confirmed by such a multiplicity of experiments, that it may be regarded as one of the best established laws in Chemistry. Nor does it apply to the true Gases merely, but to vapours likewise. For example, sulphuretted hydrogen, sulphurous Acid, and hydriodic Acid Gases are composed of

100 vol. hydrogen + 100 vol. vapour of sulphur.
100 do. oxygen... + 100 do. do. do.
100 do... do. ... + 100 do. do. iodine.

There are very good grounds to suppose, also, that solid bodies which are fixed in the fire, would, when in the form of vapour, be subject to the same law. By a method which will be hereafter explained we may calculate what the Specific Gravity of carbon would be, if converted into vapour, and 0.4166 is the number so determined, atmospheric air being unity. Now if we assume that carbonic Acid is formed of 100 volumes of oxygen + 100 volumes of the vapour of carbon, condensed into the space of 100 volumes, the Specific Gravity of carbonic Acid will be 1.1111 (the Specific Gravity of oxygen) + 0.4166 = 1.5377, which is the precise number determined by experiment. Again, it follows from our assumption, that carbonic Acid is composed by weight of

Oxygen 1.1111.....16 or 2 prop.
Carbon 0.4166..... 6 or 1 prop.

as ascertained by analysis.

If we assume that carbonic oxide is composed of 50 volumes of oxygen, and 100 volumes of the vapour of carbon, condensed into the space of 100 volumes, then its Specific Gravity will be 0.5555 (half the Specific Gravity of oxygen) + 0.4166 = 0.9721; and its composition will be

Oxygen 0.5555.... 8 or 1 prop.
Carbon 0.4166..... 6 or 1 prop.

both of which results have been determined by other methods.

The compounds of carbon and hydrogen are equally illustrative of the same point. If light carburetted hydrogen is formed of 200 volumes of hydrogen + 100 volumes of the vapour of carbon, condensed into 100 volumes, its Specific Gravity should be 0.1388 (twice the Specific Gravity of hydrogen) + 0.4166 = 0.5554; and its composition by weight will be

Hydrogen... 0.1386.....2
Carbon..... 0.4166..... 6

If olefiant Gas is composed of 200 volumes of hydrogen + 200 volumes of the vapour of carbon, its
Specific Gravity will be $0.1388 + 0.8332 = 0.9720$; and its composition by weight must be

- Hydrogen $...0.1388...2$
- Carbon $...0.8332...12$

both of which results have been obtained by analysis.

Another remarkable fact established by M. Gay Lussac in the same paper is that the diminution of bulk which Gases frequently suffer in combining, is also in a very simple ratio. Thus the 4 volumes of which ammonia is constituted, (8 hydrogen + 1 nitrogen) contract to a half or to 2 volumes when they unite. There is a contraction to two-thirds in the formation of nitrous oxide Gas. The same applies to the combination of Gases and vapours. There is a contraction to a half in the formation of sulphuric hydrogen; and to a third in that of sulphurous acid. The instances just quoted relative to the vapour of carbon confirm the same remark. There is a contraction to two-thirds in carbonic oxide, to a half in carbonic Acid, to a third in light carburetted hydrogen, and to a fourth in olefiant Gas.

The rapid progress which Chemistry has made within the last few years, is in a great measure attributable to the ardour with which Pneumatic Chemistry has been cultivated. That very department which, at first sight appears so obscure and difficult, has afforded a greater number of leading facts than any other; and the law of Gay Lussac, by giving an additional degree of precision to such researches, as well as from its own intrinsic value, is one of the brightest discoveries that adorn the annals of the Science. The practice of estimating the quantity in weight of any Gas by measuring its volume, of itself susceptible of much accuracy, is rendered still more precise and satisfactory by the operation of this law. It will not, perhaps, be superfluous, therefore, to exemplify the method of reasoning employed in these investigations by a few examples, which will serve, moreover, as a useful specimen to the beginner of the nature of Chemical proof.

One essential element in every inquiry of this kind, which is indeed the keystone of the whole, is a knowledge of the Specific Gravity of the Gases. But it is exceedingly difficult to determine the Specific Gravity of the Gases with perfect accuracy; for not only do slight alterations of temperature and pressure during the experiment affect the result, but the presence of a little watery vapour, atmospheric air, or other impurity, may cause a material error, especially when the Gas to be weighed is either very light or very heavy. The Specific Gravity of important Gases has accordingly been stated differently by different Chemists, and there is none in regard to which more discordant statements of this fact have been made than of hydrogen Gas. Fortunately we possess the power of correcting the results, and of estimating their accuracy, by means of other data, upon which greater reliance may be placed. According to our best data, the Specific Gravity of oxygen, hydrogen, and nitrogen Gases, air being 1, is

- Oxygen $...1.1111$
- Hydrogen $...0.0694$
- Nitrogen $...0.9729$

It has been proved by analysis that 200 volumes of ammoniacal Gas are composed of 80 volumes of hydrogen and 100 volumes of nitrogen, from which the Specific Gravity of that alkali may be calculated.

Thus, $0.9729 + (0.0694 \times 3) = 1.1804$, and $1.1804 \div 4$ is the Specific Gravity ammoniacal gas should have, did its constituents suffer no contraction; but as they contract to one half, the real Specific Gravity is double what it otherwise would be, or is 0.5902. Now, if by weighing a certain quantity of ammoniacal Gas, the same number is procured for its Specific Gravity, it follows that all the elements of the calculation must have been correct.

Nitric oxide is composed of 100 volumes of nitrogen $+ 100$ volumes of oxygen, united without any contraction, and forming, consequently, 200 volumes of the compound. Its Specific Gravity must, therefore, be the mean of its constituents, or $(1.1111 + 0.9729) \div 2 = 1.0416$. The coincidence of this calculated result with that determined by weighing the Gas itself, proves that all the data are true. It is obvious, indeed, that the calculated results, as being free from the unavoidable errors of manipulation, must be the most accurate, provided the elements of the calculation may be trusted.

Dr. Henry has proved by careful analysis that 100 volumes of light, carburetted, hydrogen Gas, a compound of carbon and hydrogen, require 200 volumes of oxygen for complete combustion; that water and carbonic oxide are the sole products; and that the latter amounts precisely to 100 volumes. From these data, the proportions of its constituents and its Specific Gravity may be determined. For 100 volumes of carbonic Acid contain 100 volumes of the vapour of carbon, which must have been present in the carburetted hydrogen, and 100 volumes of oxygen. One half of the oxygen originally employed is thus accounted for, and the remainder must have combined with hydrogen. But 100 volumes of oxygen require 200 volumes of hydrogen for combination, all of which must likewise have been contained in the carburetted hydrogen. The 100 volumes of light carburetted hydrogen submitted to analysis, are hence composed of 100 volumes of the vapour of carbon, and 200 volumes of hydrogen. Its Specific Gravity must, therefore, be 0.5554, that is 0.4166 (the Specific Gravity of carbon vapour) + 0.1388, or twice the Specific Gravity of hydrogen Gas.

Having ascertained that light carburetted hydrogen Gas is composed of two measures of hydrogen to one of the vapour of carbon, it is easy to calculate the proportion of its constituents in weight. For this purpose we need only multiply the bulk of the Gases by their respective Specific Gravities. Thus, $200 \times 0.694 = 13.88$, and $100 \times 0.4166 = 41.66$. Hence, light carburetted hydrogen is composed by weight of

- Carbon $...41.66...6$
- Hydrogen $...13.88...2$

The theory of volumes has very considerable analogy to Mr. Dalton's law of multiple proportions. The former is indeed, to a certain extent, a consequence of the latter; for if one body unites with another in several proportions, the quantities of the variable ingredient will stand in the same relation to one another, when expressed by volume, as they do by weight. But there is one remarkable difference. The weights of the two elements of a compound have no apparent dependence on one another. Thus, 6 carbon and 8 oxygen form carbonic acid; 8 oxygen and 14 nitrogen form nitrous oxide; 8 is no multiple by any whole number of 6; nor 14 of 8. But the elements of a compound are always united by volume, in the ratio of 1 to 1, 1 to 2, 1 to 3, and so on. This distinction is certainly very
make the atoms and volumes of bodies correspond to one another; and that it might be effected by considering water as a compound of an atom of oxygen + two atoms of hydrogen. Sir H. Davy has accordingly done so in his Elements of Chemical Philosophy, and the atom of oxygen will, therefore, be 16, while that of hydrogen is unity. But the inconvenience arising from this practice is far greater than the evil it was intended to remedy. For on this supposition, sulphuretted hydrogen must be held as an atom of sulphur with two atoms of hydrogen, while it is composed of one volume of each of its constituents. Muriatic Acid Gas would consist of one atom of chlorine, and two atoms of hydrogen, though formed of one volume of each Gas. The same remark applies to Hydriodic Acid, Hydrocyanic Acid, and most other compound Gases containing hydrogen.

The reason of this is that the atoms and volumes of all the simple Gases, (oxygen excepted,) and many compound ones also, according to the received system, correspond with one another. Sulphuretted hydrogen is composed of one volume or one atom of sulphur to one volume or one atom of hydrogen. Muriatic Acid is composed, in like manner, of one volume or one atom of each of its constituents. Light carburetted hydrogen is a compound of two volumes of hydrogen to one volume of the vapour of carbon, or of two atoms of hydrogen to one of carbon. All this advantage is lost by regarding water as a compound of two atoms of hydrogen to one of oxygen; and this forms a sufficient reason for not adopting the method of Sir H. Davy."

On the Theory of Berzelius.

(118.) "It is well known that the celebrated Professor of Stockholm has for many years devoted himself to the study of the laws of definite proportions, and that he has been led to form a peculiar hypothesis, by way of generalizing the facts which his industry had collected. To give a detailed account of his system does not fall within the plan of this Work: to treat of the atomic theory without alluding to the labours of Berzelius, would, on the other hand, be inexcusable: a middle course will here be adopted: by stating briefly the principal opinions of that eminent Chemist, offering at the same time a few comments upon them. Berzelius informs us in the Historical introduction to his Treatise on the Theory of Definite Proportions, that he commenced his researches on the subject in the year 1807; and that they originated in the study of the Works of Richter. From Richter's explanation of the fact, that when two neutral Salts decompose one another, the resulting compounds are likewise neutral, he perceived that one good analysis of a few Salts would furnish the means of calculating the composition of all others. He accordingly entered upon an inquiry, which was at first limited in its object; but as he proceeded, his views enlarged, and advancing from one step to another, he at length set about determining the laws of combination in general. In perusing his account of the investigation, we are at a loss whether most to admire the number of exact analyses which he performed, the variety of new facts he determined, his acuteness in detecting sources of error, his ingenuity in devising new analytical processes, or the persevering industry which he displayed in every part of the inquiry. But it is at the same time impossible to suppress regret, that instead of forming a complex system of his own,
he did not adopt the simple views of Mr. Dalton. This he might have done with very great propriety; since the fundamental laws which he discovered, are, with very little exception, either identical with those previously pointed out by the British Philosopher, or are the direct result of their operation.

"Berzelius assumes with Dalton the existence of ultimate indivisible atoms, to the combination of which with one another the laws of Chemical proportion are owing.

"The first law of Berzelius is the following: 'One atom of one element unites with 1, 2, 3, or more atoms of another element.' This is the grand law of Mr. Dalton, and requires no comment, further than that it has been amply confirmed by the labours of Berzelius. The second is, that 'two atoms of one element combine with three atoms of another.' These are the two laws which regulate the union of simple or elementary atoms.

"The combination of compound atoms with each other obeys another law, and is confined within still narrower limits. 'Two compounds which contain the same electronegative body, always combine in such a manner that the electronegative element of one is a multiple by a whole number of the same element of the other.' Thus, for instance, if two oxidized bodies unite, the oxygen of one is a multiple by a whole number of the oxygen in the other. Various examples may be given of this. The hydrate of potash is composed of

Potash 48, the oxygen of which is 8.
Water 9, the oxygen of which is 8.

"In like manner, if two Acids or two oxides combine the same will be observed.

"In the earthy minerals which contain several oxides, the same law is found to prevail with great uniformity.

"The composition of the Salts, likewise, is under its influence. Carbonate of potash, for example, is composed of

Carbonic Acid 22, the oxygen of which is 16.
Potash 48, the oxygen of which is 8.

And sulphate of potash of

Sulphuric Acid 40, the oxygen of which is 24.
Potash 48, the oxygen of which is 8.

"Berzelius has remarked that the nitrates, phosphates, and arseniates, may prove exceptions to the law in some instances. There is also a similar relation in Salts which contain water of crystallization, between the oxygen of the base of the Salt and that of the water. For instance, crystallized sulphate of soda is composed of

Sulphuric Acid 40.
Soda 32, the oxygen of which is 8.
Water 90, the oxygen of which is 80.

"Double Salts are also influenced by the same law. In the tartrate of potash and soda, for example, the oxygen of the potash is exactly equal to the oxygen in the soda; and the oxygen in the tartaric Acid, which neutralizes the potash, is equal to that of the soda.

"But this is not all that Berzelius has remarked with respect to the constitution of the Salts. He observes, that in each series of Salts the same relation always exists between the oxygen of the Acid and of the base.

In all the neutral sulphates this ratio is as three to one; as may be seen in the sulphates of soda and potash. In the carbonates, the oxygen of the Acid is double; and in the bicarbonates quadruple the oxygen of the base.

"The existence of these remarkable laws was discovered by Berzelius at a very early period of his researches; and he mentions, that as subsequent observation during the course of several years has not afforded a single exception to them, he now regards them as universal. He accordingly places unlimited confidence in their accuracy, and is in the constant habit of calculating the composition of bodies on this principle.

"It will, of course, be interesting to inquire into the cause of these phenomena; to ascertain if there is any property peculiar to oxygen, or other negative electrics, which might give rise to them. Berzelius himself says, that 'the cause is involved in such deep obscurity, that it is impossible at the present moment to give a probable guess at it.' I (says Dr. Turner) have the misfortune to differ entirely from Berzelius on this question. So far from being obscure, it is perfectly intelligible, and is precisely what might have been anticipated from the present state of Chemical knowledge.

Most of the Salts called neutral sulphates, are composed of one proportion or one atom of sulphuric Acid, and one atom of some peroxide. This is the case with all the alkaline and earthy sulphates, and with several of the common metals, as lead, zinc, and iron. Now an atom of sulphuric Acid is composed of

Sulphur ... 16 .... 1 atom.
Oxygen ... 24 .... 3 atoms.

And every protoxide of

Metal ............... 1 atom.
Oxygen .... 8 .... 1 atom.

"Hence a number of laws may be deduced, which must hold in every sulphate of a protoxide.

"1. The oxygen of the Acid is a multiple of that in the base.
2. The Acid contains three times as much oxygen as the base.
3. The sulphur of the Acid is just double the oxygen of the base.
4. The Acid itself is five times as much as the oxygen of the base.

"Metallic sulphures are frequently composed of an atom of each element; and should oxidation ensue, so that the sulphur is converted into sulphuric Acid, and the metal into a protoxide, they will be in the exact proportion for forming a neutral sulphate. Berzelius has proved by analysis that this happens frequently, and he is disposed to convert it into a general law.

"Again, the carbonates are composed of one atom of carbonic Acid, and one atom of some protoxide; but an atom of carbonic Acid is composed of

Carbon ... 6 .... 1 atom.
Oxygen ... 16 .... 2 atoms.

And every protoxide of

Metal ............... 1 atom.
Oxygen .... 8 .... 1 atom.

"It is inferred, therefore, that in all the carbonates, the oxygen of the Acid is exactly double that of the base; and the same mode of reasoning is applicable to the various genera of Salts. These few examples
Chemistry will serve to show, that what seemed so obscure to Berzelius, is rendered quite obvious by the Daltonian method. We perceive, moreover, that no constant ratio can exist between the quantity of the oxide and that of the Acid, or oxygen of the Acid; and the reason is, because the atomic weights of the metals are different. But this view of the subject answers another useful purpose; it enables us to see whether the law of Berzelius is or is not universal. The observations made on this subject by Dr. Thomson in his First Principles, are so much to the point that they are here given in his own words.

"Before concluding these general observations," says Dr. Thomson, "I may say a few words on Berzelius's law, that in all Salts the atoms of oxygen in the Acid constitute a multiple by a whole number of the atoms of oxygen of the base. This law was founded upon the first set of exact analyses of neutral Salts which Berzelius made. Now, as neutral Salts in general are combinations of one atom of a protoxide with an atom of an Acid, it is obvious that the atoms of oxygen in the Acid must in all such Salts be multiples of the atom of oxygen in the base; because every whole number is a multiple of unity. Neutral Salts, therefore, are not the kind of Salts by means of which the precision of this supposed law can be put to the test."

"Even in the subsalts, composed of one atom of Acid united to two atoms of base, it is obvious enough that the law will hold whenever the Acid, combined with the base, happens to contain 2 or 4, or any even number of atoms, because all even numbers are multiples of 2. Now this is the case with the following Acids:

|------------|--------|------------|--------|

Consequently the law must hold good in all combinations of 1 atom of these Acids with 2 atoms of base.

"In the case of all these Acids which contain only 1 atom of oxygen, all the subsalts composed of one atom of the Acid united to 2 atoms of the base, the law will also in some sort hold; for the atoms of the oxygen in such Acids being 1, this number will always be a submultiple of 2, the number of atoms of oxygen in 2 atoms of base. This is the case with the following Acids:

<table>
<thead>
<tr>
<th>Silicic.</th>
<th>Hyposulphurous.</th>
<th>Phosphorous.</th>
<th>Oxide of Tellurium</th>
</tr>
</thead>
</table>

"It is only in the subsalts of Acids containing an odd number of atoms of oxygen, that exceptions to the law can exist. It is to them, therefore, that we must have recourse when we wish to determine whether this empirical law of Berzelius be founded in Nature or not. Now, there are 13 acids, the integral particles of which contain an odd number of atoms of oxygen. The following Table exhibits the names of these Acids, together with the number of atoms of oxygen in each.

"Dr. Thomson informs us that the number of sub-

"The extract will suffice for placing the law of Berzelius in its true light; for showing that it is a direct consequence of the general operation of the laws of definite proportion: and that we must expect to find some exceptions to his law, derived from the very cause which gives rise to it. It is to be hoped that Berzelius will take the remarks of Dr. Thomson into mature consideration, by which he will probably perceive that his favourite canon is not so universal as he imagines, and be led to avoid the errors to which, from an indiscriminate employment of it, both himself and his pupils might otherwise be exposed.

"That part of the law which applies to the combined water is likewise more than doubtful. When the base contains 2 atoms of oxygen, and an uneven number of atoms of water are present, it cannot be correct. When the base contains 3 atoms of oxygen, the law would not apply whenever there chanced to be 2, 4, 8, or 10 atoms of water. When the base has only 1 atom of oxygen, then it must hold for obvious reasons. When the base has 1½ atom of oxygen, the law can only be true when 3, 6, 9, or 12 atoms of water are in combination. With 1, 2, 4, 5, 7, 8, or 10 it must fail. The hydrate of the peroxide of iron is an exception of this kind, and similar ones are to be looked for among the crystallized Salts of the peroxide.

"An admirable attempt has been made within this few years to determine the atomic constitution of minerals, in which Berzelius has highly distinguished himself. The composition of minerals must of course be influenced by the usual laws of combination, though there are sometimes obstacles in the way of discovering it. In the compounds made artificially, Chemists possess the power of having each constituent perfectly pure; but unfortunately we cannot always command the same condition with respect to natural productions. The materials of which a mineral is composed, once formed a part of some heterogeneous fluid or semi-fluid mass, and in assuming the solid form are very likely to have enclosed within them some substance, which, Chemically considered, does not form a part of the mineral. The result of Chemical analysis, accordingly, does not always give us a view of the actual constitution of a mineral species; some substances are often detected which are foreign to it, and the Chemist must exercise his judgment in determining what is and what is not essential. Now nothing is so well calculated to direct him as a knowledge of the laws of combination: but as a great discretionary power is in his hands, it is important that his mode of investigation should be the simplest possible, and that his rules
Chemistry should be founded on well-established principles, which involve nothing hypothetical. It is but very lately that due care has been bestowed in selecting sufficiently pure specimens for examination, or in performing the analyses themselves with the precision necessary for determining the Chemical constitution of minerals. It was much to be wished that our first essays in this difficult field should be confined as much as possible to such minerals as contain but few substances, and which occur in distinct transparent crystals.

"We are indebted to Berzelius for this mode of studying the composition of minerals; and certainly if skill in analytical investigation could encourage any one to make the attempt, none could undertake it with greater chance of success than the indefatigable Professor of Stockholm. Unfortunately his theoretical views are unnecessarily complex, and I much doubt, for reasons already stated, if his ruling law about multiples of oxygen deserves the confidence he bestows upon it. It will not, I am convinced, be adopted by the Chemists and Mineralogists of this Country, and I am much mistaken if, notwithstanding the great reputation of its author, it stand its ground long upon the Continent. To give a particular description of his method is foreign to our purpose, but the reader will find an able account of it in the IXth volume of the Annales of Philosophy, New Series, by Mr. Children." (n)

(119.) The early Chemical writers were accustomed to represent all the elementary bodies by certain symbols, arbitrarily adopted, and by combinations of these they also expressed the compound substances. Should curiosity lead any one to examine this matter, we refer him to Bergman's Work on Elective Attractions.

Professor Berzelius has adopted a method in some respects similar, but in a greatly improved form, more suited to the present state of our Science. His fundamental symbols are formed by adopting the initial or leading letters which commence the Latin name of each substance; and by the help of figures and points, placed like indices over these symbols, he represents the atomic constitution and the degree of oxidation of each substance. It was our original intention to have given a statement of his method, but we fear that want of space may prevent us from doing. We, therefore, for the present must refer our readers to his Essai sur la Théorie des Proportions Chimiques, Paris, 1819, or to Mr. Children's analysis above quoted; but should we find sufficient space, the symbols themselves shall be given in a Tabular form at the end of this Treatise.

(120.) It only now remains, before we proceed to the Chemical properties of bodies, that we should present a diagram of the method according to which each element, whether ultimate or proximate, will be considered.

A. History of discovery, and natural state.
B. How obtained pure; its constitution if a compound.
C. Physical properties.
D. Mutual action with oxygen.
E. Mutual action with chlorine.
F. Mutual action with fluorine.
G. Mutual action with iodine.
H. Mutual action with the nonmetallic electro-positive elements.
I. Mutual action with the metallic electro-positive elements.

K. Mutual action with Acids. bases.
L. Mutual action with reagents, or distinctive properties.
M. Uses in Medicine and the Arts.

It will be obvious that, by a constant use of the above letters, simplicity of reference will be obtained, and repetitions or confusion will be avoided.

Bromine is not inserted in the above scheme, in consequence of the little that is at present known of its mutual action with other bodies.

References from (41.) to (120.) inclusive.

CHAPTER II.

Non-Metallic (Electronegative?) Elements.

Of the five substances that come under the above denomination, the two first, oxygen and chlorine, when quite pure, are seen only in the gaseous form at all temperatures with which we are acquainted; though under strong pressure, the latter is a liquid. Fluorine has not as yet been exhibited in an independent form, while iodine and bromine are solid, liquid, or gaseous, according to the temperature at which we examine their properties.

§ 1.—Oxygen.

(121.) A. Oxygen Gas may be said to have been first discovered by Dr. Priestley, for on the 1st of August, 1774, he obtained it by exposing the red oxide of mercury to the heat produced by condensing the rays of solar light in the focus of a lens. Thus separated, he examined its properties, and named it dephlogisticated air. In the year following, Scheele, without being aware of Priestley's discovery, obtained it by other methods; and by Lavoisier, who undertook a further examination of its properties its present name of oxygen was proposed.

Although the word Oxygen stands at the head of this section, we are unable to speak of oxygen in its simple state. It has never yet been seen other than in the gaseous form, when it is supposed to consist of the true base, oxygen, united with caloric. When in combination it frequently loses that form and then becomes a constituent part of solid or liquid substances. It is well to bear in mind this distinction between oxygen...
and oxygen Gas, though the terms are frequently made use of indiscriminately; this would not, however, be the case were carbon a ponderable body, for now we may say, that oxide of zinc consists of 425 parts (by weight) of metal united with 100 parts of oxygen, or of oxygen Gas indifferently.

Oxygen exists in its gaseous state as a constituent part of the atmosphere: forming that portion which is essential to animal life and to combustion. Of almost every form and kind of matter which surrounds us it forms an ingredient. Its compounds are more numerous and diversified than those of any other substance with which we are acquainted. It produces most powerful effects in changing the properties of other simple bodies with which it combines. Thus when united to azote in one proportion it forms the genial air we breathe. Mild and salutary as are the properties of this well-known substance, yet if the proportions of the combining bodies be changed we have a powerful liquid Acid—the nitric, capable of dissolving metals and acting as an escharotic on living animal bodies. It forms a part of every earth we tread upon, and of every vegetable we see around us; and when combined with another gaseous body, hydrogen, it forms water: an important and essential form of food to all the animal and vegetable creation.

(122.) B. There are several methods by which oxygen Gas may be obtained for experimental purposes.

1. Priestley’s mode already described. (a.)

2. Scheele obtained it by the distillation of nitre. This method is still at times resorted to, but such oxygen is not very pure. A pound of nitre thus distilled in an earthen retort, at a red heat, will yield about 2,000 cubic inches of Gas. (b.)

3. Scheele also obtained it from a mixture of black oxide of manganese and sulphuric Acid. In this process 4 parts of manganese may be mixed with 3 parts of sulphuric Acid, in a glass retort, and the Gas may be disengaged by the heat of an Argand’s lamp.

4. Lavoisier, who had been informed by Priestley of his own researches, expelled the oxygen from red oxide of mercury by heating it in a retort; and described his process to the Royal Academy in 1755.

5. The hemideutoxide of lead, minium, or red lead of commerce, gives out pure oxygen Gas by the application of heat and is converted into the protoxide.

6. Oxygen Gas is, however, obtained most plentifully for experimental purposes, by placing any quantity of the common black oxide of manganese in an iron retort or bottle having a tube passing from it into a gasometer; this retort is placed in a fire, so as to receive a moderate red heat, when the oxygen Gas is expelled in considerable quantity.

7. But should the Gas be required of great purity it is usual to put a small quantity of the chlorate of potash into a glass retort, and to apply cautiously a very moderate lamp or sand heat. The Salt first fuses and then gradually parts with a considerable quantity of very pure oxygen Gas. In this case the oxygen is disengaged from the chloric Acid, which consists of that substance and chlorine; and also from the potash, which consists of oxygen and potassium; so that dry chloride of potassium is the sole residuum found in the retort. Some care is necessary in this process, especially if a naked glass retort be employed; as the alkaline matter combines with the glass and the bottom of the retort gives way. For this reason it is advantageous to employ a sand-bath in which the retort may be safely supported.

(123.) C. Oxygen Gas thus obtained has the following physical properties. It is without colour. It follows the general laws applying to all gaseous matter with regard to pressure and temperature. (76, and 82.) It is heavier than common air, its Specific Gravity referred to that substance being 1.1111. As 100 cubic inches of dry atmospheric air, thermometer 60° Fahrenheit, barometer 30 inches, weigh 30.5 troy grains, according to Sir G. Stuckburgh, if the above Specific Gravity be correct, (and it rests upon the reasoning of the accurate Dr. Prout, confirmed by the experiments of Professor Thomson,) the same volume of oxygen, *tidem positis,* will weigh 33.888 grains. It has neither smell nor taste. By a sudden and violent condensation oxygen Gas emits both light and heat. All Gases thus evolve heat upon condensation, but, according to M. Saisy, oxygen, chlorine, and common air are the only Gases that emit light under these circumstances. Of these oxygen emits the most, then chlorine, and, lastly, air. Of all Gases, oxygen has the least refractive power upon light. If the refractive power of air be 1, that of oxygen is 0.8616. Oxygen is more strongly electronegative than any other body at present known. When disengaged from all other substances in Nature by Voltaic electricity, it, and its compounds invariably go to the positive pole of the pile.

When oxygen Gas is left in contact with water the quantity of Gas absorbed is scarcely perceptible; but Dr. Henry found that 100 cubic inches of water, which had been freed from all air by boiling and the air-pump, would absorb 3.55 inches of Gas. (c.) Saussure estimated that 100 cubic inches would absorb 6.55 cubic inches of Gas, (d.) but Dalton considers the former estimate much more accurate. (e.)

(124.) E. See chlorine, sect. 2. reference D.

(125.) F. See fluorine, sect. 3. ref. D.

(126.) G. See iodine, sect. 4. ref. D.

(127.) H. Oxygen unites with all the substances falling under this division: it forms compounds of very varied properties. With hydrogen it forms water, chap. iii. sect. 2. subst. 1. With azote it forms atmospheric air and some strong Acids, chap. iii. sect. 8. subs. 1, 2, 3, 4, and 5. With sulphur it forms Acids, chap. iii. sect. 6. subs. 1, 2, 3, and 4. With selenium it forms a gaseous oxide, chap. iii. sect. 7. subs. 1. With phosphorus it forms acids, chap. iii. sect. 5. subs. 1 and 2. With carbon it forms an oxide and an Acid, chap. iii. sect. 3. subs. 1 and 2. With boron it forms an Acid, ch. iii. sect. 4. subs. 1 and 2. With silicon it forms a compound which on the whole may be considered as having acid properties, chap. iii. sect. 1. subs. 1.

(128.) I. With the metals oxygen invariably unites.

In some cases in one proportion only; in others in two or more proportions. Sometimes it is held by a strong affinity, sometimes the affinity is of the feeblest possible kind. From some of these unions with the metals we obtain Alkalis; from others Earths; and from others Acids. These properties will be considered in each individual case under the metals, respectively, but as general views on this subject are of fundamental importance, we offer the following general summary by M. Thenard.

"The phenomena which oxygen Gas presents when in contact with metals are of such importance as to
"Dry oxygen Gas at ordinary temperatures is absorbed by potassium; and hence we might be led to conclude that it would be also absorbed by barium, lithium, strontium, calcium, and by the metals of the first section; (i.e. those of our chap. iv. class 1) but at the same temperature it is not absorbed by sodium, nor by any of the metals belonging to the last four sections. A certain elevation of temperature favours this action prodigiously; so that in fact by this mean it may be made to act upon all the metals, with the exception of those of the last section, (class 6.) A considerable number of them absorb oxygen when the temperature is sufficiently elevated, with the evolution of light; viz. all the metals of the second class; zinc, iron, tin, and cadmium, in the third; arsenic, antimony, tellurium, bismuth, in the fourth. Tin, antimony, and bismuth being those whose combustion is most feeble. It may seem, perhaps, extraordinary to find tellurium burning with the evolution of light, while manganese, which has much greater affinity for oxygen than it has, does not possess that property. The reason, however, is simply this, that tellurium, being both fusible and volatile, forms, dato tempore, a much greater quantity of oxide than manganese which is fixed and almost infusible. In fact, in order that any substance may burn with flame it must not only have a great affinity for oxygen but it must also enter into fusion readily, or be volatile, or rather, perhaps, if the oxide which it forms is readily fusible or volatile: without this, the contact between the substance burning and the substance burned, not being intimate, the combustion cannot be vivid.

"The combination of metals with oxygen Gas may almost always be effected by filling a small retort or bent tube with the Gas, over mercury, and after having introduced a certain quantity of the metal by means of a bent wire, applying the heat of a spirit-lamp and agitating the metal with the wire if necessary. It is only when the heat required is very considerable indeed, that a porcelain tube is employed. This tube containing the metal may pass through a small furnace, and may communicate by means of small glass tubes, at one extremity with an empty bladder, and at the other extremity with a bladder full of oxygen. After the furnace is lighted and the porcelain tube has become white hot, the oxygen Gas is to be passed slowly backward and forward from one bladder to the other several times. The absorption will be entire if there be sufficient metal in the tube.

"Oxygen Gas when in a humid state attacks not only the metals of the two first classes, but even many of those belonging to the third, the fourth, and even the fifth class. With regard to the former, oxidation takes place at once at the expense of the free oxygen, and also of the oxygen of the water, which is decomposed and its hydrogen liberated. With regard to the latter, the metal receives only the free oxygen; and in this case we suppose the aqueous vapour to possess a twofold action; on the one hand it may partly become liquid and hold in solution a portion of the oxygen, thus rendering this oxygen, when deprived of its elasticity, more capable of combining with the metal; on the other hand, it may still further promote the combination by its own tendency to unite with the metallic oxide and form an hydrate. Be this as it may, the oxidation so produced is generally only superficial, and is always very slow in its progress: the interior parts of the metal are always protected by the exterior film, or at least a considerable time must elapse before they undergo any considerable alteration. The metals which most readily oxidize in this manner are arsenic, manganese, iron, zinc, lead, copper, &c.; those of the sixth class being unalterable.

"When the oxygen, whether it be dry or moist, is Atmo-mixed with azote, its action upon the metals is the spheric air same as if the azote were not present, except that possibly that action may be less intense; for the azote acts only mechanically by diminishing the points of contact in a given space between the oxygen Gas and the metals. But since atmospheric air is composed of about four-fifths azote and one-fifth oxygen, with a little aqueous vapour and a little carbonic Acid Gas, it ought to act upon metals in the same manner as oxygen does, but with some difference of intensity. This is in fact what happens: when dry, it only attacks at ordinary temperatures the metals of the first two classes, and even is without action upon sodium: when moist, it acts not only upon all these, but also upon many metals of the third, fourth, and fifth classes. Whether dry or moist, it acts upon all by the aid of heat: those of the last class alone excepted. The result of this action is an oxide, or an hydrate. But if the process take place in the open air, the product is frequently a carbonate, especially at common temperatures: thus it is that the air, being perpetually renewed, is continually yielding small quantities of carbonic Acid to the oxide, whenever these two bodies have sufficient affinity to enter into union. Thus brass statues become gradually covered with carbonate of copper; and in leaden reservoirs, there is formed immediately above the surface of the water, not oxide of lead, but carbonate of lead."

"No carbonate can, however, be formed if the temperature be considerably elevated, except those of barium, potassium, sodium, and probably lithium; because all the carbonates decompose at that temperature except those of barytes, potash, soda, and apparently of lithia. (f.)

(129.) K. Though it does not immediately appear that any actions of the kind to which this reference applies can be described, yet we are of opinion that, with a due consideration of the mutual agencies of all bodies, it would require only ordinary ingenuity to discover a series of effects which might be ranged under this head: especially if we subscribe to Berzelius's views of the constitution of mineral bodies, and extend them to all substances in Nature.

(130.) L. Oxygen Gas is distinguished from all other bodies by the following properties. It is not inflammable; is not absorbed by a solution of caustic potassa; it is capable of restoring to full combustion a match which has been partially extinguished; it combines by the electric spark with twice its volume of hydrogen, forming water and leaving no gaseous residuum.

(131.) M. Oxygen Gas is essential to the animal economy: and although, from its powerful excitative effects, it cannot be long resired alone with impunity, yet when
CHEMISTRY.

combined with four times its volume of azote it forms the compound best adapted to our organs of respiration, viz. the air we breathe. If the oxygen be in less proportion, the air is not salubrious, and if totally absent, it will not support life for a moment. When pure oxygen Gas is respired, the evil effects of an accelerated circulation arise: the lungs become inflamed and the whole system enters upon a state of fevered excitement. Attempts have been made to exhibit oxygen in some cases of disease, but as yet these have been attended with but slender success. It is not to be understood that oxygen is the only Gas that can be breathed; but it is the only one that can be permanently breathed without derangement of some sort or other arising in the system. A singular instance of its action has been related. Three men who were employed in clearing out the vault of a cabinet d'aisance at Paris were suffocated by the sulphuretted hydrogen, which always exists abundantly in such places. When taken out, they were conveyed to the Hôtel Dieu: two died on the way thither; the third arrived there alive, but without any power to move his limbs. In the haste to contrive something that should be administered to him, a bladder full of oxygen presented itself, and he was made to breathe it: the man immediately sat up, but again fell down and expired. It has been supposed that he might have been restored to life, if a small quantity of chlorine Gas, mixed with a considerable quantity of atmospheric air, had been similarly administered to him.

Combustion.

(132.) It might not, perhaps, be quite satisfactory were we entirely to omit all consideration of Combustion; and yet we feel that little real knowledge is to be gained by any detailed views of the numerous explanations that have been proposed on this subject. In the first place, the word itself is rather vague in its application by different writers. Originally, Combustion was synonymous with what in common language is called the burning of any thing. The Chemist was justly called upon to explain, in the terms of Science, the conditions, the operations, and the result of that process. Subsequently, however, the explanations which were thus given led to a great extension of the applications of the dogmas advanced: and the term Combustion was made use of in cases where burning in its ordinary sense could not be said to exist. If by Combustion we mean the union of oxygen with certain bodies, attended by the production of light and heat, it is one thing; and in this case mere oxidation is excluded. But if we apply the term to any Chemical change between the elements of Matter, wherein light and heat are evolved, it is quite another thing, and there is no essential necessity for the presence of oxygen. We are of opinion that the introduction of confusion is all that is obtained by continuing to employ the word in any other than a popular sense.

Still it may be necessary, for the information of some, to state that the first Scientific explanation of Combustion was given by Stahl, who conceived that there existed in all combustible bodies a certain elementary principle which he called phlogiston, and that the process of Combustion depended upon the evolution of this principle. Thus a body that had been burned or oxidated, he termed dephlogisticated, supposing it to have lost its phlogiston. The heat and light which accom-
in Nature: it exists, however, in great abundance as a constituent of muriatic Acid, which again is neutralized by various alkaline substances. Thus, as muriate of soda, it exists in the waters of the ocean: and is also found in the solid form (common salt) in large deposits in various parts of the Earth.

(134.) B. Chlorine Gas is most readily obtained by putting two parts of strong muriatic Acid mixed with one part of the common black oxide of manganese into a glass retort and applying a gentle heat. The Gas is evolved in considerable quantity, and should be received in inverted bottles over the pneumatic trough. The water with which the trough is filled should be quite warm, and the bottles when filled should all be closed with glass-stoppers, to which a little lead has been applied. Want of space will, for the most part, prevent us from tracing the progress of most of the decompositions which the processes recommended in this Treatise may present: but such considerations are of first-rate importance to the Chemist, and as an example we shall here note the rationale of the above decomposition.

Black oxide of manganese consists of one atom of metal + two atoms of oxygen. Muriatic Acid of one atom of Chlorine + one atom of hydrogen. In the mutual reaction of these substances, an atom of the oxide is decomposed, so that it is reduced to a lower state of oxidation; the atom of oxygen that is set free unites with the atom of hydrogen from the muriatic Acid so as to form water: the remaining atom of Chlorine is set free; the newly formed protoxide of manganese unites with an unaltered atom of muriatic Acid, and a proto-muriate of manganese remains in the retort.

For the purposes of the manufacturer a cheaper process is employed. Three parts of common salt are well mixed with one part of the black oxide of manganese, and then put into a retort. To this a mixture of four parts of diluted sulphuric Acid (containing 3-5ths acid and 2-5ths water) is added, and a moderate heat applied as before.

(135.) C. Chlorine Gas has a yellowish green colour, from whence its name is derived. It violently irritates both to the nostrils and to the fauces, and highly disagreeable and injurious if even in small quantity it reaches the lungs. By violent condensation it evolves both light and heat. Under a pressure of four atmospheres it forms a bright yellow liquid, which does not freeze at zero, Fahrenheit. Its Specific Gravity is 2.5. Cold water freed from common air by boiling will absorb and retain twice its volume of this Gas. When Chlorine Gas saturated with moisture is exposed to a cold of 32° Fahrenheit, yellow crystals are formed, containing, according to Mr. Faraday, a definite proportion of one atom of Chlorine + ten atoms of water.

(136.) D. Chlorine and oxygen when mixed together have no mutual action; but if either of the elements be present in a nascent state, by which is meant, at the instant of their disengagement from combination, a union may be effected.

In this manner four or five combinations with oxygen may be obtained. See subsects. 1, 2, 3, 4, and 5.

(137.) F. Unknown.

(138.) G. Chlorine unites with iodine, forming the chloriodic Acid. See sect. 4. subsect. 2 of this Chapter.

(139.) H. Chlorine unites with hydrogen, carbon, phosphorus, sulphur, selenion, and nitrogen. The compound with hydrogen is muriatic Acid, or as it is more properly termed, hydro-chloric Acid. See subsect. 6.

With carbon, Chlorine forms three combinations: the sub-chloride of carbon, the proto-chloride of carbon, and the hemideuto-chloride of carbon, called the perchloride, by Mr. Faraday, who discovered it. These compounds will be described in the section on carbon.

Two chlorides of phosphorus exist, which will be described in sect. 5. So also for the chloride of sulphur, see sect. 6. For its union with selenion, see sect. 7. And for the chloride of nitrogen, (azotane,) see sect. 8.

(140.) I. The metals have in general a strong affinity for Chlorine; and it would seem that both true chlorides and chlorides of their oxides exist. In fact, every metal seems to be capable of uniting with Chlorine, and sometimes in more than one proportion. All these compounds are solid, with the exception of the deutochlorides of tin and arsenic, which are liquid and volatile. Many of the chlorides are crystalline powders. Generally speaking, the metallic chlorides are not decomposed by heat, but those of gold and platinum are so. The chlorides of the first two classes of metals are insusible below a red heat, and are not volatile. But those of the other metals are much more fusible, and frequently very volatile. All are soluble in water, excepting the chloride of silver and the proto-chloride of mercury: they for the most part absorb moisture with avidity. It appears, however, that in most cases their union with water is not a case of mere solution, but that a portion of the water is decomposed, so that its hydrogen unites with the Chlorine to form hydrochloric Acid, while the oxygen goes to the metal, so as to produce a metallic oxide which, uniting with the hydro-chloric acid, produces a Salt. These phenomena are not, however, obvious in their progress, but it is very generally supposed that, in dissolving a metallic chloride, a solution of a hydro-chlorate is produced: and conversely, that in drying a hydro-chlorate sufficiently a metallic chloride is the result.

These generalizations, however, are not free from some exceptions, and some doubts which we have not space here to examine.

(141.) K. It is obvious that, strictly speaking, Chlorine has no action that can be referred to this division of our scheme.

(142.) L. The distinguishing properties of Chlorine are, that it has a greenish yellow colour: that it is unaltered by exposure to heat: that it immediately combines with mercury at ordinary temperatures: that it destroys vegetable colours. When present in a liquid, a white curdy precipitate is produced by nitrate of silver; which precipitate is insoluble in nitric Acid, but soluble in ammonia. A solution of the white of egg (albumen) produces a white flocculent precipitate composed of flexible and elastic fibres, which are insoluble in water and alcohol.

(143.) M. The first and most important use of Chlorine in the Arts is in Bleaching, which will form a por-
Gas is also the most powerful corrective or destroyer of noxious miasmata. For this purpose it has long been employed in lazaretos and hospitals. It forms the powerful ingredient in Labaracq’s disinfecting liquor; where it is combined with lime or soda. This last preparation has only recently been introduced into this country, under the name above mentioned: and we think that, in cases of infectious disease, even in private families, its use cannot be too strongly recommended.

Subsect. 1.—Protoxide of Chlorine.

(144.) All the combinations between chlorine and oxygen are held together by a very feeble affinity, and are, therefore, readily decomposed. Four are at present known, though from inadvertency two only are put down in our synoptic view. (4.) The atomic constitution of these, together with the circumstance just adverted to, would lead us to suppose that some intermediate combination may be found to exist whensoever our means may be found sufficiently delicate for their detection. Indeed a fifth oxide is described by Count Von Stadion.

Protoxide of chlorine was discovered by Sir H. Davy in 1811, and was named by him Euchlorine. It is most readily obtained by placing two parts of the chlorate of potassa, one part of muriatic Acid, and one of water, in a small retort, and then applying a very gentle heat. The Gas evolved should be collected over mercury. A portion of chlorine is produced, but this unites with the mercury, while the protoxide of chlorine is collected pure.

The colour of this Gas is a yellowish green, but more vivid than that of chlorine. It has a smell something like that of burned sugar. Water will absorb eight or ten times its volume of this Gas. Euchlorine does not unite with alkalis. Like chlorine it discharges vegetable colours, but with less energy than the latter substance. It is so highly explosive, that the heat of the hand is sufficient to produce a separation between its constituents. Phosphorus, also, immersed in it, produces explosion and undergoes combustion. When exploded with hydrogen by the electric spark, water and muriatic Acid are the results. Euchlorine consists of two volumes of chlorine and one of oxygen. Its atomic constitution and specific gravity will be seen in the general tables. (a.)

Subsect. 2.—Tritoxide of Chlorine.

(145.) The tritoxide of chlorine was discovered and is described by Count Von Stadion in Gilbert’s Annalen. (b.) Some doubt, however, yet remains about this substance.

Subsect. 3.—Tetartoxide of Chlorine. (Peroxide of Davy.)

(146.) The tetartoxide of chlorine was discovered by Sir H. Davy in 1815, and also by Von Stadion about the same period. About 50 or 60 grains of the chlorate of potassa is reduced to fine powder, and formed into a paste with strong sulphuric Acid. This paste is to be put into a glass retort, and then to be submitted to the heat of a water bath, not reaching so high as 212° of temperature. The Gas evolved is of a higher colour than chlorine or its protoxide, having an aromatic odour without any smell of chlorine. It does not combine with mercury, but is absorbed by water in considerable quantity. It does not combine with alkalis, but it destroys vegetable blue colours without previously reddening them, in which respect it differs from the protoxide. Phosphorus introduced into it produces decomposition and undergoes combustion. By the experiments of Davy and Gay Lussac, it appears that 40 volumes of the Gas become 60 after explosion; and are then found to consist of 40 volumes of oxygen and 20 of chlorine.

Subsect. 4.—Chloric Acid. (Pemptoride of Chlorine.)

(147.) Chloric Acid was first recognised as such in the chlorates, and pointed out by Mr. Chenevix. Its more careful examination was undertaken by M. Vauquelin (d.) and by M. Gay Lussac. (e.)

Vauquelin’s process for obtaining it is as follows. To a solution of pure chlorate of baryta add, by degrees, diluted sulphuric Acid as long as any precipitation takes place. Thus the chloric Acid remains pure, combined with water only: care must of course be taken to add no more sulphuric Acid than is just sufficient to effect the separation of the baryta. The true point has been obtained when neither sulphuric Acid nor chlorate of baryta will produce a precipitate when added to separate portions of the liquid.

The solution of chloric Acid thus obtained is colourless, having an acid or astringent taste. It reddens litmus: is volatilized by heat, but undergoes some decomposition in the process. It does not produce any precipitate from nitrates of silver, mercury, or lead. When chloric Acid and hydrochloric Acid are mixed together in just proportion, a complete decomposition is effected, chlorine and water resulting. It is decomposed by sulphuretted hydrogen or by sulphurous Acid, but none of the Acids which are saturated with oxygen have any action upon chloric Acid. It is also decomposed by all the metals which are capable of decomposing water, and chlorides of their oxides are produced. The constitution of chloric Acid is most generally supposed to be one atom chlorine + five atoms oxygen. (f.)

Subsect. 5.—Perchloric Acid. (Heptoride of Chlorine.)

(148.) In obtaining the tetartoxide of chlorine by the process already given, (146.) a peculiar Salt was detected in the residuary matter by Count Von Stadion. It is found in octahedral crystals mixed with bisulphate of potassa. These crystals are soluble in hot water, and also in 55 times their weight of water, at 60° Fahrenheit. It is insoluble in alcohol. By mixing this Salt with an equal quantity of sulphuric Acid, and distilling it at a temperature of 280° Fahrenheit, the salt is decomposed, and an Acid which has been called the perchloric may be distilled off. (g.)

Subsect. 6.—Hydro-chloric Acid. (Muriatic Acid.)

(149.) A. Professor Thomson is of opinion that by Hydro-chloro-chloric Acid was known to the alchemists, and states that it is mentioned in the writings of Basil Valentine. Glauber, he says, seems to have contrived the present mode of obtaining it by distillation from sulphuric
Acid and common salt. Mr. Cavendish first described the mode of obtaining it in the Gaseous form, in 1766. (h.) Priestley more fully described its properties. (l.) The experiments of Gay Lussac and Taffanel (k.) tended to prove that muriatic Acid Gas is a compound of chlorine and hydrogen: and the further researches and reasoning of Davy went far towards establishing the same opinion, which is in fact now almost universally admitted. (l.)

Muriatic Acid exists, as has already been stated, (133.) in great abundance in the earth and in sea water, combined with alkaline bases: but in the state of a free Acid it does not seem to exist at all, unless, possibly, it may be evolved among the Gaseous products of active volcanos.

(150.) B. Hydro-chloric Acid, as it is commonly known and made use of, is a Liquid, consisting of the pure Acid Gas combined with water. This Gas is most readily obtained by putting chloride of sodium, (common Salt,) well dried, into a tubulated retort, and then adding to it strong sulphuric Acid. By applying the heat of a sand-bath, muriatic Acid Gas is evolved in considerable quantity. If this operation be conducted over mercury the Gas is obtained in great purity, but not without a considerable degree of hygrometric water. If, however, the beak of the retort be made to terminate in a receiver containing water the Gas is absorbed, and a strong liquid solution of the Acid is obtained. But in purposely preparing the liquid muriatic Acid, it is most convenient to employ a series of two or three Woulfe’s bottles, having small quantities in each, so that whatever Gas may escape from solution in the first bottle, can only pass on and be taken up by the Liquid in the second or third. The proportions recommended for this process are as follow: dried chloride of sodium eight parts; strong sulphuric Acid seven parts; water placed in the Woulfe’s bottles five or six parts. The proportions recommended by the College of Physicians is two pounds troy of dry chloride of sodium; 20 ounces troy of strong sulphuric Acid mixed with half a pint of water. A pint of water is to be put into the receiver to absorb the Gas. For a very clear view of the rationale of this process for obtaining muriatic Acid, see Mr. Phillips’s excellent and scientific translation of the Pharmacopœia.

Hydro-chloric Acid Gas may also be formed by the direct synthesis of its constituents. Thus, if equal volumes of chlorine and hydrogen Gases be mixed together in a bottle, and kept from the influence of light, no change is produced; but by applying a lighted taper, or passing an electric spark through the mixture, or even by exposing it to the light of the sun, combination is instantly effected. Mr. Brande found that the intense light from charcoal points, ignited by the Voltaic pile, were capable of producing the same effect: (m.) and Seebeck states that, among different colours, the blue rays of the spectrum are more effectual than those which are red. (n.)

Hydro-chloric Acid Gas, for experiment, may also be obtained by heating a little strong muriatic Acid in a retort over a spirit-lamp. This Gas, when quite dry, consists of one atom chlorine + one atom hydrogen, or 36 of the former + one of the latter by weight. (T51.) C. In the Gaseous state, hydro-chloric Acid has the following Physical properties. Its smell and taste are extremely pungent, and it is quite unfit for respiration. It is heavier than common air; the best esti-
Chemistry.

Acid, even when cold, and still more easily by the aid of heat. With heat the muriates are decomposed by the phosphoric, arsenic, and boracic Acids, when water is present. The nitric Acid has the same property in proportion to its strength.

(159.) L. The hydro-chloric Acid is recognised in a solution by its property of producing a white curdy precipitate with nitrate of silver, a test of very great delicacy. The precipitate thus produced is the chloride of silver, which should be well washed, dried, and fused in a glass vessel. In this state it contains one atom of chlorine + one atom of silver, or 36 parts of the former + 110 of the latter by weight, indicating 37 parts by weight of dry muriatic Acid.

(160.) M. In the Arts hydro-chloric Acid is frequently employed as a solvent: and in Medicine it is given as a tonic. Dr. Prout made the singular discovery of its existence among the fluids of the stomach, sometimes in considerable quantity, in which case it seems to indicate a diseased action of that organ: and the mode of its production there appears extraordinary, since he could detect its presence in the stomachs of rabbits which had been fed on substances not apparently containing that Acid or its chief elementary constituent, chlorine. (q.)

(161.) We have adverted only slightly to the controversy that has existed between Chemists of first-rate excellence respecting the nature of chlorine and muriatic Acid. The one party having regarded chlorine as the simple elementary body, and muriatic Acid a compound formed by the addition of hydrogen: the other party having supposed muriatic Acid Gas the simple body, or at least that it consisted of an unknown radical united to oxygen; and that chlorine, or as it was by them termed, oxymuriatic Acid Gas, was a compound of oxygen with muriatic Acid Gas. The former, which is now the prevailing opinion, we have followed; but there is much in the controversial writings on this point that we strongly recommend to the attention of the Chemical reader, produced as they have been by the most distinguished Chemists of the Age. For this purpose consult reference. (p.)

References to § 2.

§ 5.—Fluorine.

Fluorine. (162.) In assigning to Fluorine its present situation in our system, we acknowledge that we are acting upon supposition, and not upon fact. We are aware that in so doing we shall find the opinions of some very distinguished Chemists opposed to us: but after all, in a matter confessedly undecided, we are willing to shelter ourselves from absolute censure, by saying that we only adopt the opinions of Sir H. Davy, by Dr. Thomson, and perhaps by Berzelius also. On the whole, it seems to us the more plausible of the two generally proposed. It may be well just briefly to state that the one of these suppositions is, that Fluorine is a highly electronegative body, (analogous to chlorine,) and that by its union with hydrogen Fluoric Acid is formed, which should, therefore, be called hydro-fluoric Acid. On the other supposition Fluorine is a base, (analogous to boron,) and that Fluoric Acid arises from the union of this base with oxygen.

(163.) A. Fluorine is so far from existing at all free in any part of the kingdom of Nature, that it has never yet been exhibited alone and uncombined by the utmost efforts of Chemical ingenuity. Fluoric Acid had long been suspected to be a compound of some unknown base with oxygen: but in 1810, M. Ampere was led by the analogy of chlorine to view it in the light of a compound of that base with hydrogen. This he communicated to Sir H. Davy, who published in 1813 and 1814 two very valuable papers in support of that opinion. To these papers we are indebted for the little that we know concerning the base of Fluoric Acid.

(164.) B. Sir H. Davy did not obtain Fluorine in a separate state, but the following were the modes by which he attempted to do so; together with the evidence which he obtained in favour of Ampere's and his own opinion. Potassium was added to Fluoric Acid, a violent degree of action ensued, hydrogen Gas was evolved, and a solid white residuum was obtained. Now, if it were certain that Fluoric Acid contained no water, we must infer that the Fluoric Acid underwent decomposition by the escape of its hydrogen, and that the white mass was a Fluoride of potassium. To ascertain whether the strong liquid Fluoric Acid (Specific Gravity 1.0609) contained water, Davy enclosed some in a platinum capsule within dry ammoniacal Gas, until it became saturated with that alkali. Thus dry Fluate of ammonia was obtained. According to the belief of Davy and Thomson, "when any Acid that contains water is combined in this manner with ammoniacal Gas, if we heat the Salt formed, water is always disengaged. Thus sulphuric, or nitric, or phosphoric Acid, when saturated with ammoniacal Gas and heated, give off always abundance of water." (Thomson.) Fluate of ammonia thus treated gave out no water. (c.) Upon this ground it seemed that Fluoric Acid contained no water.

The analogy with muriatic Acid seems plausible also. By heating potassium with muriate of ammonia, the Salt and its Acid are both decomposed. Chloride of potassium is formed, and the hydrogen and ammonia both escape, in the proportion of one volume of the former to two of the latter. So also if Fluate of ammonia be heated with potassium, a mixture of hydrogen and ammonia escapes containing precisely the same proportions as in the former case, and a solid white residuum is found and by analogy inferred to be the fluoride of potassium. (b.)

Again, by exposing Fluoric Acid to the Galvanic pile: hydrogen was evolved at the negative wire, and the composite wire, which was of platinum, was coated with a chocolate-coloured powder. (c.) When muriatic Acid is similarly acted upon, hydrogen is given out at the negative wire, and a chloride is formed round the extremity of the positive wire. Reasoning upon this...
Hydro-fluoric Acid.

A. Hydro-fluoric Acid has been long known by the name of fluoric Acid. The following is Thomson's summary of its history.

"Fluor spar, a well-known mineral, is mentioned by Agricola under the name of fluor as a flux for metallic ores. (c) Its property of corroding glass when mixed with sulphuric Acid was known at Nuremberg as early as 1670. The first attempt to ascertain the composition of this mineral was made by Margraff. His experiments were published in the Memoirs of the Berlin Academy for 1768, but he informs us that they had been made in 1674. He reduced the mineral to powder, mixed it with its own weight of sulphuric Acid, and distilled it in a retort. He obtained a white, saline sublimate, and remarked with surprise that the retort was corroded into holes in several places. (f)

In the year 1771 Scheele published a set of experiments on fluor spar. In the Memoirs of the Academy of Sciences of Stockholm. He showed that the mineral was a compound of lime and of a peculiar Acid, to which he gave the name of fluoric Acid. He determined the properties of this Acid, and showed it to differ from every other previously known. (g) Dr. Priestley found that the Acids when obtained by Scheele's process, is a Gas possessed of peculiar properties, which he investigated and described. (h)

"It was shown by Weiglib (i.) and Bucholz, (k) and still more completely by Meyer, (l) that the fluoric Acid of Scheele contained silica as a constituent; and Dr. John Davy ascertained the proportion of fluoric Acid and of silica that exist in the Acid of Scheele, and demonstrated that it is a peculiar compound of fluoric Acid and silica, in which the constituents always exist in the same proportions. (m) Gay Lussac and Thenard, in 1811, published a method of preparing pure fluoric Acid, and were the first to determine its properties." (n)

Four fluorides exist in Nature; the one already mentioned, fluore of cerium, double fluore of cerium and yttria, and the double fluore of soda and alumina, cryolite.

B. The method of Gay Lussac and Thenard is generally adopted. A retort and receiver of lead are made to fit well together. Into the retort put a quantity of pure fluor spar in fine powder, together with twice its weight of sulphuric Acid. Lute the apparatus, and apply a gentle heat to the retort; at the same time surrounding the receiver with a freezing mixture of snow and salt. The fluoric Acid is condensed in the receiver in the liquid form.

C. "At 32°F Fahrenheit it is a colourless Liquid, like water. It does not congeal though cooled down to —4°F Fahrenheit, and it remains a Liquid at 60°F Fahrenheit. Its boiling point has not been determined, but it is low. When exposed to the air, it smokes violently, giving out a smell similar to that of muriatic Acid, but much stronger. It is very speedily dissipated in open vessels, and can only be preserved in metallic ones. The best are those formed of pure silver, and they must have a silver stopper which should be air-tight." (Thomson.)

This Acid, as obtained by Davy at its utmost concentration, was of Specific Gravity 1.0609. In this state he considered it quite free from water. If a drop of the Acid be let fall into water it combines with a hissing noise, like that which would be produced by red-hot iron; but when a few drops of water are poured into fluoric Acid ebullition is produced.

Fluoric Acid acts powerfully upon the animal system, the least drop acting as an escharotic, and producing a sore which is healed with difficulty. The fumes of it are repelled by the lungs with violence, and are so deleterious that scarcely the smallest portion can enter those organs with impunity.

D. The action of hydro-fluoric Acid upon the metals has been already noticed (168.) in connection with what we conceive to be the decomposition of this Acid to obtain fluorine. Its union with potassium and sodium, as examined by Thenard and Gay Lussac, is extremely violent, great heat, with effervescence, and the evolution of hydrogen, all resulting. Thenard states, also, that they tried three other metals, zinc, iron, and manganese. All three decompose the hydro-fluoric Acid with the evolution of heat and hydrogen Gas.

M. Thenard considers it scarcely probable that any other metals, except those of his first two sections, and perhaps tin and cadmium, would produce any action upon this Acid. We have already stated our belief that fluorine will unite with every metal, but this is not opposed to M. Thenard's opinion, because it does not thence
Chemistry. follow that every metal will decompose the hydro-fluoric Acid for the purpose of uniting with its base, without some other determining agency; such, for instance, is Volatile electricity. (173.) E. and F. none.

(174.) E. and F. none.

(175.) G. none, or unknown.

(176.) I. none, or unknown.

(177.) K. With regard to the compounds formed by hydro-fluoric Acid with salifiable bases, we shall abridge the following general notice from Thenard's system.

The hydro-fluate of ammonia is obtained by adding a dilute solution of ammonia to hydro-fluoric Acid, until the alkalii be slightly in excess, and then evaporating by a gentle heat.

Of the metallic hydro-fluates there are twenty-one single ones already described, besides some double ones. Of these twenty-one, fifteen belong to the first three sections, and the six others are those of cobalt, copper, silver, lead, and mercury.

All these hydro-fluates are fusible by heat, provided they do not undergo decomposition. None of these Salts, if perfectly dry, could be decomposed by fire; but if humid, it is possible that many of them might undergo partial or total decomposition, because water has a strong affinity for hydro-fluoric Acid, and consequently in disengaging itself it might either wholly or in part carry off the Acid along with it. This effect is never produced upon the neutral hydro-fluates of the second section, nor on those of magnesia, silver, zinc, and iron; but it does take place with those of lead, cobalt, and copper, and they become reduced to the state of subhydro-fluates.

With regard to the action of the simple combustibles upon the hydro-fluates, much might be said, which entirely depends upon the theoretical view taken of the elementary body we are now describing. The relation existing between boron and this base has already been noticed; and it seems probable that combinations with other substances of this class may yet be discovered.

(178.) Water dissolves none of the metallic hydro-fluates at present known when in the neutral state; except those of potash, soda, and silver. But all are soluble in an excess of Acid.

(179.) The salifiable bases seem to unite with hydro-fluoric Acid through the medium of water in this order: lime, barytes, strontian, potash, soda, ammonia, magnesia, &c.

(180.) "The boracic Acid is the only one which is capable of decomposing the hydro-fluates per se, without the aid of water. If a mixture of two parts of flour spar and one part of boracic Acid be heated nearly to redness in a bent gun-barrel, we obtain a residue of hydro-fluate of lime and boro-fluoric (fluo-boric) Acid Gas. On the other hand, there are many Acids capable of decomposing the hydro-fluates through the medium of water; such are the sulphuric, the phosphoric, the arsenic. When a concentrated solution of these Acids is heated with a hydro-fluate in a leaden or silver vessel, there results a fixed sulphate, phosphate, or arseniate; and a compound of hydro-fluoric Acid and water, which is disengaged with effervescence, and disperses white pugent vapours through the atmosphere. Sulphuric Acid can even decompose many of these Salts at our ordinary atmospheric temperature. Many also are decomposed by the nitric, hydro-chloric, hydriodic, and especially by the hydro-sulphuric; but in no case by the sulphurous, nitrous, or carbonic Acids."

(181.) Silica has, like water, the property of facilitating the decomposition of the hydro-fluates. For example, if pure fluor spar be inclosed with acid phosphate of lime in an iron tube, the vitreous Acid phosphate of lime does not decompose the fluor at the highest temperature. But if pure dry silicas or sand be added, the decomposition takes place at a low red heat; and phosphate of lime, with a great quantity of silico-fluoric Acid Gas, are the results. From this experiment Thenard infers, that most of the hydro-fluates of the last four sections, which are not decomposable by charcoal at any temperature when dry, might easily be decomposed by that body, if a quantity of silica were added to the mixture. Or even it is probable that this might be effected by silicas alone; for, on the one hand, it would tend to unite with the metallic oxide, and on the other hand, with the hydro-fluoric Acid; and, indeed, it is not impossible that many fluorates of the first two sections may be similarly affected, especially at very elevated temperatures.

(182.) If a solution of hydro-fluate of ammonia, potash, or soda, be added to a solution of a Salt of barytes, strontian, lime, magnesia, alumina, zinc, iron, lead, mercury, &c., the insoluble hydro-fluates of these bases are precipitated; at least if the solution be nearly neutral. But the soluble salts of glycina, vitria, and zirconia present some singularities. In fact, by adding a solution of hydro-fluate of potash slightly acid to a solution of the hydro-chlorate of each of these salts, all being slightly acid, we obtain on the one hand a precipitate of the neutral insoluble hydro-fluates, and on the other, the soluble hydro-chlorate of potash sensibly alkaline. (o.)

(183.) L. On this point we have little to add to that information which may be collected from the last article. The presence of hydro-fluoric Acid in a compound is usually recognised by decomposing that compound with sulphuric Acid, and allowing the escaping Gas to corrode glass. Berzelius has given modes for recognising it in mineral bodies in his Étude de l'Employ du Chalumeau, p. 159.

(184.) M. The only use to which the hydro-fluoric Acid has been applied is in the etching upon glass. This process is not difficult, and is sometimes very useful. Coat the glass with a thin but uniform layer of bees'-wax, then write or scrape off the parts that are to be etched with some sharp instrument, so as to leave the surface of the glass quite exposed. Then mix some well-pounded fluor spar with sulphuric Acid in a leaden or platinum crucible, and expose it to a moderate lamp heat. The hydro-fluoric Acid Gas will escape in white fumes, and eat into the exposed surface of the glass. The wax may then be removed by heat and an indelible writing or etching is found upon the glass.

Subsect. 2.—Silico-fluoric Acid.

(185.) By this term we mean the silicated fluorie Gas Silico- of Scheele, fluo-silicat Acid of Thomson, and fluate of silicat of Thenard. It may be said that, as we adopt Davy's and Thomson's opinions on the nature of this Acid, we ought to adopt Thomson's name for it. We by no means claim the right of introducing new names, a process ever replete with confusion; but if the compound of hydrogen with fluorine be called hydro-fluoric
Acid, so also should the compounds of silicon and boron, being also Acids, be called silico-fluoric and boro-fluoric Acids. Witness also hydro-chloric Acid, hydro-sulphurous Acid, &c.

(165.) A. We now return to the acid compound of silicon and fluorine mentioned Art. (163.) A Gaseous body which does not exist naturally in its simple form. It was discovered by Scheele. (p.) Priestley examined it further; (g.) and Dr. John Davy published a paper on it in 1812. (r.)

(187.) B. To obtain this Gas, let equal quantities of fluor spar and glass, both in fine powder, be just formed into a paste with sulphuric Acid. This paste is to be exposed to a moderate lamp-heat in a small retort, which in this case may be of glass. The silico-fluoric Acid Gas will be evolved in considerable quantity, and may be collected over the mercurial trough. Silico-fluoric Acid consists of

(188.) C. This Gas is colourless, has a smell much like that of muriatic Acid, has an acid taste, and reddens vegetable blues. It produces white fumes on mixing with atmospheric air. It does not support combustion, nor must any quantity, however small, be suffered to enter the lungs. Its Specific Gravity, according to Dr. Davy, is 3.5783, or 3.6111 according to Thomson. Water absorbs this Gas in great quantity, but at the same time the Gas suffers decomposition, and part of the silica is deposited. Heat alone is not capable of decomposing this Gas.

(189.) D. E. F. G. Unknown.

(190.) H. No substance from this class of bodies will decompose silico-fluoric Acid even with the aid of heat.

(191.) I. The metals of the last four sections have no action on this Acid at any temperature. But if potassium or sodium be placed in this Gas, and then heated, a violent action takes place, the Gas is absorbed, all metallic appearance is lost, and a chocolate-brown substance remains. When this substance is put into water there is a slight effervescence, hydrogen escapes, and hydro-fluates of silica and of potash or soda are formed.

(192.) K. Silico-fluoric Acid Gas unites with twice its volume of Gaseous ammonia, and forms a Salt which is volatile below a red heat, and from which water can separate some part of its silica; but if placed in contact with liquid ammonia, the whole of the silica separates, and hydro-fluate of ammonia is formed. The silico-fluates of potash, soda, lime, and barytes, are formed by adding a solution of silico-fluoric Acid Gas in water to the solutions of these bases respectively; but it must be remembered that, in all these compounds, the silica exists in a smaller proportion than in the original Gas, as some portion of that earth will separate whenever the gas enters into union with water.

(193.) L. Nothing can be said on this point in addition to what is obvious from the properties already noticed.

(194.) M. None.

Subject 3.—Boro-fluoric Acid.

(195.) A. Gay Lussac and Thenard first discovered that boron united with fluorine to form a powerfully acid Gas. (e.)

(196.) B. The process for obtaining this Gas, recommended by Dr. J. Davy, is to mix fused boracic Acid in fine powder one part; fluor spar in powder two parts; and sulphuric Acid twelve parts. This compound is to be gently heated over a lamp, and the Gas collected over mercury; or by exposing mixture of boracic Acid and fluor spar in fine powder to a red heat in a gun-barrel. (l.)

(197.) C. Boro-fluoric Acid Gas thus obtained is colourless, has the smell of hydro-chloric Acid, reddens vegetable blues, and has an acid taste. Dr. Davy states, that water will absorb 700 times its volume of this Gas; it then becomes a highly Acid Liquid, capable of forming an ether when distilled with alcohol. It has no action upon glass; instantly carbonizes animal and vegetable substances; is not decomposed by a red heat.

(198.) D. When this Gas is mixed with oxygen no decomposition is produced; but it seizes with avidity any moisture that may be present, and thus forms white fumes of vapour. The same takes place with all other gases.

(199.) E. As with oxygen.

(200.) F. Unexamined.

(201.) G. Unexamined.

(202.) H. No simple composition has any action on this Gas.

(203.) I. Among the metals, those of the third, fourth, fifth and sixth classes will not decompose boro-fluoric Acid Gas. Its decomposition has, however, been effected by potassium and sodium. These metals, when heated in the Gas, burn almost as in oxygen; boron and fluoride of potassium or sodium result from that decomposition. When water is added, an alkaline hydro-fluate is formed in solution, and boron remains.

(204.) K. The combination of this Gas with ammonia is the only Salt of this Acid that has been examined. Of the boro-fluate of ammonia there exist three varieties; the first a solid opaque Salt; the second and third both are Liquids, though they contain no water: by exposure to the air they part with ammonia, and pass into the first variety. (i.)

(205.) L. The only application of this substance which has been suggested, is as a reagent, to detect moisture in other Gases, which it readily does, by the white fume formed when even only a very small portion of aqueous vapour is present.

(206.) M. None.

References to § 3.

§ 4.—Iodine.

(207.) A. The discovery of Iodine resulted from an examination made by M. Courtois, a saltpetre-manufacturer at Paris, into the cause of the corrosion which took place upon the metallic vessels in which he separated soda from the ashes of sea-weeds. It was in 1812 that he thus detected this curious body and submitted it to MM. Clement and Desormes for further examination. The more complete inquiries into its nature were, however, made by M. Gay Lussac and Sir H. Davy, about the same time, viz. in 1818. The name Iodine was derived by M. Gay Lussac from 

(208.) B. The marine plants that we have mentioned are collected in large quantities, and burned in heaps on the sea-shore. The ashes are collected and sold under the name of kelp to the soap-manufacturers for the sake of the soda that they contain. It is from this kelp that Iodine is most readily obtained. The process for which we are indebted to Dr. Wollaston is much the most commodious. The soluble part of the kelp is to be dissolved in water; evaporate the liquor so as to separate all the crystals that can be obtained. Pour off the remaining liquid into a clear vessel, and add to it an excess of sulphuric acid. By boiling this liquid for some time sulphur is precipitated and hydrochloric acid is driven off. Decant the clear liquor and strain it through wool. Then put it into a small flask, and mix it with as much black oxide of manganese as will form a peculiar acid, the hydriodic, to be described in subsect. 3. This mixture in the flask is heated, and the Iodine sublimes into the glass tube.

Dr. Ure obtained Iodine in considerable quantity from the waste ley which had been employed in making soap from Scotch kelp. (b.)

(209.) C. Iodine thus obtained is considered a simple body. It is solid at our ordinary temperatures. It is generally seen in small imperfect crystals of a lamellar structure; is of very slight tenacity; is of a blackish blue colour, with some metallic lustre; and has a good deal the appearance of a granular plumbago, or native sulphur of antimony. By careful sublimation it is readily obtained in crystals, the primary form of which has been determined by Dr. Wollaston to be an octahedron, whose axes are nearly in the ratio of 2 : 3 : 4. (c.) Its specific gravity is 4.948 at temperature 62°.5 Fahrenheit, (d.) according to Thenard, but only 3.0844 according to Thomson. The taste of Iodine is acrid and hot, and its effects are poisonous. Its smell is like that of chlorine or chloride of sulphur. It is slightly volatile at our ordinary atmospheric temperatures; it fuses at 226° Fahrenheit, and boils at 347° Fahrenheit, but the colour of its vapour may be rendered obvious even at 100° Fahrenheit; and it entirely assumes the form of a beautiful violet coloured Gas much below 212° Fahrenheit, under the common atmospheric pressure. It is not a conductor of Electricity, for if a small fragment be placed between wires, so as to form a part of the Voltaic circuit, the decomposition of water does not take place. Iodine is soluble in 7000 times its weight of water, but it is much more soluble in alcohol, and still more so in ether.

(210.) D. The union of oxygen with Iodine may be effected indirectly: and thus a peculiar proximate element is formed, the iodic acid. See subsect. 1. Iodine is, in fact, capable of expelling oxygen from both sulphur and phosphorus. Professor Sementini of Naples has discovered another compound of oxygen and iodine which he calls iodous acid, but as yet its properties are little known. (o.)

(211.) E. Sir H. Davy formed the combination between Iodine and chlorine at Florence in 1814, and thus discovered chloriodic acid. See subsect. 2.

(212.) F. The direct union between Iodine and fluorine is of course yet unknown, but M. Gay Lussac examined the action between fluate of potash (or fluoride of potassium) and Iodine: he says, "Sulphate of potash was not altered by iodine, but what may appear astonishing, I obtained oxygen with the fluate of potash, (fluoride of potassium,) and the glass tube in which the operation was conducted underwent corrosion. On examining the circumstances of the experiment, I ascertained that the fluate became alkaline when melted in a platinum crucible. This happened to the fluate over which I passed iodine. It appears then that the iodine acts upon the excess of alkali and decomposes it. The heat produced disengages a new portion of fluoric acid or its radical, which corrodes the glass; and thus, by degrees, the fluate is entirely decomposed."

(213.) H. Of the substances belonging to this division iodine combines with hydrogen, phosphorus, sulphur, and azote. The affinity of iodine for hydrogen is very considerable. It decomposes many substances in order to obtain it, and by the aid of heat, it is capable of absorbing a considerable quantity of this gas. Thus is formed a peculiar acid, the hydriodic, to be described in subsect. 3.

(214.) Iodine and phosphorus unite when gently heated together in a glass tube over charcoal. The formation of iodide of phosphorus takes place with increase of heat, but without the evolution of light. (d. p. 9.)

(215.) Sulphur unites with Iodine readily, but not with energetic action. Iodide of sulphur may be formed by combining the substances at a moderate heat; which heat, if again increased, readily produces their separation, and iodine vapour escapes.

Iodine and carbon have not yet been united, nor have we any information respecting the action of iodine with boron or selenium.

(216.) The compound of iodine with azote was first formed by M. Courtois, by simply putting a quantity of iodine into a solution of ammonia in water. A process of decomposition takes place, ammonia is decomposed, and the new compounds resulting are iodide of azote and hydriodate of ammonia. The latter remains in solution; the former falls down in the form of a black powder. In a quarter of an hour the process is complete and the iodide may be washed upon a filter. This substance possesses violent detonating properties; when quite dry it will explode spontaneously; and when moist it will do so with only a very slight pressure.
When this detonation is made in close vessels, azote and Iodine are found to be the sole products. (h.) (i.)

(217.) I. "Though as yet Iodine has been united only to potassium, sodium, zinc, tin, antimony, bismuth, copper, lead, mercury, and silver, yet it appears that this substance possesses, like chlorine, the property of combining with all the metals. It is also certain that the Iodides are subject to the same law of composition with the chlorides and the sulphures; for first, when they are placed in water they decompose it, and possess themselves of its two constituent elements, thus transforming themselves into hydriodates. 2. If we calcine the hydriodates of the protoxides of potassium, sodium, &c. the result is water and Iodides. 3. When the hydriodic Acid is placed in contact with oxides, it decomposes them, there also result Iodides and water. The quantity of Iodine in Iodic acid is therefore proportional to the quantity of oxygen in the oxides.

All the Iodides at present known are solid, brittle, and scentless: the greater part have some flavour, and the greater part also crystallize: many are without colour. Among those that are coloured, many have a very deep tint. The Iodide of lead is a vivid yellow; the protiode of mercury is a beautiful yellow; and the deutiodide is a vermilion red.

2. Some Iodides are volatile: such as those of potassium, sodium, zinc, and mercury. All, excepting those of potassium, sodium, lead, and bismuth, are decomposed by oxygen at a red heat. Iodine is disengaged in violet vapours and the metal is oxidized. Some, like the Iodide of zinc, deliquesce by exposure to the air.

When placed in contact with water, the Iodides of potassium, sodium, zinc, and iron decompose it instantly, and dissolve therein, passing to the state of hydriodates. It is probable that the same takes place with the remaining Iodides of the two first classes of metals.

The Iodides of tin and antimony also affect, at common temperatures, the decomposition of water; but the hydriodic Acid does not unite to the metallic oxides: these are precipitated, while the Acid remains in the liquid state.

Those of bismuth, copper, lead, mercury, silver, and, in general, almost all those formed of metals which do not decompose water, are, on the contrary, inert when placed in it, and are not dissolved.

Iodine is expelled from its combinations with metals by chlorine at a high temperature: but at such a temperature it has almost always an affinity for the metals superior to that of sulphur and phosphorus.

Lastly, there is no Iodide known, wherein the concentrated sulphuric or nitric Acids cannot oxidize the metal and disengage the Iodine." (e. Art. 248.)

(218.) L. The mutual action between starch and Iodine is very striking. Stromeyer asserts that a solution containing only 1 - 450000th part of Iodine produces a blue colour when mixed with a solution of starch. (f.) This colour varies from a delicate blue to a deep black, in proportion to the quantity of Iodine present. To ascertain whether a vegetable root contains starch, the root is cut transversely, and a drop of alcoholic solution of Iodine is let fall upon the cut surface; if the root contains any of that succulent of which starch consists, the drop exhibits a blue tint. Should the Iodine exist in a state of combination, it is necessary to add a few drops of sulphuric Acid to disengage it, previous to the application of the test. With this reagent the presence of starch may be recognised in the solutions of some gums but not in those of others. By the help of this substance metallic palladium may be distinguished from metallic platinum. A drop of the tincture of Iodine is placed upon the polished surface and suffered to remain there. A black spot will be found upon both metals, but that upon palladium may be removed by heating the metal while that on palladium cannot.

(219.) M. Several preparations of Iodine have been recently introduced into Medical practice, for although this substance is an active poison, yet, as in many such cases, it may be exhibited in very small quantities: and the general opinion seems to be that it will form a valuable addition to the Materia Medica. On this head we can only direct our readers to M. Majendie's interesting Work. (g.) The most striking effects seem to have consisted in the dispersion of the goitre; and for this purpose it is now much employed in Switzerland.

Subsect. 1.—Iodic Acid. Oxiodic Acid of Davy.

(220.) A. This Acid is said to have been first recognized by M. Gay Lussac, but it was first obtained in a pure state by Sir H. Davy. It is entirely an artificial product, not having been found in Nature either in a simple or combined form.

(221.) B. To obtain Iodic Acid:—"Put 40 grains of Iodine into a thin, long-necked receiver. Into a bent glass tube, shut at one end, put 100 grains of chlorate of potash, and pour upon it 400 grains of hydrochloric Acid, of Specific Gravity 1.105: then make the bent tube communicate with the receiver and apply a gentle heat. Protoxide of chlorine is generated, which should be made to pass through dry chloride of calcium, in order to separate moisture. As soon as it meets with the Iodine two new compounds are formed: 1st, a compound of Iodine and chlorine—chloriodic Acid: and, 2dly, a compound of oxygen and iodine—oxiodic Acid. When heat is applied to this mixture, the chloriodic Acid, which is volatile, flies off, and the oxiodic Acid is left pure." (k.)

(222.) C. In this state it is a white semitransparent solid, without smell, but having a strongly acid flavour. In Specific Gravity it exceeds sulphuric Acid, as it will sink in that fluid. It first reddens and then destroys the colour of vegetable blues. It attracts moisture from the air slightly, and is very soluble in water. Such a solution gradually thickens by evaporation; then becomes pasty, and ends by remaining pure Iodic Acid. By a heat rather below the boiling temperature of olive oil it is decomposed into oxygen Gas and Iodine vapour. (d. p. 75.) and (k.)

(223.) D. E. F. G. unimportant or unexamined.

(224.) H. The combustible bodies exert a powerful action on Iodic Acid: for when it is heated with carbon, sulphur, resins, or sugar, a sudden detonation takes place.

(225.) I. The same effects are produced by many of the metals when they are in a state of minute division.

(226.) K. Iodic Acid unites with the sulphuric, phosphoric, nitric, and boracic Acids, forming crystalline compounds with the three first. It is decomposed by
As an example of one of these compounds: let sulphuric Acid be added drop by drop to a cold concentrated solution of Iodic Acid. A precipitate immediately takes place of Iodo-sulphuric Acid. This compound fuses when exposed to a gentle heat, and crystallizes, on cooling, in rhomboids of a pale yellow colour. By a more powerful heat, it is partly sublimed unchanged, and partly decomposed into oxygen, iodine, and sulphuric Acids. These compound Acids have such energy in their action upon metals as to dissolve even platinum. The Iodic and hydro-chloric Acids mutually decompose each other; producing water and chlorioidic Acid.

With the salifiable bases Iodic Acid forms Salts: and these when neutral are in general of very slight solubility. So great is its affinity for the oxides of lead and mercury, that it precipitates them both from their solution in nitric Acid. The iodates of ammonia, soda, potash, lime, barytes, strontia, zinc, and silver have been described. (n.)

(227.) L. See (215.)

(228.) M. None at present known.

Subsect. 2.—Chloriodic Acid.

(229.) A. This substance, which is entirely an artificial production, was discovered about the same time both by Sir H. Davy and M. Gay Lussac.

(230.) B. Chloriodic Acid is formed by passing a current of chlorine Gas into a vessel containing iodine. The iodine absorbs the Gas and a yellow substance results, which, by being fused with a gentle heat assumes an orange colour; but is red if the iodine be in excess. For the complete saturation of the iodine, this red substance must be dissolved in water, and then through this solution a current of chlorine is to be passed until saturation takes place. Solution of Chloriodic Acid thus formed is a clear liquid, provided neither of the elements be in excess.

(231.) C. It would seem from Davy's experiments that it is difficult to form Chloriodic Acid as a definite compound. When the chlorine is in defect the substance is solid, but when the quantity of chlorine is considerable, both substances seem to rise in vapour, though still in a state of combination. The solution has action acid properties and destroys vegetable blues.

(232.) D. F. H. Unexamined, or unimportant.

(233.) I. Chloriodic Acid seems to have a powerful mutual action with some of the metals, for it is decomposed by mercury, which renders experiments upon this substance extremely difficult and unsatisfactory.

(234.) K. It seems impossible to combine this Acid with bases, for whenever such were presented to it, the water was decomposed, muriatic and iodic Acid being the result.

(235.) L. On this head consult Iodine L, and Chlorine L.

(236.) M. None at present; but Sir H. Davy, by feeding birds on bread soaked in the solution of this Acid, proved that it is not poisonous like pure iodine. (d. and h.)

Subsect. 3.—Hydriodic Acid.

(237.) A. This Acid was doubtlesst first produced either during the experiments of M. Courtois or of MM Clement and Desormes, but its accurate examination was undertaken by M. Gay Lussac and Sir H. Davy. It would seem that the hydriodate of potash exists in the Fuci only and in some of the Sponges.

(238.) B. Hydrogen and iodine if placed in contact enter into combination upon a moderate elevation of temperature. But there are other and better processes for obtaining Hydriodic Acid which depend upon presenting the hydrogen to the iodine in a nascent state. Of these we prefer the following. Put into a small tube retort eight parts of iodine and one of phosphorus, and let this mixture be slightly moistened with water. Then by the application of a very gentle heat the Hydriodic Acid comes over rapidly in the form of a Gas which may be collected over mercury, though mercury decomposes some of it: or it may be passed into water in which it is soluble, and may be kept for use as a test. Another excellent method is to diffuse iodine through water and then to pass a current of hydro-sulphuric Acid through the water: the hydrogen combines with the iodine, the Hydriodic Acid remaining in solution, and the sulphur is precipitated. Time should be allowed for the sulphur to subside, and any excess of Hydro-sulphuric Acid remaining in the liquid may be dissipated by the application of a moderate heat. In this manner, also, the Acid may with care be considerably concentrated. This Acid consists of one volume of iodine vapour + one volume of hydrogen.

(239.) C. Hydriodic Acid when pure is a colourless Gas, very acid to the taste, strongly reddening vegetable blues, and having a powerful smell, extinguishing combustion, and forming white fumes as it comes in contact with atmospheric air. Water absorbs this Gas with avidity, and by careful evaporation a solution of Specific Gravity 1.7 may be obtained. A red heat decomposes Gaseous Hydriodic Acid.

(240.) D. By admixture with oxygen Gas, Hydriodic Acid Gas is entirely decomposed. Water being formed, the iodine remains free.

(241.) E. By admixture with chlorine decomposition also takes place: the chlorine seizes upon the hydrogen to form hydrochloric Acid: and the iodine vapour gradually condenses into the solid form.

(242.) F. and H. Unknown.

(243.) I. Potassium, sodium, zinc, iron, mercury, and many other metals decompose this Acid: hydrogen is liberated, and metallic iodoses are formed. Then by the application of a very gentle heat the Hydriodic Acid comes over rapidly in the form of a Gas which may be collected over mercury, though mercury decomposes some of it: or it may be passed into water in which it is soluble, and may be kept for use as a test. Another excellent method is to diffuse iodine through water and then to pass a current of hydro-sulphuric Acid through the water: the hydrogen combines with the iodine, the Hydriodic Acid remaining in solution, and the sulphur is precipitated. Time should be allowed for the sulphur to subside, and any excess of Hydro-sulphuric Acid remaining in the liquid may be dissipated by the application of a moderate heat. In this manner, also, the Acid may with care be considerably concentrated. This Acid consists of one volume of iodine vapour + one volume of hydrogen.

(244.) K. The hydrochloric, hydro-sulphuric, and sulphurous Acids do not affect the Hydriodic Acid when brought in contact with it, but concentrated sulphuric and nitric Acids cede a part of their oxygen to its hydrogen, so that from this double decomposition there results a deposit of iodine, sulphurous Acid Gas, or deutoxide of azote and water. Solutions of iron, also, in a high state of oxidation, throw down the iodine: as also some other metals which produce iodoses.

There are also two compounds of the two varieties of phosphuretted hydrogen with Hydriodic Acid, and for these see (l.)

With bases the Hydriodic Acid forms Salts, which are all soluble in water, and for the most part crystallizable. For the properties of these we would refer our readers to Thomson's Chemistry, vol. ii. p. 277.

(245.) L. " Hydriodate of potash does not precipitate solutions of manganese, nickel, or cobalt. Hence the hydriodates of these metals are soluble in water. Gay Lussac is of opinion that all the hydriodates of the 4th part II.
Bromine. M. Balard has, however, succeeded in forming the Bromide of carbon. With selenium, Bromine has been also combined by M. Serullas.

(255.) I. With the metals the action of Bromine is much similar to that of chlorine. Antimony, tin, and potassium burn in it, the latter with great energy. M. Balard supposes that the soluble metallic Bromides are, like the soluble iodides and chlorides, converted into neutral hydro-bromuates; and conversely, that the solutions of hydro-bromates are, by evaporation, converted
Chemistry.

Hydro-bromic Acid.

The Bromides are all decomposed by chlorine, which unites with the metal setting the Bromine free. The attraction of Bromine for mercury is very strong, producing during combination considerable heat, but no light. M. Balard describes the Bromides of lead, mercury, silver, gold, and platinum: those of arsenic and bismuth are described by M. Serullas. (c.)

(256.) K. The only actions that can take place between Bromine and the Acids, is of the nature of decompositions: these, however, at present require further examination.

(257.) L. Bromine, or its combinations, produce no action whatever upon solutions of starch, by which it is clearly distinguished from iodine. An effort has been made to employ it as a test for all the vegetable alkalies; but complete success has not been obtained. (c.) The Bromate of potassa affords no precipitate with the Salts of lead; but a white one with the nitrate of silver, and a yellowish white one, soluble in nitric Acid with the proto-nitrate of mercury. By these characteristics it is well distinguished from the chlorate or iodate of the same alkali.

(258.) M. Bromine appears to possess poisonous properties; for by placing a drop of it upon the beak of a bird, the animal was destroyed.

Subsect. 1. — Bromic Acid.

Bromic Acid.

(259.) When Bromine is agitated with a concentrated solution of potassa, or when the solid alkali is mixed with an ethereal solution of Bromine, two Salts, the Bromate and hydro-bromate of potassa, are formed. By evaporation, these are obtained in separate crystals; those of the hydro-bromate being cubic, and those of the Bromate acicular. The Bromate of potassa is separated from the hydro-bromate by being very sparingly soluble in cold water, while the latter is readily so. The Bromates possess properties analogous to those of the iodates and chlorates. Thus the Bromate of potassa when heated becomes Bromide of potassium, oxygen being disengaged; it deflagrates when thrown on ignited charcoal, and when mixed with sulphur it detonates upon percussion. The Acid of the Bromates is decomposed by substances that abstract oxygen, such as the sulphurous and hydro-sulphurous Acids. The Bromates also are decomposed by the hydro-chloric and hydro-bromic Acids.

The Bromic Acid is obtained in a separate state, by adding dilute sulphuric Acid to the Bromate of barytes. This Bromate may either be formed from the Bromate of potassa, or directly upon the general principle, that all the alkaline earths, except magnesium, seem to form with solutions containing Bromine the Bromic and hydro-bromic Acids, which may be separated as above described.

The Salts of lead produce no precipitate with solutions of Bromate of potassa, but abundant ones with the hydro-bromate of that alkali. M. Balard supposes the Bromic Acid to contain five atoms of oxygen + one atom of Bromine.

Subsect. 2. — Hydro-bromic Acid.

Hydro-bromic Acid.

(260.) The action between bromine and hydrogen has been already noticed, (254.) but the best process for forming Hydro-bromic Acid is to mix together a small quantity of phosphorus and bromine in a retort; some moisture should be present; and by application

of a gentle heat Hydro-bromic Acid Gas is copiously evolved. This Gas may be collected over mercury or dissolved in water.

Hydro-bromic Acid Gas has a pungent odour and an acid taste. On meeting with moist air, it produces very dense white vapours. It is not decomposed by being passed through a red-hot tube, even when mixed with oxygen. Chlorine immediately decomposes it, though iodine does not. Potassium decomposes it at all temperatures; and tin also when heated. Nitric Acid decomposes the watery solution of Hydro-bromic Acid with evolution of bromine; and the mixed liquid will dissolve gold. The alkalies, earths, the oxides of iron, and the peroxides of copper and mercury unite with Hydro-bromic Acid to form true Hydro-bromates; but with the oxide of silver and the protoxide of lead, a double decomposition takes place, producing a metallic bromide and water.

Iron, zinc, and tin dissolve in Hydro-bromic Acid; hydrogen being evolved. Hydro-bromic Acid consists of equal volumes of its two elements in the Gaseous state.

CHAPTER III

Non-metallic (Electro-positive?) Elements.

The substances which we shall consider in this Chapter are in number eight, exclusive of some important compounds, which will also be noticed as proximate elements; viz. silicon, hydrogen, carbon, boron, phosphorus, sulphur, selenion, and nitrogen. Of these, hydrogen and nitrogen are at present considered permanent Gases; but there is some reason to conclude from analogy, that, by enormous pressure, these and all Gaseous fluids might be reduced to the liquid form. The six remaining bodies are solid at our ordinary temperatures. Phosphorus, sulphur, and selenion are fusible and volatile; while silicon, boron, and carbon are generally considered as insusceptible and fixed. Not one of these has any action on oxygen at the ordinary atmospheric temperatures. Nitrogen has none at any temperature, however elevated; but hydrogen, boron, carbon, phosphorus, sulphur, and selenion are capable of combination with it, heat and light being evolved.

That silicon may be converted into an Acid is doubtful. Hydrogen is acidifiable by chlorine, fluorine (?) iodine, and bromine. Carbon, boron, phosphorus, and nitrogen by oxygen only; but sulphur and selenion by both oxygen and hydrogen.

§ 1. Silicon.

(261.) A. The name Silicon has been proposed by Dr. Thomson (a.) for the base of the well-known earth silica.

The Hydro-bromic Acid Gas is evolved; he gave to its base the name of silicium, and such it continues with M. Thenard, and those who consider
Chemistry.

this base entitled to rank among the metals. But if, with the greater number of Chemists, we consider this base analogous to boron and carbon, and destitute of metallic properties, Silicon is the more appropriate term.

Sir H. Davy, after having succeeded in decomposing the fixed alcalies and alkaline earths by the action of the Galvanic battery, was naturally led to try the effects of the same powerful agent upon silica. But his experiments were not attended with success. (b) But the analogy between silica and other bodies containing oxygen is so great, that it was universally considered as a compound of oxygen and a combustible base. Berzelius succeeded in separating this base from silica, and uniting it to iron, (c) and his experiments were successfully repeated by Professor Stromeyer. (d) About the end of 1813, Sir H. Davy succeeded in obtaining the base of silica in a separate state, although he was not able to collect and examine its properties in detail. (e) Thomson. (a) Berzelius completed the evidence of the nature of this substance in 1824. (aa)

(262.) B. Davy decomposed silica by passing excess of potassium through it in a heated tube of platinum. The potassium was converted into potash, through which the Silicon was disposed in the form of a dark-coloured powder.

Berzelius says nothing is more easy than to procure Silicon; the method by which it is obtained is this. The double fluote of silica with potassa or soda, heated almost to a red heat, for the purpose of driving off the hygrometric water, is introduced into a tube of glass closed at one end. Some fragments of potassium are introduced, and care is taken to mix the potassium with the powder, by applying a heat sufficient to fuse the metal, and gently tapping the tube. The heat of a lamp is then applied, and before the mixture arrives at a red heat there is a feeble detonation, and the Silicon is produced. The mass is then left to cool, and afterward washed with water as long as anything is dissolved. At first there is a disengagement of hydrogen Gas, because a silicuret of potassium is obtained, which cannot exist in water. The washed substance is a hyduret of Silicon, which at a red heat burns vividly in oxygen Gas; though the Silicon does not become oxidated. This hyduret is then to be put into a covered platinum crucible, and heated by slow degrees up to redness. The hydrogen becomes oxidated alone, and the Silicon will no longer burn in oxygen, though chlorine attacks it readily. A small quantity of silica is produced, which may be dissolved by fluoric Acid. If the Silicon has not been well heated to redness, the Acid dissolves it with slow disengagement of hydrogen. (aa)

(263.) C. Silicon is a dark nut-brown powder, having no metallic lustre. It is a nonconductor of Electricity, and is insusible before the blowpipe.

(264.) D. Silicon does not burn in atmospheric air, or oxygen Gas, but it indirectly will form a very firm compound with that substance; thus producing the well-known earth silica, which exists in great abundance in Nature. See subsect. 1.

(265.) E. Silicon readily unites with chlorine as already stated.

(266.) F. With fluorne, Silicon unites to form an Acid Gas which has been already noticed. (184)

(267.) G. Unexamined.

(268.) H. Silicon unites with hydrogen, but its habitudes with other bodies of this class require investigation.

(269.) I. There is great reason to suppose that Silicon may unite with most of the metals, but as yet its combinations with iron and potassium are all that are mentioned.

(270.) K. Silicon is neither oxidated nor dissolved by the nitric, hydro-chloric, sulphuric, or fluoric Acids; but it is readily soluble in even a cold mixture of the nitric and fluoric Acids.

Silicon is not changed by being ignited with chlorate of potassa. It does not deflagrate in nitre, until the temperature is raised high enough to decompose the Acid; and then oxidation takes place in consequence of the concurrent affinities of oxygen for Silicon, and of silica for the disengaged potash. By a similar play of affinities, Silicon burns vividly when brought into contact with carbonate of potassa or soda, even below a red heat. When dropped upon fused hydrate of potassa, soda, or baryta, hydrogen is evolved with such rapidity as to produce explosion.

(271.) L. M. All that need be said on these heads will be found in subsect. 1. L. and M.

Subsect. 1.—Silica.

(272.) A. From the element silicon we proceed to its oxide Silica, which has long been known as one of the earths, and forms, in its various combinations with other mineral bodies, the largest proportion of the substance of our planet. "Quartz, chalcedony, flint, sand, and some other minerals consisting principally of Silica, have the property of melting into glass when strongly heated with potash or soda, and, therefore, were classed together by the early Mineralogists under the name of vitriifiable stones. Mr. Pott, who first described the properties of these minerals in 1746, gave them the name of Siliceous stones, supposing them to be chiefly composed of a peculiar earth, called Siliceous Earth, or Silica. This earth was known to Glauber, who describes the method of obtaining it from quartz. But it was long before its properties were accurately ascertained. Geoffroy endeavoured to prove that it might be converted into lime, (f) ; Pott (g) and Beaume (h) that it might be converted into alumina; but these assertions were refuted by Cartheuser, (i) Scheele, (k) and Bergman. (f) To this last Chemist we are indebted for the first accurate description (m) of the properties of Silica." (n)

(273.) B. Pure Silica is obtained by fusing pulverized flint with thrice its weight of caustic potash in a silver crucible. The spongy mass thus obtained is to be dissolved in water, and then super-saturated with muriatic Acid, and slowly evaporated to dryness. By subsequent affusion of water the alkaline Salt is removed, and the Silica remains pure.

(274.) C. Thus obtained Silica is a white powder, without taste or smell. Not soluble in water. "But when the compound of Silica and potash is dissolved in water, and sufficiently diluted, the Silica cannot be precipitated from it by any addition of Acid; showing that in this state it is really soluble in water." After it has been thoroughly dried it seems quite insoluble; but when fresh precipitated, and still moist, it dissolves, according to Kirwan, in 1000 parts of distilled water, and it exists naturally in minute proportions in some mineral waters, such as the Geyser springs in Iceland.
Silica is infusible, except by the heat of the Gas blowpipe. It is not volatile under our ordinary processes, though it would seem from some observations of Bergman, and also from a more recent notice, that it is capable of volatilization by intense heat. (r.)

The crystallization of Silica forms a marked feature among its Physical properties. In Nature it is found in this state abundantly. There must be few who have not admired the beautiful hexagonal prisms of quartz, terminated by hexahedral pyramids, which occur in every Country of the Earth. This is rock crystal in its most common secondary form. We are frequently led to suppose that the process of the formation of crystals in the earth is a very tedious process, requiring the quiet operation of Ages to accomplish, but Chemistry offers many reasons to induce us to suspect that this may easily be overrated. The following confirmation of this view is taken from Thomson's System: "There are two methods of imitating these crystals by art. The first method was discovered by Bergman. He dissolved Silica in hydrofluoric Acid, and allowed the solution to remain undisturbed for two years. A number of crystals were then found at the bottom of the vessel, mostly of irregular figures, but some of them cubes with their angles truncated. They were hard, but not to be compared in this respect with rock crystal. (o.) The other method was discovered by accident. Professor Seiglino of Erfurt had prepared a Liquor Silicum, which was more than usually diluted with water, and contained a superabundance of alkali. It lay undisturbed for eight years in a glass vessel, the mouth of which was only covered with paper. Happening to look at it by accident, he observed it to contain a number of crystals, on which he sent it to Mr. Tromsdorf, Professor of Chemistry at Erfurt, who examined it. The liquor remaining amounted to about two ounces. Its surface was covered by a transparent crust, so strong that the vessel might be inverted without spilling any of the liquid. At the bottom of the vessel were a number of crystals, which proved on examination to be sulphate of potash and carbonate of potash. The crust on the top consisted partly of carbonate of potash, and partly of crystallized Silica. These last crystals had assumed the form of tetrahedral pyramids in groups: they were perfectly transparent, and so hard that they struck fire with steel." (p.)

If lime water be added to a solution of Silica in potash, a precipitate falls down containing the two earths in a state of combination. (w.) The compounds formed by fusing these two substances together, have been examined by Mr. Kirwan: (t. p. 56.) when the earths were in equal quantities an imperfect sort of enamel was formed. Silica has a strong affinity for alumina; for, according to Morveau, (s. p. 248.) if equal parts of Silicated potash and Silicated alumina, both in solution, be mixed together, a brown cloud appears, which by gentle agitation spreads throughout the whole Liquid. In the course of an hour this cloud gelatinizes. These two earths, however, cannot be heated so as to run into fusion. (s. and t.)

(281.) L. Silica is recognised by its insolubility in all Acids except the fluoric: by forming a compound entirely soluble in water upon calcination with twice its weight of potash in a silver crucible. The solution when concentrated forms a coagulum upon the addition of an Acid.

(282.) M. The uses of Silica are numerous and important. A variety of rock crystal, which occurs in rolled masses in the Island of Madagascar, being beautifully diaphanous, is cut for spectacles, and goes by the common name of crystal. The rich amethysts that come from Spain, Siberia, and Brazil, are only the same substance naturally coloured by the oxide of manganese. The manufacture of Glass will require a more extended detail in another part of this Work: for the present, therefore, we must be satisfied with stating, that two parts of Silica fused with from one to one and a half of carbonate of potash or soda, forms this most beautiful and useful substance. The more pure the ingredients the more clear will be the Glass; but as both the substances employed are not previously purified by the tedious and costly Chemical processes, the manufacturer is obliged to resort to other artifices for the improvement of his metal, as the fused compound is technically called. The finer kinds of Glass are made from pounded flint and the best pearl ash, or sometimes
Hydrogen.

(283.) A. With regard to the discovery of Hydrogen Gas, Dr. Thomson states that "Mayow, (a.) Boyle, (b.) and Hales procured it in considerable quantities, and noted a few of its mechanical properties. Its combustibility was known about the beginning of the XVIIIth century, and was often exhibited as a curiosity. (c.) But Mr. Cavendish (d.) ought to be considered its real discoverer; since it was he who first examined it, who pointed out the difference between it and atmospheric air, and who ascertained the greatest number of its properties." (e.)

Hydrogen Gas is frequently generated in considerable quantities in mines, or in other parts of the Earth where metallic bodies exist. (f)

(284.) B. Hydrogen Gas is readily obtained by acting upon iron turnings or small nails with sulphuric Acid, diluted with five or six times its weight of water. Granulated zinc may also be employed, in which case the dilute Acid may consist of eight-ninths of water. In both cases the metal is to be placed in a retort or glass proof, and the Gas, which is rapidly evolved, may be collected in jars over the water-trough. A very convenient instrument for obtaining and preserving a constant supply of this Gas in a laboratory was contrived by Gay Lussac, and is described in the Annales de Chimie et de Physique. (g.)

Hydrogen Gas, however, thus obtained from metals, is not absolutely pure, (k.) and requires to be washed with a solution of caustic potassa. Berzelius discovered that Hydrogen Gas produced from iron filings and dilute sulphuric Acid, might be deprived of all scent by being passed through pure alcohol; and that when the alcohol is diluted with water, and kept a few days, the odorous volatile oil is separated. (i.) Hydrogen Gas may also be procured in very considerable quantities by passing the vapour of water over coils of iron-wire heated to redness in a gun-barrel: the iron undergoes oxidation and the Hydrogen is set free.

(285.) C. Pure Hydrogen Gas is free from smell and taste. Water will absorb only about two per cent. of its own volume. It is unsalted by heat and electricity. Its action on the rays of light is more highly refractive than that of any other Gas. It is inflammable, and the lightest of all known substances. It will not support animal life, though its properties do not seem to be poisonous. When breathed from a bladder or oil-silk bag, it renders the tone of the voice of a much higher pitch than usual: an effect which shortly goes off again. (p.)

The combustion of Hydrogen with oxygen affords many interesting particulars, for the full details of which we can only point out the references. (k.) Water is the sole produce of this combustion, subsect. 1. The proportion in which these two elements unite is precisely two volumes of Hydrogen + one volume of oxygen.

When Hydrogen Gas, issuing from a small orifice, is burned in common air, and a glass tube is held over the flame, musical sounds are produced. (m.)

(286.) D. Hydrogen and oxygen do not unite when merely placed in contact with each other, but by violent compression. M. Biot found a mixture of these Gases might be made to unite. The combination took place with evolution of light and heat. Biot also found that a pressure of thirty atmospheres, produced by sinking a vessel of the mixed Gases to a depth of one hundred and fifty fathoms in the sea, did not cause their union. (a.)

The combination of these Gases may also be produced by the electric spark, by a glowing coal, or a red-hot wire; but if the heat of these bodies be below redness, the combination takes place gradually and silently. When the Gases are in the just proportion to form water, the.
detonation is very violent; upon this combination depends the eudiometer of Volta, and the philosophical experiment of the air-pistol.

Döbereiner discovered that the sub-oxide of platinum, and also the pulverulent metallic platinum, obtained by heating the ammonium-muriate, would, if plunged into the mixed gases, condense the hydrogen in its pores so violently as to become red hot, by which means instantaneous combustion is produced. It has been proposed to employ this method also for eudiometry. Upon this property is founded an elegant instrument for obtaining an instantaneous light.

The intense heat developed by the combustion of hydrogen with oxygen has been applied to the construction of a blowpipe for the fusion of refractory bodies, and there is scarcely any substance in nature that can resist its action. See Blowpipe, in the Miscellaneous Department of this Work, or Professor Clarke's Treatise on the Gas Blowpipe.

Hydrogen and oxygen may also be made to unite in a proportion different from that in which they form water. See Subsect. 2.

Hydrogen forms with potassium two compounds; the solid hydriuret discovered by MM. Gay Lussac and Thenard, and also a gaseous compound described by M. Sementini of Naples. With arsenic, also, two analogous compounds are formed; the one solid, the other gaseous. Tellurium forms with hydrogen two compounds; the one gaseous, telluriated hydrogen, which has acid properties; the other a white powder discovered by Ritter, but at present little known.

Hydrogen is principally recognised by its property of combustibility, and by its union with oxygen, determinable by the electric spark in Volta's eudiometer.

Subsect. 1.—Water.

Water.

The chemical history of this well-known and essential substance, formerly called one of the four elements of the Earth, possesses considerable interest; both with regard to its actual properties, and the elaborate researches to which it has given rise.

Pure water is a colourless liquid, having neither scent nor taste. It refracts light very strongly, is an imperfect conductor of electricity, and a very slow conductor of heat. It is now admitted to be a compressible fluid. Its specific gravity is called one, being made the unit of the scale to which the gravity of all other solid and liquid bodies is referred. Water is obtained in the greatest purity by slow distillation; but it is also sufficiently pure for many purposes when procured by melting snow, or by collecting rain water at a distance from houses or large towns. One cubic inch of water at 60° Fahrenheit and 30° in Ber. weighs 252.525 grains. Its weight is 828 times that of an equal volume of atmospheric air under the same circumstances.

The decomposition of water may be effected in various ways. By submitting it to the action of a voltaic battery, the two constituent gases oxygen and hydrogen may be obtained separately. The same may be performed by a current of electricity from the common electrical machine.

The hydrogen may be obtained in the gaseous form by passing steam over coils of iron wire made red hot in a gun-barrel, or in a porcelain tube. In this case the oxygen assumes the solid form in combination with the iron.

To obtain the oxygen gas alone, a few sprigs of mint be placed in an inverted jar filled with water over the pneumatic trough; as long as the vital functions of the plant are going on hydrogen is taken up by its leaves, pure oxygen gas is evolved, and is collected in the jar.

The converse operation of the synthesis of water is effected by mixing together oxygen and hydrogen gases, and then applying a lighted taper, a piece of spongy platinum, or by passing an electric spark through the mixture. This experiment requires care, as the detonation of the mixed gases is very violent.

The just proportion, so as to leave no residuary gas, is one volume of oxygen gas + one volume of hydrogen gas. If a jet of hydrogen gas be lighted, and then an empty glass balloon be inverted over it, the water that is formed by this union with oxygen will condense in drops of water on the sides of the balloon. It is now generally admitted that water consists of precisely two volumes of hydrogen combined with one volume of oxygen, or by weight eight parts of oxygen + one part of hydrogen; or, according to the present views of the atomic theory, of one atom of each of these elements. The atom of water, therefore, upon the hydrogen scale = 9.

Water generally contains within its pores atmospheric air; and it is capable of absorbing various proportions of the different gases. It exists also at all times in the atmosphere in the state of vapour; the quantity differing greatly at different temperatures. Pulverulent substances also absorb and retain considerable quantities of aqueous vapour. Water is one of the most universal solvents in nature. It enters also frequently into combination with other substances, and assumes the solid form; of this the slaking of lime is an example; as also the common hydrates of potash, soda, &c. which, in appearance, are quite dry. The point at which water has its maximum density is generally stated to be 39° Fahrenheit, but M. Biot places it at 38° 15'. It congeals at 0° Fahrenheit, and boils at 212° Fahrenheit, Ber. 30°, but it rises in vapour at much inferior degrees of temperature.

Subsect. 2.—Deutoxide of Hydrogen.

This substance was discovered by M. The-

Deutoxide of Hydro-

CHEMISTRY.

Chemistry. The Deutoxide of Hydrogen is limpid, like water; has scarcely any smell. It gradually destroys the colour of papers stained with vegetable blues. It readily attacks the epidermis, whitens it, and causes a prickling sensation, the continuance of which varies in different individuals. Applied to the tongue it produces similar effects, together with a sort of slightly metallic taste. The elastic force of its vapour is much less than that of water, at any given temperature. It will entirely rise in vapour, even at low temperatures, though but slowly. Thenard was not able to freeze this Liquid by any degree of cold that he could produce. It must always be kept surrounded with ice, for it decomposes rapidly at a temperature of 56° Fahrenheit; and the heat of boiling water is sufficient to produce an explosion from the rapidity of the decomposition. The Specific Gravity of this Liquid is 1.425. It will mix with water, but if poured gently into that Liquid it passes through it like a sirop. From the analysis of M. Thenard it appears that the Deutoxide of Hydrogen contains twice as much oxygen as the protoxide; that is to say, two atoms of oxygen = 16 + one atom of hydrogen = 1, so that the weight of its atom = 17.

Light does not produce any very marked change upon this Liquid. The metals act upon it variously; some abstract a portion of its oxygen and reduce it to the state of water; others set a part of the oxygen free and take the remainder into combination; while others liberate all the oxygen without possessing themselves of any of it; and a few seem to possess no action upon it whatever. The Acids, especially the stronger ones, render the combination between its elements more firm. By the Voltaic pile it undergoes decomposition like water, as must be expected.

References to § 2.

CHEMISTRY.

Pure Carbon is insoluble, and has neither smell nor taste. Charcoal, in consequence of its numerous pores, is capable of absorbing and even condensing within itself very considerable quantities of Gaseous fluids; but these quantities differ for different Gases. On this point the experiments of Saussure seem the most satisfactory; but others will be found by reference. (f.) It has also a great tendency to absorb moisture from the atmosphere, and in this respect the different woods vary in their powers. (g.)

(300.) D. In atmospheric air charcoal will just burn, but a small piece will not keep up a state of combustion without a current of air, or the aid of adventitious heat. In oxygen, however, a piece of charcoal, heated previously, burns with vigour. The diamond will burn in atmospheric air when heated on a muffle; and in oxygen Gas it continues to support its own combustion, if previously heated by being placed in the focus of a lens. It burns, also, by being thrown into melted nitre. The produce of this combustion is Carbonic oxide. (2.) With oxygen, also, another compound may be formed, to which the name of Carbonic oxide may be given. See subsect. 1.

(301.) E. If charcoal be ignited in chlorine Gas no combination is produced, but by an indirect process Mr. Faraday succeeded in forming two chlorides of Carbon, and another such combination has been subsequently discovered.

Olefiant Gas consists of one atom Carbon + one atom hydrogen. If this Gas be mixed with an equal volume of chlorine, the three elements all unite. From this compound the hydrogen may be abstracted by treating it with pure chlorine, and a true chloride of Carbon results. For the minutiae of the process we must refer to Mr. Faraday’s Memoir. (h.) This substance Mr. Faraday calls the Perchloride of Carbon. It is a solid, pulverulent, or crystalline substance, having an odour something like that of camphor. Its refractive power is greater than that of flint glass. Specific Gravity about 2.0. It does not conduct electricity. Its melting point is 320° Fahrenheit, and it boils at 360° Fahrenheit. It is scarcely soluble in water, but dissolves in ether or alcohol, and in both the fixed and volatile oils. In the flame of a spirit-lamp it burns with a red light, and supports a vivid combustion in oxygen. The produce of this combination is Carbonic acid. See subsect. 2. With oxygen, also, another compound may be formed, to which the name of Carbonic oxide may be given. See subsect. 1.

(302.) By passing the vapour of the substance just described over fragments of rock crystal in a red-hot glass tube, a partial decomposition is effected; one portion of chlorine escapes, and a liquid Chloride of Carbon, containing one atom of each of its elements, condenses in the cooler parts of the tube. The Specific Gravity of this fluid is 1.5526. Its refractive power 1.4575. It is perfectly limpid, and is not combustible per se, but burns in the flame of a spirit-lamp. It remains fluid at 0° Fahrenheit; rises in vapour between 160° and 170° Fahrenheit. It does not mix with water, but dissolves in ether and alcohol; is unaffected by Acids or alkalis; but is decomposed at high temperatures by oxygen, hydrogen, and the metals.

(303.) The sub-chloride of Carbon was brought to England from Sweden by M. Julin of Abo, in Finland, where it had formed accidentally during the distillation of nitric Acid from nitre and sulphate of iron. (i.) This substance is in the form of soft white fibres, insoluble in water; not acted upon by boiling Acids or alkalis; soluable in heated turpentine, and also in alcohol; but most of it again separates in a crystalline form when it is cooled. It sublimes slowly at 250° Fahrenheit; but fuses, boils, and is volatilized between 350° and 450° Fahrenheit. Potassium burns in its vapour with deposition of the Carbon. It is decomposed by passing over fragments of rock crystal heated to redness. From the analysis of Messrs. R. Phillips and Faraday, it appears to consist of one atom chlorine + one atom Carbon.

(304.) Chloro-carbonic Acid. This name is now applied to a Gas called by Dr. Davy, its discoverer, Phlogene Gas, from the mode of its preparation. When equal volumes of chlorine and Carbonic oxide Gases are made perfectly dry and exposed in a flask for a quarter of an hour to bright sunshine, the green colour disappears and a condensation of one half the volume takes place. This Gas has a very pungent odour, redens litmus paper, is decomposed by water into muriatic and Carbonic Acid Gases. It forms a Salt with ammonium: thus affording the rare instance of a simple base united to two acidifying principles. Its constitution is one atom Carbonic oxide + one atom of chlorine. (k.)

(305.) F. Unknown.

(306.) G. Undiscovered. (l.)

(307.) H. With the substances under this head Carbon forms most important combinations, which will for the most part be noticed hereafter. The compound of Carbon with nitrogen is called Cyanogen. See sect. 3. Its combinations with hydrogen will be found in subsect. 3, 4, 5, 6, 7, and 8, and a curious substance formed by its union with sulphur, in sect. 6, subsect. 7.

(308.) I. With the metals Carbon forms several compounds. Those with iron are of first-rate importance in the Arts. Plumbago has been already mentioned. Steel, in all its various forms, consists essentially of iron united to Carbon.

(309.) K. The distinguishing characteristics of Carbon are, that it is solid, insipid, inodorous, fixed under ordinary processes, and (the diamond excepted) black. By combustion with oxygen it forms Carbonic Acid, a substance readily recognized.

(310.) L. The uses of Carbon are as a fuel; in the manufacture of gunpowder; as a pigment; in the formation of steel; for the production of coal Gas for the purposes of illumination; as a polishing powder. It has also a very singular power of depriving many substances of colour, and of rendering them inodorous. The principle of its action in these cases is by no means well understood. (m.) It is highly antiseptic, and hence it forms a good tooth-powder; it will remove the smell from tainted meat; and water may be preserved pure in long sea voyages by charring the inside of the casks. (n.)

Subsect. 1.—Carbonic Oxide.

(311.) The discovery of this Gas was made by Dr. Priestley, who obtained it from the distillation of charcoal with Oxide of zinc. Its properties were more fully developed by Mr. Cruickshank, (o.) and subsequently by M.M. Clement and Desormes. (p.) The associated Dutch Chemists proposed a different view of its nature, (q.) which, however, has proved erroneous. It may be obtained:
1. By distilling one part of charcoal with eight parts of oxide of zinc in an earthen or coated glass retort. Finery einder, which is iron in a low degree of oxidation, may be used instead of the oxide of zinc.

2. By transmitting Carbonic Acid Gas over ignited charcoal in a porcelain tube: a convenient apparatus for the purpose is described by M. Barel.

3. By distilling dry Carbonate of lime or barytes, with one-fifth its weight of charcoal, or with dry iron, or zinc filings.

The gas so obtained must be purified by agitation with lime water, or solution of a caustic alkali.

Carbonic Oxide has an unpleasant smell: it is inflammable, burning with a blue flame. Mixed with half its volume of common air it forms an explosive compound, which may be ignited by a hot wire, or a piece of lighted charcoal. It is lighter than common air. Its action with oxygen, when in contact with spongy plate-iron, is described by Dr. Henry. This Gas is but slightly soluble in water, and does not cause any precipitation in lime water. It is noxious to animal life. Dr. Henry found that it was decomposed into Carbonic oxide and oxygen; and when all excess of Carbonic Acid is removed, the remaining mixed gases may be again united by the electric spark, so as to reproduce Carbonic Acid.

On the other hand, its analysis may be effected by various methods.

1. By passing a succession of electric discharges through a quantity of Carbonic Acid Gas confined over mercury, Dr. Henry found that it was decomposed into Carbonic oxide and oxygen; and when all excess of Carbonic Acid is removed, the remaining mixed gases may be again united by the electric spark, so as to reproduce Carbonic Acid.

2. By heating potassium in Carbonic Acid Gas, Davy found that the metal took to itself oxygen, and that Carbon was deposited.

3. By heating phosphorus in Carbonic Acid Gas, no decomposition is produced; but Mr. Tennant found that if the vapour of phosphorus were passed over small fragments of Carbonate of lime made red-hot in a coated tube of glass, decomposition takes place; phosphoric Acid is formed, and Carbon is found as a black powder mixed with the marble.

(313.) B. Carbonic Acid is readily procured by putting a few small lumps of marble or chalk into a Gas bottle, and pouring upon them either sulphuric Acid diluted with six times its weight of water, or muriatic Acid, which is still better, and may be rather more diluted. The Gas disengaged may be received in jars over the mercurial trough, or even over water, though in this case some is absorbed by that fluid. The composition of this Gas is best shown by exhibiting both its synthesis and analysis. By the combustion of a known weight of charcoal or of diamond in oxygen Gas, a quantity of Carbonic Acid Gas is generated, which may be weighed or otherwise estimated; and hence the quantity of oxygen taken into combination may be ascertained.

On the other hand, its analysis may be effected by various methods.

1. By passing a succession of electric discharges through a quantity of Carbonic Acid Gas confined over mercury, Dr. Henry found that it was decomposed into Carbonic oxide and oxygen; and when all excess of Carbonic Acid is removed, the remaining mixed gases may be again united by the electric spark, so as to reproduce Carbonic Acid.

2. By heating potassium in Carbonic Acid Gas, Davy found that the metal took to itself oxygen, and that Carbon was deposited.

3. By heating phosphorus in Carbonic Acid Gas, no decomposition is produced; but Mr. Tennant found that if the vapour of phosphorus were passed over small fragments of Carbonate of lime made red-hot in a coated tube of glass, decomposition takes place; phosphoric Acid is formed, and Carbon is found as a black powder mixed with the marble.

From these and such processes it is ascertained that Carbonic Acid consists of two atoms of oxygen + one atom of Carbon; or, according to Gay Lussac's views, of one volume of Gaseous Carbon + one volume of oxygen, condensed into one volume.

(314.) C. Gaseous Carbonic Acid has the following properties. It instantly extinguishes flame, and is quite fatal to animal life. It is heavier than common air; having a Specific Gravity of 1.52778. It is absorbed by water, and the quantity so taken up is in proportion to the pressure employed. From such water it is again expelled by boiling, by the exhaustion of an air-pump, or by the freezing of the water. When moisture is present, it reddens vegetable blue colours. It is highly antiseptic, preventing the putrefaction of animal substances immersed in it.

Carbonic Acid has been exhibited in a liquid state by Mr. Faraday. This excellent Chemist procured it in this form by disengaging it from Carbonate of ammonia, under the violent compression of a sealed tube, one end of which was placed in a freezing mixture. The Liquid was a colourless Fluid, floating upon sulphuric Acid and water contained in the tube. It distils rapidly over at a temperature below 32° Fahrenheit. Its refractive power is much below that of water. The pressure under which this Fluid formed was found to be thirty-two atmospheres.

The action of the other elementary bodies upon Carbonic Acid has been but little examined, so that we here pass on to the principal purpose for which it is prepared. Soda water, as it is called, consists of water strongly impregnated with this Gas, and is both formed and preserved under considerable pressure, which is never removed until the bottles are opened for
Compounds of Carbon and Hydrogen.

So numerous and varied are the compounds of Carbon and Hydrogen, which have been obtained by Chemical processes, that some Chemists have been led to suppose that these two elements are capable of uniting in almost an indefinite variety of proportions. It is, however, much more probable, that these Gases are, in fact, only admixtures containing different quantities, of two or three well-defined combinations. There is also this peculiarity in the compounds which we are about to notice; that Gases differing in properties are produced by the very same proportionate combination of the two constituent elements. The only appreciable difference in their constitution is, however, one which we might readily suppose would produce a very marked effect upon the combination formed; viz. that the degree of condensation undergone by the Gaseous elements in one case, may be double or triple of that which they suffer in another case, though a Gas be still the result. Thus, if the views of Mr. Dalton be correct, one atom of Carbon + one atom of Hydrogen produces olefiant Gas; and three atoms of Carbon + three atoms of Hydrogen produce superolefiant Gas; both the compounds presenting only one volume of resulting Gas.

We shall here notice in succession, the various described compounds of Carbon and Hydrogen, though our information concerning them is at present far from being full and satisfactory; some resting on much stronger evidence than others. They are as follows:

(315.) Mr. Dalton was the first to examine this Gas with care, though it was known to Priestley and Cruickshanks. It may be obtained by disturbing the mud at the bottom of any stagnant pond, from which it rises in bubbles through the water, and is to be collected in a jar or bottle as usual. Thus obtained it contains about five per cent. of carbonic Acid, and rather less nitrogen. It may also be obtained from coal Gas, of which it forms a part, by removing other Gaseous products with which it is mixed.

This Gas has neither scent nor taste; it extinguishes burning bodies, and is itself combustible, burning with a bright yellow flame. It is not decomposed by being passed through moderately heated tubes. Chlorine aided by light decomposes this Gas, if moisture be present; the Hydrogen unites with the chlorine to form muriatic Acid; and the oxygen and carbon produce carbonic Acid or carbonic oxide, according to the proportions employed. By exposing the mixed Gases to electricity or to a red heat, hydrochloric Acid is formed and carbon deposited. (y.)

From the researches of Dr. Henry, it was first clearly ascertained that the Fire Damp of coal mines is chiefly this Gas. Its formation takes place spontaneously in the beds of coal; it then collects in cavities, and becoming mixed with atmospheric air, it forms that highly explosive compound, which lights by the approach of a candle and causes frequent melancholy accidents in mines.

The researches made by Sir H. Davy, and the result of them, must be considered as among the most striking and beneficial applications of Chemical Science to the purposes of life. He first ascertained that when the inflammable Gas is mixed with three or four times its volume of air it is not explosive. When mixed with five or six times its volume it detonates feebly; but powerfully when the proportion is one to seven or eight: it ceases to be explosive when more than fourteen times the volume of common air is mixed with it.

With regard to the temperature at which the mixed Gases will unite, it was found that iron at even white heat was insufficient, but that any flame, however small, would cause the Gases to explode.

It had been shown by Profesor Tennant, in his Lectures at Cambridge in 1814, that flame would not traverse tubes of small diameter: (x) but there is no evidence to prove that Sir H. Davy's researches were directed by a knowledge of this fact, though it is not improbable that he was acquainted with it. However, proceeding in his experiments, he found that not only extremely short tubes but even a net of wire gauze was sufficient to interrupt the course of flame; and he made the admirable application of this principle to the construction of the Safety Lamp. This instrument consists of a lamp of the common construction, but entirely surrounded with a case of wire gauze. When the miner, guided by this lamp, arrives in mixed air of such quality as to be explosive, the flame of the wick at first enlarges, and should the Gas within the lamp take fire, it extinguishes the flame of the lamp and the miner must withdraw: for although no flame passes through the apertures of the gauze to ignite the Gas of the mine, yet in a short time the iron net may be destroyed by the intense heat within. Some lamps have been made with a sort of cage of platinum wire hanging over the wick. The effect of this is, that should an explosion take place within the lamp, so as to extinguish it, the platinum wire becomes sufficiently heated to continue to glow at a red heat by the silent combination that is being produced between the Gases of the explosive compound, and thus to afford the miner a feeble light for his escape. (aa.)

This sort of action may be elegantly exhibited by twisting a few coils of platinum wire round the wick of a spirit-lamp, so that the five or six last turns of the wire stand about one-fifth of an inch above the wick. The lamp is thus lighted, and when the wire is red-hot may be suddenly extinguished. The platinum will continue to glow for many hours in consequence of the slow combustion which it produces between the vapour of the spirit and the atmospheric air. (bb.)

This Gas consists of carbon one atom + Hydrogen two atoms.
Chemistry. Subsect. 4.—Olefiant Gas. (Bicarburetted Hydrogen: Per-carburetted Hydrogen: Hydroguret of Carbon, Thomson.)

Olefiant Gas. (317.) The discovery of this Gas was made by the associated Dutch Chemists in 1796. They named it Olefiant Gas, from its property of forming an oil-like substance with chlorine.

To obtain it, let three measures of strong sulphuric Acid be distilled with one measure of alcohol in a glass retort by a very gentle heat. The Gas may be collected over water and freed from carbonic Acid by a solution of caustic potassa.

Olefiant Gas has a slight odour of sulphuric ether, which is formed during its production. It burns with a flame much more luminous than that of light carburetted hydrogen, and it detonates violently when mixed with oxygen in Volta's eudiometer.

When equal quantities of Olefiant Gas and chlorine are mixed together, the volume immediately diminishes and a substance is formed resembling oil in its appearance, but being more like an ether in its properties. To obtain it quite pure, it should be washed with water, and then distilled over from dry chloride of calcium.

This liquid boils at 152° Fahrenheit. Its Specific Gravity at 45° Fahrenheit = 1.2201. It consists of equal volumes of the two elements, chlorine and Olefiant Gas, or of two atoms of the latter to one atom of the former.

Dr. Henry proposes to call it Hydro-chloride of Carbon, which seems a very appropriate name. (cc.)

A compound somewhat analogous, formed of iodine and Olefiant gas, is described by Mr. Faraday. (dd.) Another combination of the same substances was discovered by M. Serullas. (ee.)

Subsect. 5.—Superolefiant Gas. (Dalton.)

(318.) Under such respectable authority as that of Mr. Dalton and Dr. Henry, we cannot omit to mention a Gas discovered and so named by the former Chemist. We are very sensible that these compounds of carbon and hydrogen are by no means fully understood; and therefore there is the greater need to call the attention of Chemists to the point.

Mr. Dalton adduces very strong evidence of the presence of this Gas among the various products obtained by the distillation of oil and coal; but he has not as yet exhibited it in a separate form. Dr. Henry says that it must be a permanent Gas at our temperatures, and not a vapour, for he was unable to condense it by artificial cold. He considers it as composed of three volumes of the vapour of carbon and three volumes of hydrogen condensed into one volume. (ff.)

Subsect. 6.—Bicarburet of Hydrogen. (Faraday.)

(319.) There is an instrument called Gordon's portable Gas lamp, consisting of a cylindrical copper vessel, into which oil Gas is forced and compressed with a power equivalent to thirty atmospheres. During the process of compression a considerable quantity of Fluid is condensed, and remains a Liquid at the ordinary atmospheric pressure. As thus obtained it boils at 60° Fahrenheit; but the temperature gradually rises, and the whole is not dissipated under a temperature of 230° Fahrenheit. In consequence of the boiling point appearing more steady between 176° and 190°, Mr. Faraday carefully examined the Fluid which came over at that temperature. By various precautions he thus obtained the Fluid which he calls the Bicarburet of Hydrogen.

It is a colourless transparent Liquid, having a Specific Gravity of 0.85 at 60° Fahrenheit. It congeals at 32° Fahrenheit, and boils at 186°. It is slightly soluble in water, but readily so in fixed and volatile oils, ether, or alcohol. It burns with a bright yellow flame. Potassium does not obtain any oxygen from it. It is decomposed by passing its vapour through a red-hot porcelain tube, by which carbon is deposited and Carburetted Hydrogen escapes. According to Mr. Faraday's Analysis its constitution is six atoms of carbon + three atoms of hydrogen.

Subsect. 7. —— (Faraday.) Quadro-carburetted Hydrogen of Thomson.

(320.) Another combination also of carbon and hydrogen was recognised by Mr. Faraday, but he did not propose a name for it. It is obtained by heating in the hand the condensed Liquid obtained from oil Gas, and suffering the vapour thus raised to pass through tubes cooled down to zero Fahrenheit. A Liquid is thus condensed which boils upon a very slight elevation of temperature; and before the thermometer rises to 32° Fahrenheit it is wholly reconverted into vapour.

This vapour burns with a brilliant flame. At 60° Fahrenheit and bar. 29.94 it has a Specific Gravity of about 1.9065. The Specific Gravity of the Liquid is 0.627; so that it is the lightest substance known among Liquids or Solids.

It appears that this substance consists of four atoms of carbon + four atoms of Hydrogen; and that in its state of vapour eight volumes of its constituents in the Gaseous state are condensed into one volume.

Subsect. 8.—Nafta from Coal Tar.

(321.) During the distillation of Coal Tar, this volatile Liquid is condensed, and has received its name from its similarity to mineral Nafta. It is highly inflammable and has a strong empyreumatic odour. Dr. Thomson says that the vapour of this Liquid requires nine times its volume of oxygen Gas to condense it completely; and when one volume of it is consumed in this way, there remain behind six volumes of Carbonic Acid Gas as a residue. He states, also, that this vapour is not condensed by passing it through water. Thus it consists of six atoms = six volumes of carbon vapour + six atoms = six volumes of hydrogen, condensed into one volume of vapour. (gg.)

Subsect. 9.—Naphthaline.

(322.) The substance to which this name has been given was first brought into notice by Mr. Gordon in 1820. (hh.) It also is obtained from the Nafta of coal tar by very gentle distillation. The Nafta at first passes over in consequence of its greater volatility, and the Naphthaline afterwards rises in vapour and condenses upon the neck of the retort, in the form of a white crystalline Solid. Crystallized Naphthaline is rather heavier than water, has a slight and not unpleasing odour, and a nacreous appearance. It fuses at 180° Fahrenheit, and boils at 410° Fahrenheit. Naphthaline
Chemistry is not readily inflamed, but when once set on fire it burns freely with much smoke. It is little soluble in either cold or hot water, but readily so in alcohol, ether, olive oil, or turpentine. The alkalis do not affect it, but acetic and oxalic Acids dissolve it, and form pink-coloured solutions. Sulphuric Acid combines with it to form a new compound Acid which Mr. Faraday has called the Sulpho-Naphthalic Acid. (ii.) Dr. Thomson analyzed Naphthaline, and supposes it to consist of an atom and a half of carbon and one atom of hydrogen. The properties of this substance have been chiefly made known, by a very able Memoir on the subject by Professor Kidd of Oxford. (kk.) We have in this subsection adhered to the spelling made use of by Dr. Kidd, but usually we have followed the spelling of Naphtha, proposed by the late amiable and distinguished traveller Dr. E. D. Clarke. Consult also ref. (ll.) and the very important remarks of Professor Thomson in his First Principles, vol. i. p. 150; but it must be acknowledged that the whole of this subject requires further investigation.

Gas Light.

(323.) The honour of having first introduced the carburet of hydrogen for common purposes of illumination seems due to Mr. Murdoch. The Gas is obtained by heating coal or oil in iron retorts; and, if necessary, the Gas evolved undergoes various processes of purification before it arrives at the large gasometer, in which it is kept for the supply of the numerous and distant burners wherein it is consumed. All statements tend to show, that the Gas thus evolved consists of a mixture of the several carbures of hydrogen, and that in very variable proportions. As first produced, there is also carbonic Acid, hydrogen, sulphuretted hydrogen, and some nitrogen; all which are injurious to the ultimate purpose of the manufacture. It appears quite certain, the goodness of Gas varies directly in proportion to the quantity of those Gases present, which contain the largest proportion of carbon in their constitution. Thus, olefiant Gas, superolefiant Gas, and the very able Essay by Drs. Turner and Christison.

An equal quantity of light from sperm oil, consumed in an Argand lamp, will cost........... 0 6d. Ditto from whale oil Gas....................... 0 4d. Ditto from coal Gas.............................. 0 2d.

For further particulars on this subject, consult reference (nn.), but especially the Papers of Dr. Henry, and the very able Essay by Drs. Turner and Christison.

References to § 3.

§ 4.—Boron. (Bore, Thenard; Boracium, Davy.)

(324.) A. "The saline substance called Borax has long been familiar to European artists, being employed to facilitate the fusion of the precious metals, and in the formation of artificial imitations of the precious stones. It comes from the East Indies, and is said to be found chiefly in certain lakes in Thibet and China. The word Borax occurs first in the writings of Geber, an Arabian Chemist of the Xth century. In the year 1702, Homberg, by distilling a mixture of Borax and green vitriol, obtained a peculiar substance in small white shining plates, which he called sedative, or nar-
remedy in continued fevers. (a.) Lemeruy the younger, chemistry, cotic salt, and which was considered as an efficacious remedy in continued fevers. (b) In 1731, Geoffroy ascertained that sedative salt gave a green colour to the flame of alcohol; and that Borax contains in it the same alkaline substance that constitutes the basis of common salt. (c) In 1752, Baron demonstrated by satisfactory experiments that borax is composed of sedative salt and soda. (d.) Sedative salt was found to possess the properties of an Acid; it was therefore called Boracic Acid: but the composition of this Acid remained altogether unknown. Crell, indeed, published a set of experiments on it in the year 1800, in which he endeavoured to show, that its basis was a substance very similar to charcoal in its properties. (e.) But when his experiments were repeated by Sir H. Davy they did not succeed. Davy, in the year 1807, exposed a quantity of Boracic Acid to the action of the Galvanic Battery, and observed that a black matter was deposited upon the negative wire, which he considered as the basis of this Acid, but he did not prosecute the discovery further at that time. In the summer of 1809, MM. Gay Lussac and Thenard succeeded in decomposing this Acid by heating it in a copper tube with potassium. They examined the properties of its base, which the name of Boron has been given, and published a detailed account of these properties. (f.) Davy, in 1809, decomposed the Acid by the process of the French Chemists, and published likewise an account of the properties of Boron.” (g.) (325.) B. “Boron may be obtained by the following process. One part of pure Boracic Acid, previously melted and reduced to powder, is to be mixed with two parts of potassium, and the mixture put into a copper or iron tube, and gradually heated till it is slightly red, and kept in that state for some minutes. At the temperature of 300° the decomposition begins, and the mixture becomes intensely red-hot, as may be perceived by making the experiment in a glass tube. When the tube is cold, the matter in it is separated out with water, the potash formed is to be neutralized with muriatic Acid, and the whole thrown upon a filter. The Boron remains upon the filter, and may be washed and dried in a moderate heat.” (h.) Dr. Thomson, however, recommends avoiding the use of a filter by washing the Boron in a glass vessel, repeatedly drawing off the liquid with a syphon after the Boron has been allowed to subside. (326.) C. Boron has neither scent nor flavour; its colour is an olive brown; it is not soluble in water, ether, alcohol, or oil, even assisted by heat; it is insusceptible, and in close vessels remains unchanged. When first prepared it does not sink in sulphuric Acid of Specific Gravity 1.844; but after having been strongly heated it sinks rapidly through that Fluid. It is a non-conductor of Electricity. Heated in water to 176° Fahrenheit it does not decompose that Fluid. (327.) D. At ordinary temperatures it does not undergo any change in atmospheric air or oxygen Gas; but at a temperature below 600° Fahrenheit it undergoes a rapid and vivid combustion. The process, however, is not altogether complete, for as Boracic Acid, the product of this combustion, is fusible, each globule of Boron becomes coated with the vitrified Acid, and a mucilaginous film of the base remains unoxidized. For Boracic Acid, see subsect. 1. (328.) E. According to Davy, when Boron is heated in chlorine Gas, the substances unite, evolving a brilliant white flame; a white sublimate condenses on the sides of the vessel in which the experiment is made, and the Boron receives a white coating, which on being washed off proved to be Boracic Acid. (g. p. 41.) On the other hand, Gay Lussac and Thenard state that Boron is not sensibly affected by dry chlorine Gas. (i.) (329.) F. With fluorine Boron unites to form a powerful Acid, the Boro-fluoric already noticed. (194.) (330.) G. Unexamined. (331.) H. Sir H. Davy could not unite Boron to nitrogen, (g. p. 42.) nor was he more successful in his attempts upon hydrogen. Gmelin, however, effected this in the following manner. He exposed a mixture of four parts of iron filings, with one part of Boracic Acid, to a full red heat for half an hour in a crucible. The fused mass dissolved with effervescence in dilute muriatic Acid and borurreted hydrogen Gas was evolved. The Gas had the smell of common hydrogen Gas from iron, mixed with a slight smell of garlic. It burned with a reddish yellow flame, surrounded by a green border: some white fumes appearing in the vessel in which the combustion took place. (k.) As yet the union of Boron with carbon has not been effected. (333.) K. Boron decomposes nitric Acid with rapidity, nitrous Gas being evolved, and the Boron becoming boracic Acid. It also decomposes the sulphuric Acid, when aided by heat; and at a high temperature it takes oxygen from a number of the compound Salts, nitrates, sulphates, and carbonates. It reduces also some of the metallic oxides. (334.) L. M. On these heads we have nothing to remark. Subsect. 1.—Boracic Acid. (335.) A. We have already seen (324.) that Boracic Acid was obtained in 1702 by Homberg from the decomposition of Borax, in which Salt it is found naturally combined with soda. Boracic Acid is found combined with magnesia in the mineral called Boracite found in the Kalkberg, near Lunenburg, also in the Tincalbe mentioned, and in several thermal lakes in Tuscany. (336.) B. Boracic Acid is most readily obtained by dissolving Borax in hot water, gradually adding sulphuric Acid to the filtered solution, until the Liquid becomes rather acid. A number of small shining laminar crystals gradually form and subside as the liquor cools. These are crystals of Boracic Acid, which must be well washed with clean water, and then dried between folds of blotting paper. In this state it is a hydrate: the water may be driven off by fusion, and the Boracic Acid remains pure. (337.) C. This hydrate exhibits thin hexagonal scales with a pearly lustre; has something the appearance and feel of spermaceti; its Specific Gravity is .479, but the pure Acid after fusion is 1.603. Boracic
Acid has no smell, but by affusion of a little Sulphuric Acid a musky odour is developed. Boracic Acid is not volatile, but after fusion, at a red heat, it becomes on cooling a hard transparent glass, which becomes opaque externally by exposure to the air, but does not deliquesce. It has the property of reddening vegetable bluses.

(388.) D. E. F. G. None yet recognised.

(389.) H. Neither have these substances any action upon Boracic Acid; but it is soluble in alcohol, and by the aid of considerable heat in oils also.

(390.) I. Of the metals, potassium and sodium alone have been found capable of decomposing Boracic Acid. With regard to the action of its solution upon metals, it dissolves iron, zinc, and perhaps copper.

(391.) K. Boracic Acid combines with the oxides of every class of metals to form Salts, which are called Boroates.

(392.) L. The presence of Boracic Acid is most easily recognised by its property of colouring the flame of burning bodies green. This is easily exhibited by the combustion of alcohol holding it in solution; but the neatest method, when the quantity is small, is to dip a cotton thread into a Boracic solution, and then, after drying the thread, to set fire to it.

(393.) M. Boracic Acid is used in the fabrication of pastes for the imitation of precious stones; and in the analysis of minerals, which naturally contain the fixed alkalies. Borax, the Borate of soda, is employed in soldering to clean the metallic surfaces, and by its fusion to prevent oxidation, and thus to facilitate the union of the metallic surfaces.

References to § 4.

§ 5.—Phosphorus.

(344.) A. Phosphorus "was accidentally discovered by Brandt, a Chemist of Hamburg, in the year 1669, (a.) as he was attempting to extract from human urine a liquid capable of converting silver into gold. He showed a specimen of it to Kunkel, a German Chemist of considerable eminence, who mentioned the fact as a piece of news to one Kraft, a friend of his at Dresden. Kraft immediately repaired to Hamburg, and purchased the secret from Brandt for 200 dollars, exacting from him, at the same time, a promise not to reveal it to any other person. Soon after he exhibited his Phosphorus publicly in Britain and France, expecting doubtless that it would make his fortune. Kunkel, who had mentioned to Kraft his intention of getting possession of the process, being vexed at the treacherous conduct of his friend, attempted to discover it himself; and about the year 1674 he succeeded, though he only knew from Brandt that urine was the substance from which Phosphorus had been procured. (a.) Accord-ingly he is always reckoned, and deservedly too, as one of the discoverers of Phosphorus."

"Boyle likewise discovered Phosphorus. Leibnitz, indeed, affirms that Kraft taught Boyle the whole process, and Kraft declared the same thing to Stahl. But surely the assertion of a dealer in secrets, and one who had deceived his own friend, on which the whole of this story is founded, cannot be put in competition with the affirmation of a man like Boyle, who was not only one of the greatest Philosophers, but likewise one of the most virtuous men of his Age; and he positively assures us that he made the discovery without being previously acquainted with the process." (c.) "Mr. Boyle revealed the process to his assistant, Godfrey Hankowitz, a London apothecary, who continued for many years to supply all Europe with phosphorus. Hence it was known to Chemists by the name of English Phosphorus. (d.) Other Chemists, indeed, had attempted to produce it but without success, (e.) till in 1737, a stranger appeared in Paris, and offered to make Phosphorus. The French Government granted him a reward for communicating his process. Heliot, Dufay, Geoffroy, and Duhamel saw him execute it with success; and Heliot published a very full account of it in the Memoirs of the French Academy for 1737." (f.)

Thomson, Syst.

The process for obtaining Phosphorus was further improved by Margraf. (g.) Gahn first detected its presence in bones; and Scheele devised a method for obtaining it from that source.

In its pure state Phosphorus is not known to exist in nature, but its combinations are found in many animal substances, and also in some minerals.

(345.) Phosphorus is now usually obtained by calcining bones; the solid residuary matter consists for the most part of phosphate of lime. This white substance is pulverized and digested for several hours with half its weight of concentrated sulphuric acid: but to this water is added, sufficient to reduce the mass to the consistency of cream. By this process the phosphate of lime is decomposed; sulphate and biphosphat of lime result. The latter salt is dissolved out by boiling water, then evaporated to the consistency of sirup, mixed with one fourth its weight of powdered charcoal; and submitted to a good heat in an earthen retort. The beak of the retort should terminate in cold water; the Phosphorus is condensed by the water, and falls down in drops. Phosphorus is further purified by fusing it in hot water, and carefully pressing it through chamois leather; or else by a subsequent gentle distillation.

(346.) C. Phosphorus is generally seen of a light brown colour, but when quite pure it is nearly colourless, with a waxy appearance and fracture. It fuses at about 108° Fahrenheit, and rises fully in vapour at 550° Fahrenheit, but at 219° Fahrenheit in vacuo.

It may be readily cut with a knife, and has a specific gravity about 1.77.

(347.) D. The affinity of Phosphorus for oxygen is very considerable, and most energetic combinations take place between these substances. In atmospheric air Phosphorus undergoes a slow combustion even when no extraordinary heat has been applied, and to this cause must be attributed the luminous appearance which it exhibits in the dark. A very slight elevation of temperature, even that produced by gentle friction, is sufficient to throw it into a state of vivid com-
bution, during which intense light and heat are developed.

The following is a more specific summary of the mutual action of Phosphorus and oxygen given from M. Thenard, who cites the experiments of M. Bellani de Monaz. (h.)

1. Phosphorus placed in pure oxygen at an ordinary atmospheric pressure and temperature undergoes no change; but by diminishing the pressure, combination takes place, the gas is absorbed, and hypophosphoric acid is formed. And, generally, the more the pressure is diminished, the lower is the temperature at which the substances unite; but that no combination takes place below 41° Fahrenheit.

2. Further that if greater pressures are employed, a greater elevation of temperature is required to produce combination.

3. The addition of a greater or less quantity of azote or hydrogen, or carbonic acid to a given volume of oxygen, produces with reference to the combustion of phosphorus therein below 80°6 Fahrenheit, the same effects as diminution of pressure. Hence the luminous appearance of phosphorus in atmospheric air; it burns slowly, absorbing the oxygen and leaving the azote.

4. Phosphorus ought to pass into the state of vapour at ordinary temperatures by its own elastic force, in any gas that does not act upon it chemically. Hence if phosphorus be allowed to vapourize in oxygen gas, and then hydrogen, or azote, be admitted to this gas, a luminous cloud is seen; or if, on the contrary, its vapour be formed in hydrogen, or azote, or carbonic acid, and oxygen be admitted to this, the same effect is produced.

Whether any combination between oxygen and phosphorus exist in such proportions as to form oxides, is a point not fully ascertained; but it is generally admitted that there are three such combinations by which distinct acids are formed. These are the phosphoric acid, subsect. 1; the phosphorus acid, subsect. 2; and the hypophosphoric acid, which we shall be able here briefly to describe.

(348.) The hypophosphoric acid was discovered by M. Dulong, in 1816. Phosphuret of baryta is put into water. Phosphate of baryta is formed, and being insoluble is precipitated; to the clear filtered liquor just enough sulphuric acid is added to remove the baryta; and the remaining solution produces, by evaporation, a viscid uncrystallizable solution of the hypophosphoric acid. By increased heat this acid undergoes decomposition. (i.) The salts formed by this acid are remarkable for being all soluble and highly deliquescent. The acid itself is supposed to contain one atom of oxygen + two atoms of phosphorus, but with regard to the comparative proportion of the elements of all the compounds of oxygen and phosphorus, there still seems a little uncertainty. By some this acid has been even supposed to be an hydracid, that is to say, to contain hydrogen as a constituent element.

(349.) E. Chlorine combines with phosphorus in two proportions. The prot-hydroguret of phosphorus (or chloride) is best prepared by passing the vapour of phosphorus over corrosive sublimate heated in a glass tube. Thus prot-hydroguret of mercury (calomel) is formed and the phosphorus unites with the remaining atom of chlorine which is set free. This prot-hydroguret is a liquid whose specific gravity is 1.45. It is a neutral substance not affecting vegetable colours, and contains one atom of each of its constituents.

(350.) Deutochloride of phosphorus (bichloride of some authors) is formed by placing phosphorus in chlorine gas; spontaneous combustion takes place, and a white solid substance forms on the sides of the retort. This substance is volatile at temperature below 215° Fahrenheit. It acts violently on water; hydrochloric acid and phosphoric acid being the results. When transmitted through a red-hot porcelain tube with oxygen gas, the chlorine is set at liberty and phosphoric acid is produced, showing that at high temperatures the affinity of oxygen for phosphorus is superior to that of chlorine for the same substance. This deutochloride contains two atoms of chlorine + one atom of phosphorus.

(351.) F. unexamined.

(352.) G. Iodine combines with phosphorus at ordinary atmospheric temperatures; heat is evolved, and, as it appears from Dr. Traill's experiments, there is or is not light according to the mode in which the experiment is conducted. Two compounds are supposed to exist, but do not seem to be very tenacious of a definite state of combination. (k.)

(353.) H. Phosphorus combines with hydrogen in two proportions. The resulting substances are both gaseous, and some little difficulty may occur to the student from the varied nomenclature employed by Chemists in speaking of these compounds. We shall adhere to the general rules proposed in (110.) and (111.) The prot-hydroguret of phosphorus (phosphuret of hydrogen of Gengembre and Kirwan; hydroguret of Thomson) was discovered in 1783 by Gengembre, (l.) and independently, in 1786, by Kirwan; (m.) it has been further examined by Raymond, (n.) Dalton, (o.) and Thomson. (p.) It may be obtained by heating phosphorus in a solution of pure potassa; or by heating a paste formed of small fragments of phosphorus, newly slaked lime, and a little water; or by filling a small retort with water acidulated with muriatic acid, and then raising to it a few lumps of phosphuret of lime; a very gentle heat is to be applied, and the gas evolved must be received over water.

The prot-hydroguret of phosphorus has a peculiar and disagreeable odour. It is slightly soluble in water; inflames spontaneously, and burns with splendour when it comes in contact with atmospheric air or oxygen gas. It is decomposed by a strong heat, or by the electric spark. It consists, as the name indicates, of one atom of each of its elements.

(354.) The deut-hydroguret of phosphorus (bi-hydroguret of Thomson) was discovered by Davy in 1812. He procured it by heating crystallized phosphoric acid. The prot-hydroguret is also reduced to this state by exposure to the sun, one proportion of its phosphorus being deposited. This gas has a scent similar to that of the proto-hydroguret, but less strong; it does not inflame spontaneously by contact with common air or oxygen gas, but burns with a white flame in chlorine. This gas contains two atoms of hydrogen + one atom of phosphorus. These two compounds might also be called sub-prot-hydroguret and phosphuret of hydrogen.

(355.) Phosphorus unites with carbon. This phosphuret was first formed by Proust. Thomson gives the following as the readiest method for obtaining it:
PHOSPHURET.

Allow Phosphuret of lime to remain in water till it has given out all the Phosphuretted Hydrogen Gas that it is capable of evolving. Then add to the Liquid a considerable excess of muriatic Acid, agitate for a few moments, and throw the whole upon a filter. Phosphuret of carbon will remain upon the filter. Let it be properly washed and dried.

Phosphuret of carbon is a soft powder of a dirty lemon-yellow colour, without either taste or smell. When left in the open air it very slowly imbibes moisture, emits the smell of carburetted hydrogen, and acquires an acid taste. Hence it decomposes the water which it absorbs, and its Phosphorus is slowly converted into Phosphoric Acid. It does not melt when heated, nor is it altered when kept in a temperature higher than that of boiling water. It burns below a red heat, and when heated to redness gradually gives out its Phosphorus. The charcoal remains behind in the state of a black matter, being prevented from burning by a coating of Phosphoric Acid with which it is covered. When the powder is thrown upon the fire in small quantities, it burns in beautiful flashes. It is composed of one atom of Phosphorus + one atom of carbon. (q.)

Phosphorus combines readily with sulphur in several proportions. The Phosphuret of sulphur has a yellow colour, and possesses great tendency to crystalline structure. Its properties are not very interesting, but for those who may wish to be made acquainted with them in detail, references are given. (r.)

Phosphorus is soluble in nitrogen Gas, forming a Gaseous compound which has been little examined. (356.)

Alcohol, ether, and oils dissolve Phosphorus more or less, and these solutions when spread upon paper become luminous in the dark, especially in a warm atmosphere. (357.)

The metals are almost all capable of being united to Phosphorus. (358.)

Phosphorus in its pure state cannot, of course, perform the part of either an Acid or a base. The action which it possesses upon Acids and bases depends in general on its affinity for oxygen; thus it decomposes the nitric Acid to obtain a portion of its oxygen, forming an oxide of nitrogen, which is capable of being evolved. By a similar action it is capable of decomposing many, if not all, the metallic oxides.

In its elementary state Phosphorus is easily recognised by its luminous properties, and by its ready combustibility. Its properties when acidified will be considered hereafter.

The immediate uses of Phosphorus are very limited, but it has served to make a small portable instrument for obtaining a light. A small quantity of Phosphorus is fused with a little lime in the bottom of a bottle; in this process it undergoes a partial oxidation, so that when a common sulphur match is introduced and again removed into the air, it inflames. Phosphorus, when administered internally, proves one of the most powerful stimulants of the animal economy, thus forming a most powerful aphrodisiac.

Subsect 1.—Phosphoric Acid.

The discovery of Phosphorus led to the immediate formation of Phosphoric Acid, which is produced by its combustion; but its true nature could not have been understood previous to the theory of acidification by oxygen. This Acid does not exist in a free state in nature, but when combined with lime it forms a principal ingredient in bones, and also a part of most animal matters.

Phosphoric Acid may be obtained quite pure by burning Phosphorus in oxygen gas. White vapours are produced which condense in snowy crystals on the bottom of the retort. This solid anhydrous Acid attracts moisture from the air with great avidity, and soon becomes liquid. Phosphoric Acid may also be obtained by the action of Phosphorus on nitric Acid, but the experiment requires caution, as the decomposition takes place with violence. From Phosphoric Acid the water may be driven off by heat, and the pure Acid remains in a glassy state. Generally speaking, however, Phosphoric Acid is procured from bones by a process already adverted to. (359.) The biphosphate of lime is boiled for a few minutes with excess of carbonate of ammonia; thus carbonate of lime is precipitated, and a solution of phosphate and sulphate of ammonia remains. By evaporation, and finally by a strong heat in a platinum crucible, every thing except the Phosphoric Acid is driven off. This Acid is now for the most part supposed to consist of one atom of Phosphorus + two atoms of oxygen.

Phosphoric Acid is not generally employed in Medicine, but M. Lentin has recommended its exhibition in doses of twenty-five drops, to be taken in any diluent Liquid for phthisis.

Subsect 2.—Phosphorous Acid.

The combustion of Phosphorus frequently produces both Phosphoric and Phosphorous Acid; but
the best process for obtaining the latter substance is to pass the vapour of Phosphorus through powdered corrosive sublimate in a glass tube. Chloride of Phosphorus is formed, and condenses in a liquid form. By putting this substance into water a decomposition takes place, the hydrogen and chlorine form hydrochloric Acid, and the oxygen unites to the Phosphorus to form Phosphorous Acid. The solution must then be evaporated, so as to drive off the hydrochloric Acid, and the remaining hydrous Phosphoric Acid will on cooling assume a crystalline structure. The spontaneous oxidation of Phosphorus in atmospheric air produces the same Acid.

With bases this Acid is capable of forming Salts, but they have not been examined much in detail. It appears, however, that there exist sub, neutral, and super-phosphites. Consult the Memoir of M. Dulong.

§ 6.—Sulphur.

(376) A. Sulphur is on the whole a plentiful substance, and has been known from the very earliest times. It occurs abundantly among the various products of volcanic fires, and is found also in certain mineral formations chiefly connected with clays and schists. Several of the metalliferous ores consist chiefly of this substance. When mixed with much earthy matter it is amorphous, but if its formation has taken place in cavities, or by slow processes, it presents very beautiful crystalline forms. The Island of Sicily produces it in great abundance.

(377) B. Sulphur is obtained pure by gentle sublimation; it is then called Flowers of Sulphur, or Flour of Sulphur, but it is at first contaminated with a little sulphurous Acid, which must be removed by careful washing. Sulphur is at present considered a simple substance, though it has been difficult for some eminent Chemists to satisfy themselves that some hydrogen did not enter into its composition.

(378) C. At our ordinary temperatures, Sulphur is a solid, brittle, and frequently crystalline substance. It fuses at about 160° or 190° Fahrenheit, and is completely fluid at 220°. It rises in vapour slightly about 170°, but becomes gaseous at 600° Fahrenheit. If melted Sulphur be poured into hot water it remains a tenacious waxy substance, and in this state is frequently employed to take impressions of gems, coins, &c. Sulphur is a nonconductor of electricity, and becomes negatively electric by friction. It possesses high refractive power upon light.

(379) D. When heated in atmospheric air, or oxygen Gas, Sulphur takes fire, combining with the oxygen and forming Sulphurous Acid; but by various processes four distinct combinations between Sulphur and oxygen may be produced. These will be described in subsections 1, 2, 3, and 4.

(380) E. Chloride of Sulphur is readily formed by passing a current of chlorine through Flowers of Sulphur, or by heating Sulphur in dry chlorine Gas. This substance was first described by Professor Thomson, (a) and subsequently examined by A. Bertholet, (b) and by Bucholz. (c) Sir H. Davy discovered another combination between the same elements. (d)

The subchloride of Sulphur formed by Thomson's process, is described by himself "a liquid of a brownish red colour, when seen by reflected light; but yellowish green when seen by transmitted light." Its smell is strong, and somewhat similar to that of sea plants. The eyes, when exposed to it, are filled with tears. The taste is acid, hot, and bitter, affecting the throat with painful tickling. It does not change the colour of dry litmus-paper; but if the paper be moist it immediately becomes red. Specific Gravity 1.6789 or 1.7. It readily dissolves Sulphur and phosphorus, forming a permanent solution. Chloride of Sulphur smokes violently in the open air, and soon dies off, leaving crystals of Sulphur if it contains that substance in solution. When dropped into water it is decomposed, Sulphur being evolved. When dropped into nitric Acid a violent effervescence is produced, and sulphuric Acid is formed. This substance is supposed to consist of one atom of chlorine + two atoms of Sulphur.

The chloride of Sulphur formed by Davy's process is described as having properties similar to those of the substance just described, and Davy seems to have considered the substances identical; but Thomson supposes the latter to contain one atom of each of the elements.

(381) F. Unknown.

(382) G. Iodide of Sulphur was first described by Gay Lussac. (a.) It is supposed to contain one atom of each element; and is formed simply by heating iodine and Sulphur together in a glass tube. This compound has the appearance of sulphurate of antimony.

(383) H. Sulphur combines with hydrogen, forming a peculiar substance formerly called sulphuretted hydrogen Gas, but now more appropriately hydro sulphuric Acid. In fact, hydrogen and Sulphur unite in two proportions. See subsect. 5.

The combination of Sulphur with carbon forms a substance of considerable interest. It was first described by MM. Clement and Desormes, (c.) though it had been obtained by Lampadius in 1796. (f) These Chemists obtained it by adding Sulphur to charcoal contained in a porcelain tube at a red heat. This process is rather uncertain and inconvenient. The writer of this Synopsis has obtained it readily and in large quan-
Chemistry. 

By fixing a tabulated porcelain retort filled with bits of charcoal into a Black's portable furnace: to the tube of the retort an earthen tube a foot long was luted and closed by a cork. Through this tube small fragments of Sulphur were dropped down upon the heated charcoal. The sulphuret of carbon as it formed passed off in vapour by the beak of the retort, into which a glass tube was fixed and terminated under water. Here the sulphuret was condensed in drops, and remained at the bottom of the jar of water. To obtain the Liquid in a state of purity, a subsequent distillation at a very gentle heat (110^o) is required.

Bisulphuret of carbon is a limpid Liquid, of Specific Gravity about 1.27. It boils at 105^o or 110^o, and does not freeze at - 60^o Fahrenheit. It is so extremely volatile as to produce a greater degree of cold by its evaporation than any other known substance. Thus mercury may be frozen conveniently by covering the bulb of a thermometer with cotton wool moistened with this substance, and placed under the receiver of an air-pump. In the open air it takes fire at a very low temperature, and burns with a blue flame; is not soluble in water, but readily so in ether and alcohol. It is considered to consist of one atom of carbon + two atoms of Sulphur. Consult also ref. (9.)

Sulphur combines with phosphorus (356.) and solution, but not with boron, silicon, or nitrogen. (364.) L Sulphur combines readily with almost all the metals, and in some cases these compounds are regulated by the laws of definite proportions. (385.) K. Under this head there is not much to notice: by digestion with nitric Acid, Sulphur itself undergoes acidification, and is converted into Sulphuric Acid. Upon the earthy oxides Sulphur exerts no action; but at a temperature sufficiently elevated it acts upon all other oxides, in some cases reducing the metals, in others forming sulphurets.

(385.) L. Sulphur is readily recognised by its Physical properties; or, if in small quantity, it may be acidified by nitric Acid, and tested with great accuracy as Sulphuric Acid.

(387.) M. This substance is of great service in the Arts: the Sulphuric Acid produced in its combustion is used to bleach woollen substances and straw bonnets. With nitre and charcoal it forms gunpowder. It is an important ingredient in the cement used in joining iron pipes for Gas and water. In Medicine it is applied externally in cutaneous disorders. Internally, it is sometimes given in visceral obstructions, and as an alternative. It possesses a rapid effect in counteracting the specific action of mercury on the system. For this purpose sulphuret of potash is perhaps the best form of exhibition.

Subsect 1.—Hyposulphurous Acid.

(388.) The Salts formed by this Acid were first noticed by M. Thenard (A.): its relation to the other compounds of sulphur and oxygen were then pointed out by Dr. Thomson; and lastly Mr. Herschel (I.) added very considerably to our knowledge of its compounds and their mode of decomposition.

Hyposulphurous Acid may be formed by passing a current of sulphuric Acid through water in which finely-powdered peroxide of manganese was suspended. A neutral solution of hyposulphate and sulphate of manganese is produced. The solution is to be concentrated, and then by adding an excess of pure baryta to the heated solution, and agitating it well, the oxide of manganese is separated, as also the insoluble sulphate of baryta. The filtered Liquid contain hyposulphate of baryta and some excess of that earth in solution. This excess may be removed by a stream of carbonic Acid, and an excess of that Acid may be got rid of by boiling. The pure hyposulphate of baryta is then to be crystalized, redissolved in water, and the baryta precipitated by cautiously adding the requisite quantity of sulphuric Acid. The filtered Liquid is to be concentrated by sulphuric Acid placed in the receiver of an air-pump till it has a Specific Gravity 1.347.

Subsect 2.—Sulphurous Acid.

(389.) Sulphurous Acid Gas is produced whenever sulphur is burned in common air or oxygen Gas; but it is most readily obtained by putting three parts of Sulphuric Acid and two parts of mercury into a small glass retort. The heat of an Argand lamp produces a copious evolution of the Gas, which ought to be received over mercury. Here a part of the sulphuric Acid gives up its oxygen to the metal, and is reduced to the state of Sulphurous Acid, while the remainder unites to the oxidated metal, and produces a residuum of sulphate of mercury in the retort.

This Gas has a pungent and very characteristic odour: it extinguishes combustion, and is not itself combustible. It is quite unfit for respiration. Water, especially when hot, is capable of dissolving a considerable quantity of this Gas. The bleaching properties of burnt sulphur already mentioned (387.) are due to its action; and it is singular that if litmus-paper be so bleached, the colour seems not to be absolutely destroyed, but may be again developed either by an Acid or alkali. If moisture be present, Sulphurous Acid Gas will unite with oxygen, and pass to the state of Sulphuric Acid. Nitric Acid, or oxide of manganese, produce the same effect. Of all the Gases, this one is most readily condensed into the liquid form. Mr. Faraday effected this by a pressure equivalent to two atmospheres; and M. Bassy (L.) produced the same effect under the ordinary atmospheric pressure by subjecting it to the cold produced by snow and salt. This Acid unites with bases, and produces Salts called sulphites. It is believed to consist of equal volumes of sulphur, vapour, and oxygen, or of sulphur one atom + oxygen two atoms.

Subsect 3.—Hyposulphuric Acid.

(390.) MM. Walter and Gay Lussac first discovered this Acid, and formed it by passing a current of sulphurous Acid Gas through water in which finely-powdered peroxide of manganese was suspended. A neutral solution of hyposulphate and sulphate of manganese is produced. The solution is to be concentrated, and then by adding an excess of pure baryta to the heated solution, and agitating it well, the oxide of manganese is separated, as also the insoluble sulphate of baryta. The filtered Liquid contain hyposulphate of baryta and some excess of that earth in solution. This excess may be removed by a stream of carbonic Acid, and an excess of that Acid may be got rid of by boiling. The pure hyposulphate of baryta is then to be crystalized, redissolved in water, and the baryta precipitated by cautiously adding the requisite quantity of sulphuric Acid. The filtered Liquid is to be concentrated by sulphuric Acid placed in the receiver of an air-pump till it has a Specific Gravity 1.347.

4 2
Subsect. 4.—Sulphuric Acid.

(391.) A. As far as is known, Sulphuric Acid was first obtained by Basil Valentine, in the XVth century. He procured it by the dry distillation of sulphate of iron. Subsequently it has been obtained by other processes, and is extensively employed in the Arts. It is found in combination with bases in several mineral substances, but does not exist free in nature, except possibly in small quantities among the products of active volcanoes.

(392.) B. Sulphuric Acid is now chiefly made by burning a mixture of one part of nitre with six or eight parts of sulphur in large leaden chambers, having the floor covered with a thin stratum of water. (m.) The Liquid thus produced consists of a solution of Sulphuric Acid in water. By subsequent evaporation the greater part of the water is driven off, and a concentrated Sulphuric Acid remains. In its highest state of concentration liquid Sulphuric Acid contains dry Sulphuric Acid one atom + water one atom.

(393.) At Nordhausen, in Thuringia, a strong liquid Sulphuric Acid is prepared from sulphate of iron by dry distillation, in earthen retorts. This Acid may be put into a glass retort, to which a large tube is attached and surrounded with ice. Ignited charcoal is placed under the retort, and the Liquid being brought to ebullition, vapours of an hydrous Sulphuric Acid pass over, and are condensed in the cold tube. This Acid, at a temperature below 77° Fahrenheit, is solid, white, and opaque, at 77° it fuses and forms a Liquid, which strongly refracts light; having a density of 1.57. At a higher temperature it is volatile, so as indeed not to be easily fused, except under some pressure. This substance possesses strongly acid properties, and attracts moisture with great avidity. (n.) It consists of sulphur one atom + oxygen five atoms.

(394.) C. Sulphuric Acid is an oil-like fluid, and when pure is colourless. It has a very strong vapour for moisture, and produces, when mixed with water, a very considerable degree of heat. Dr. Ure states that 73 parts by weight, mixed with 27 parts of water, exhibit this property in the most striking manner. The Specific Gravity of the strongest liquid Acid is 1.850; but Dr. Ure states that if pure it is not beyond 1.595. Mr. Dalton has given a Table exhibiting the real Acid in mixtures of Acid and water of different densities. See Part V. Table IV. Consult also, Mr. Parke's Essay, (o.) and Dr. Ure's Paper. (p.) Liquid Sulphuric Acid may be frozen by artificial cold. In distilling over Sulphuric Acid from glass vessels there is great danger of the vessel being broken by the violent detonations with which the heated Liquid bursts into vapour; this may, however, be remedied by placing in the retort a few fragments of pounded glass, or platinum wire: the sharp points of these bodies determining the evolution of vapour in smaller bubbles, and, therefore, with less violence of effect. The nature of this action, with reference to some other curious points in the extrication of Gases, and of vapours arising during ebullition, has been examined by Gay Lussac. (q.) Sulphuric Acid is decomposed by the Voltaic pile.

Subsect. 5.—Compounds of Sulphur with Hydrogen.

In examining this part of our subject we encounter some difficulties, which chiefly arise from the confused state of our nomenclature; and in attempting briefly to dispel them, we shall be under the necessity of making a slight change in the language of some Chemists; but we trust that no confusion will thence arise, as we shall carefully present the synonyms of other authors.

Sulphur and Hydrogen unite in two proportions;—are these to be called Sulphures of Hydrogen, or Hydurets of Sulphur? The former was the plan at first adopted, and Berthollet, to preserve a distinction, employed the...
Y-v- 

The proportions are now known to be Hydrogen; one atom + Sulphur two atoms; and Hydrogen one atom + Sulphur one atom. The former compound unites with bases, but it has not been shown to possess acid properties; though in some sense it is probable that it does so. The latter also unites with bases, and possessing decidedly acid properties, Gay Lussac proposed to call it Hydro sulphuric Acid; thus recognizing that Hydrogen is its acidifying principle, and preserving the analogy for Hydroiodic, Hydrochloric Acid, &c. &c. If we consider the compound of one atom Hydrogen + two atoms Sulphur not an Acid, we may consistently with our plan call it Hyduret of Sulphur; but if we deem it an Acid, we may call it Hydro sulphurous Acid. For the second compound consisting of one atom of Hydrogen + one atom of Sulphur, we unhesitatingly adopt Gay Lussac's name of Hydro sulphuric Acid.

Hyduret of Sulphur, or Hydro sulphurous Acid. (Soufre Hydrosulfuret of Thenard; Hydrosulfurous acid of Thomson; Bisulphuretted Hydrogen of Henry.)

(404.) The following are the properties of this substance as detailed by Berthollet, (x.) and abstracted by Dr. Henry. (t.)

"This substance is obtained when the compound produced by boiling Flowers of Sulphur with liquid potassa is poured by little and little into muriatic Acid. A very small portion only of Gas escapes; and while the greater part of the Sulphur separates, one portion of it combines with the Hydro sulphuric Acid, assumes the appearance of an oil, and is deposited at the bottom of the vessel. Or dissolve Sulphur in a boiling solution of pure potassa; and into a phial, containing about one-third its capacity of muriatic Acid, of the Specific Gravity 1.07, pour about an equal bulk of the liquid compound. Cork the phial, and shake it; the Hyduret of Sulphur gradually settles to the bottom in the form of a brown, viscid, semifluid mass; its properties are the following.

1. "Its taste and smell resemble those of putrid eggs, but are less offensive. Its precise Specific Gravity is unknown, but it is heavier than water, and descends through it. It is inflammable, and burns in the air with a smell of Sulphurous Acid.

2. "If gently heated, Hydro sulphuric Acid Gas ex-hales from it, the bisulphuret loses its fluidity, and a residue is left consisting merely of Sulphur.

3. "It combines with alkalis and earths."

Its constitution has been already described.

(405.) The combinations of this substance with alkalis and earths might be called Hydro sulphurates, or Hydro sulphites, according as we deemed the substance itself an Acid or not; but unfortunately the former term has been by some applied to the true Hydro sulphates. In some Treatises the combinations now before us are called Hydroguretted Sulphurets, a term we cannot employ consistently with our plan.

The Hydro sulphurates then, or Hydro sulphites, are "formed by boiling along with a sufficient quantity of water, the alkaline or earthy base, with Flowers of Sulphur. Thus a solution of pure potassa, pure soda, or of baryta, or stronnia, may be changed into a Hydro sulphuret.

"Another method of forming by a very simple process the Hydro sulphurates consists in digesting in a gentle heat a Hydrosulphate with powdered Sulphur, an additional portion of which is dissolved, while part of the Hydro sulphuric Acid Gas escapes.

"Hydrosulphurets have the following properties.

1. "They have a deep greenish yellow colour, an acrid and intensely bitter taste, and an excessively offensive smell.

2. "They deposit Sulphur when kept in close vessels, become much more transparent and lighter coloured, and less offensive to the smell.

3. "They rapidly absorb oxygen from the atmosphere and from oxygen Gas. Hence their employment in Eudiometry.

4. "On the addition of dilute Sulphuric, or Hydrochloric, or of certain other Acids, they are decomposed, Hydro sulphuric Acid Gas is evolved, and Sulphur is precipitated.

5. "When boiled in contact with filings of silver, or of copper, and of those metals only, Vauquelin found that they lose their excess of Sulphur, and become Hydrosulphates."

Hydrosulphuric Acid. (Sulphuretted Hydrogen.)

(406.) This Gas, though known before, was first examined with care by Scheele about 1777. It is frequently produced during the spontaneous decomposition of organic substances, and from the receptacles for excrementitious matters. Also as an element in numerous mineral waters, such as those of Borrowes, Shinznach, Harrowgate, &c.

For Chemical purposes, it is most readily procured by heating powdered sulphuret of antimony in a retort with four or five times its weight of strong muriatic Acid. Or a protosulphuret of iron may be made by placing a mixture of two parts of iron filings and one part of sulphur in a common earthen or iron crucible, well closed, and then giving it a low red heat. The sulphuret thus formed may be pulverized when cold, and acted upon by muriatic Acid diluted with thrice its weight of water.

Hydrosulphuric Acid Gas consists of one atom of each of its elements, occupying the same volume as the hydrogen of which it is formed. This Gas is without colour, but has a very peculiar and disagreeable taste and odour, similar to that of rotten eggs. At 50° Fahrenheit it may be reduced to a Liquid by a pressure of seventeen atmospheres. It extinguishes all burning bodies, but when ignited burns with a pale blue flame. It detonates by the electric spark when mixed with oxygen. This Gas has decidedly acid properties, as it reddens litmus-paper, and may be made to neutralize alkaline bases. Chlorine and iodine decompose it, separating the sulphur and producing hydrochloric or hydroiodic Acid. An atmosphere in which this Gas abounds may be purified by chlorine in a very few minutes. Hydrosulphuric Acid produces very marked effects upon metals and metallic oxides. The sulphur entering into combination tarnishes gold and silver readily. White paint is immediately discoloured for a like reason. The most delicate test of the presence of Sulphuretted Hydrogen is to paint a piece of paper with flake white, (carbonated oxide of lead.) This is instantly coloured by Hydrosulphuric Acid Gas, even when, according to Dr. Henry, only a twenty-thousandth part of the volume of air consists of this Gas. Hydrosulphuric Acid Gas is one of the most deleterious that can be respired. Dupuytren and Thenard found that
The hydrosulphates, as the name implies, consist of combinations of Hydrosulphuric Acid (sulphuretted hydrogen) with bases.

This Acid combines with bases from the second class of metals, and, perhaps, also with glycyna and ythia; with oxide of zinc, with the protoxides of manganese and iron, the oxides of tin, and the protoxide of antimony. With the oxides of the last four classes, no such union is formed, for the oxides themselves are decomposed and sulphurets produced. The alkaline and earthy hydrosulphates are soluble in water, are colourless, and have a sharp and rough taste. The rest, which are inaciable, have neither scent nor taste; and three only, viz. those of iron, antimony, and tin, are coloured. All Acids except the carbonic decompose the hydrosulphates, by setting the Acid Gas free.

The hydrosulphates of potash, soda, barytes, strontia, lime, and magnesia are prepared by passing a current of the Gas through these substances dissolved or suspended in water by means of a Woulfe's bottle. The insoluble hydrosulphates are obtained by double decomposition.

The great and constant utility of the hydrosulphates as tests of metallic substances, will induce us to give a table of these indications. See Part V. Table V.

(408.) On the whole then it appears, that sulphur, Hydrosulphurous Acid, (hydroguretof sulphur, of some,) and Hydrosulphuric Acid (sulphuretted hydrogen of some) will all unite with metals and their oxides. In the first case, the result is a sulphuret; in the second, it is a hydrosulphite, or, as we might call it, a Hydrosulphuric Acid; (hydroguretted sulphuret of some;) and in the last it is a hydrosulphate (hydrosulphuret of some.) The sulphurets can only continue stable in a dry state, for so soon as they begin to dissolve in water, that Fluid is decomposed, Hydrosulphurous Acid Gas is formed and evolved, while Hydrosulphuric Acid being also formed unites with the base. (4.)

§ 7.—Selenion.

(409.) A. Messrs. Gahn, Eggertz, and Berzelius are the proprietors of a manufactury of sulphuric Acid from the sulphur obtained in the copper-mine of Fahalan, in Sweden. In examining, in 1817, the brown residuum or sediment on the floor of a leaden chamber in which the sulphur is burned, Berzelius found that this substance, besides containing sulphur and other impurities, consisted in part of a peculiar substance, which proved to be a simple body heretofore unknown. He considers it a metal, and named it Selenium, from σέλενος, the moon, in consequence of its properties greatly resembling those of tellurium. In describing these properties, we are inclined to think that many will agree with us in removing it from the rank of a metal, and placing it among the combustible nonmetallic elements, in which we follow the plan of Thomson and Thenard. Selenion has hitherto not been found principally in two minerals, the seleniuret of copper, and eukairite, a seleniuret of silver and copper, discovered by M. Berzelius in the abandoned copper-mine at Skrickerum, in the parish of Tryserum, in Smoland. The pyrites of Fahalan also contain it, and it has subsequently been recognised with sulphur in the volcanic districts of Italy.

(410.) B. The residuary powder which contains the Selenion has also an admixture of several other substances; viz. sulphur, mercury, lead, tin, iron, copper, zinc, and arsenic. For the complete process of separation, which is very complex, we must refer to the original Memoir of Berzelius. (a.) The following are its principal features. The reddish brown powder is digested in nitro-muriatic Acid to acidify the Selenion. Water is then to be copiously added, and the Liquid filtered. To this clear solution, which contains the Selenic Acid, together with some other substances, a solution of muriate of ammonia is then added in excess, by which the Selenion is thrown down pure in a pulverulent state, and is to be well washed with water, then dried and carefully fused.

(411.) C. Selenion is at ordinary temperatures a solid, tasteless, and scentless substance, of a deep chocolate brown colour with a sort of metallic lustre. It is brittle, has a conchoidal fracture producing a lead-coloured surface. The powder is of a deep red colour, and thin fragments transmit the red rays of light. It may be scratched with a knife. Selenion does not readily crystalize, but the forms it is supposed to assume are those of a cube, and a quadrangular prism with a pyramidal summit.

It is a very bad conductor of heat, and is a nonconductor of electricity, which seems a strong argument against its being a metal; and yet, on the other hand, Berzelius was not able to produce electric excitement in it by friction. Upon being heated Selenion softens; at 212° it becomes semifluid, and is quite liquid at 230° Fahrenheit. It may be kneaded between the fingers, drawn out into threads like sealing-wax. Filaments so produced are white and transparent, and their reflected light is grey. In a retort, Selenion boils at a heat below redness, and its vapour is a yellow, deeper in colour than chlorine Gas, but not so deep as
The vapour of sulphur. This vapour condenses in the neck of the retort in black drops, similar to those produced in the distillation of mercury. But when this substance is heated in large vessels, or in the open air, the condensed vapour actually becomes a fine powder of its appropriate red colour: a formation analogous to the flowers of sulphur. Selenium when heated dissolves in the fat oils, in lard, and in wax, but is not soluble in the essential oils.

D. Selénion has no action on oxygen gas without the aid of heat; but by the help of that agent it may be made to combine with oxygen in two proportions. Fill a balloon with oxygen gas, and put into it a small piece of selénion, allowing the balloon to communicate with a gasometer of oxygen gas by a tube. Then apply a gentle heat to the matras. If the balloon be only about an inch in diameter, the selénion will inflame the moment it enters into ebullition, and will burn with a feeble flame, white at its base, and greenish at its apex. By this combustion selénic acid is produced, which sublimes and is condensed in a white powder, while the selénion totally disappears.

But if this experiment be made in a large balloon holding some pints, the selénion does not take fire, but unites all at once with the oxygen; and in this case, instead of the acid there is an oxide of selénion formed which is gaseous, and has the smell of decayed cabbage, or horse-radish. Berzelius attributes this variety of action to the pressure existing in the small vessel, which does not suffer the dispersion and volatilization of the oxide as in the more roomy one. The gaseous oxide of selénion is colourless; does not affect vegetable colours; is very slightly absorbable by water, but communicates to it its own peculiar odour; does not unite with alkalis. Berzelius thinks that it can only exist as a gas.

E. Berzelius placed selénion in a glass tube, and passed a current of chlorine through the tube as long as the selénion continued to absorb any of the gas. The chlorine so formed was at first a liquid, but gradually became a white solid, as it approached the point of saturation. It contracts slightly by heat but does not melt, and then sublimes in the form of yellow vapour, conveniently combining with any cool part of the apparatus in small white crystals. It dissolves in water with slight effervescence, and the selénic and hydrochloric acids are found mixed with the water.

F. G. Unexamined.

H. Selénion has been combined with hydrogen, phosphorus, and sulphur. By the first hydroselénic acid is produced. See subsect. 2. By dropping selénion into melted phosphorus it rapidly dissolves, forming at the same time a compound which sinks in red streaks passing through the phosphorus. But these two substances will unite in any proportion by fusion. Berzelius, however, supposed that he obtained a definite phosphuret of selenium, and he found that by digesting this phosphuret in water the water was decomposed, hydroselénic acid gas was evolved, and some selénium precipitated.

Sulphuret of selenium is formed by passing hydrosulphuric acid gas through an aqueous solution of selénic acid. The liquid becomes turbid and yellow; and the addition of a little hydrochloric acid causes the sulphuret of selenium to fall down as a deep orange-coloured powder. This sulphuret softens at 212° Fahrenheit, and liquefies by a few degrees further access of temperature. It may be boiled and distilled over. The portion so distilled is transparent, of a reddish orange colour, resembling meltedorpiment. It is not acidifiable by nitric acid, but is more powerfully affected by the nitro-muriatic. It is soluble in caustic fixed alkalis, and in the hydrosulphurets, but again precipitable by acids as a sulphuret of selénion.

The relation of selénion with carbon, boron, and silicon have not been investigated; but with the first of these substances Berzelius thinks it may form a substance analogous to the sulphuret of carbon.

I. We are at present acquainted with fifteen metallic seléniers, and for this knowledge we are indebted to Berzelius. These seléniers are of potassium, zinc, iron, tin, arsenic, antimony, cobalt, bismuth, copper, lead, telurium, mercury, silver, palladium, and platinum; and it is probable that this substance will be found to unite with all other metals on trial.

The metallic seléniers seem to be subject to the same chemical laws with the metallic sulphurets. They are similarly affected by air, water, oxygen gas, and by changes of temperature. They are also definite compounds, and, as in the case of the sulphurets, it seems probable that there exists more than one definite compound to each metal.

The best process for obtaining the seléniers as definite compounds is to precipitate their metallic solutions by hydroselénic acid. By this method the deuto-seleuiers are formed. To obtain the proto-seleuiers we must heat the metals in contact with selénion, and then drive off the excess of the latter by heat.

J. The nitric and hydrochloric acids, when cold, do not act upon selénion, but with the aid of heat they rapidly convert it into selénic acid.

K. The nitric and hydrochloric acids, when very disagreeable odour of decayed horse-radish which a very minute quantity produces when placed in the exterior flame of the blowpipe.

M. The rarity of selénion would preclude its application to the arts, even if it were found serviceable. Its medicinal properties are unknown; but the fumes of hydroselénic acid inhaled appear to be extremely pernicious, and Berzelius thinks that a very small quantity would prove fatal to animal life.

Subsect. 1. Selénic Acid.

A. B. This acid was discovered by Berzelius, and one method of obtaining it has been already described; (412.) but in practice it is found more convenient to add one part of selénion to three or four parts of pure nitric acid. The mixture is gradually raised to ebullition, and at that temperature the selénion rapidly decomposes the nitric acid, seizing on a part of its oxygen. When all the selénion is dissolved, it is entirely acidified: the solution is to be evaporated to dryness in a porcelain capsule, and is then pure selénic acid. But if the solution be only concentrated and not evaporated, the selénic acid will, upon cooling, crystallize in six-sided prisms. By a considerable increase of heat this acid parts with water, and lastly rises in a yellow vapour. This vapour condenses on the upper part of the apparatus in long, slender, tetrahedral prisms.
Chemistry. C. Selenic Acid has no scent, but a strongly acid taste, and reddens vegetable blues. It is volatile but not decomposed by heat. It attracts some moisture from the air, but does not actually deliquesce. It is very soluble in cold water, and still more so in hot water. Alcohol also dissolves it readily. Hot water, which has been saturated with it, lets fall the Acid in small crystals, if rapidly cooled, but in striated prisms when slowly so.

(429) A. Hydroselenic Acid is, as the name implies, an Acid compounded of hy-rogen and selenium, analogous to the hydrosulphuric, hydriodic, hydrochloric, &c. For the knowledge of this proximate element we have still to refer to the experiments of Berzelius.

(430) B. The best process for obtaining this Acid in the Gaseous state is to act upon the seleniuret of iron with hydrochloric Acid in a glass proof or small retort; but as the Gas is soluble in water, it must be collected over mercury. In this process, water is decomposed, protoxide of iron is formed, which combines with the hydrochloric Acid, and Gaseous Hydroselenic Acid is evolved. M. Thenard, however, states that in this process another Gas is also formed, which is neither soluble in water nor in alkalis, and that, therefore, to obtain the Hydroselenic Acid quite pure, it might be advisable to employ the seleniuret of potassium.

(431) C. This Gas is colourless, and reddens the tincture of turnsole. Its odour, which at first resembles that of hydrosulphuric Acid Gas, gradually changes to a sharp astringent sensation, not entirely devoid of pain. The eyes become red and inflamed, and all sense of smell is for a time destroyed. A bubble the size of a small pea is sufficient to produce these effects. So at least M. Berzelius found, to such an extent, that he was able to apply the strongest solution of ammonia under his nose, and did not recover any power of sensation in it until five or six hours had elapsed. At the same time a very copious defluxion from the mucous membrane of the nostrils came on and continued fifteen days. Similar, though less violent, effects took place on subsequent occasions, when bubbles no larger than a pin's head escaped accidentally, and became mingled with the atmospheric air. These were not all the ills that resulted from breathing this noxious Gas; for even in this mitigated form M. Berzelius perceived the approach of a dry fixed cough, which came on in half an hour, remained a long time, and finally was accompanied by an expectoration, giving a taste precisely like that of the vapours of a boiling solution of corrosive sublimate, and did not depart until he had applied a blister to his chest. In short, this admirable Chemist considers this the most noxious Gas at present known. Water absorbs a greater proportion of this Gas than of the hydro sulphuric Acid; but even when it holds half its volume in solution, the water has acquired but little smell. The Liquid so formed causes an indelible brown mark on the human skin, and is itself colourless if the water be quite free from air; but if left exposed, the Hydroselenic Acid is decomposed, and the Liquid becomes turbid from the flocculi of selenium that present themselves. Hence it is apparent why a solution of this sort becomes turbid next to the exposed surface first.

(432) D. E. F. G. H. I. Imperfectly known.

(433) K. Nitric Acid, when added in small quantity to the aqueous solution of Hydroselenic Acid, produces no effects.

(434) L. The aqueous solution of Hydroselenic Acid causes precipitates in almost all the metallic solutions of the four last classes. These precipitates are for the most part black or brown, and take a brilliant metallic lustre by friction with polished hematites. Those, however, of zinc, manganese, and cerium are to be excepted; they are flesh-coloured, and are supposed to be hydroseleniurets of the oxides, while the others are metallic seleniurets. Consequently Hydroselenic Acid will for the most part decompose the oxides of the last four classes, even when united with the strongest Acids.

§ 8.—Nitrogen.

(435.) A. This Gas was first discovered in 1772 by Professor Rutherford of Edinburgh. Scheele also had made himself acquainted with it previous to 1777. Nitrogen forms a very considerable proportion of the atmosphere in which we exist. Lavoisier called it azote, from its not having the power of supporting animal life.

(436.) B. There are several methods employed for procuring Nitrogen Gas.

1. Let equal weights of iron-filings and sulphur be made into a paste with water, and let the vessel containing this paste be placed on a stand over the pneumatic trough. Invert over it a jar of common air, and let it stand for a day or two. One-fifth of the volume of the air will disappear, and the remainder is Nitrogen Gas.
2. Phosphorus burned in a close vessel of atmospheric air over water removes the oxygen and leaves the Nitrogen. The residual Gas should be well agitated with water to remove the phosphoric Acid formed.

3. Nitrogen may also be obtained by putting some lean beef into a glass proof with very dilute nitric Acid. A heat of about 100° disengages the Gas, which must be collected over water.

4. But perhaps the most speedy way of obtaining it is to pass nitrous Gas copiously through a solution of protosulphate of iron. An ounce or two of this solution is then to be put into a phial, which must be closely corked or stopped with the thumb and well shaken; the phial is then to be inverted with its neck in another portion of the solution and unstopped, a fresh portion of the liquid will enter to supply the absorption that has taken place. By a few repetitions of this process all the oxygen Gas will be removed, and pure Nitrogen will remain.

(437.) It has been supposed by very able Chemists, Davy and Berzelius especially, that Nitrogen is a compound body. Berzelius thus reasons on theoretical grounds chiefly: and Davy from a very curious experiment made with the Voltaic pile. Let a small hole be made in the surface of a lamp of muriate of ammonia, and in this hole place a globule of mercury. Connect the saline mass with the positive pole of the battery and the mercury with the negative pole; an action is immediately perceived in the metallic globule; its volume becomes enlarged, and more solid ramifications are perceptible in the fluid metal. This enlargement sometimes extends to ten times the original volume of the mercury. When completed, the amalgam (if such it be) is of the consistency of butter. It soon, however, returns to its original state by the formation of films of saline matter over its whole surface. The best experimentalists, however, could only obtain mercury, hydrogen, and azote from the amalgam so formed, (a.)

(438.) D. In speaking of Nitrogen with reference to oxygen, we are first called upon to mention the great mass of our atmosphere, which consists almost entirely of these two Gases: but from the importance of this agent we shall consider its properties apart in subsect. 1.

When Nitrogen and oxygen are mixed together, no combination takes place. But when either of the elements is presented to the other in a state of condensation, or having the repulsive force of its molecules diminished by a decrease of heat, a union is effected, and the nature of the resulting compound is dependent upon the respective proportions of the two elements. Some of these combinations are always gaseous, others, though in themselves gaseous also, are always seen in combination with so much of the elements of water as to be liquids.

The following is a synoptic view of the compounds of Nitrogen and oxygen:

</table>

These substances will be noticed in subsects. 2, 3, 4, 5, and 6.

(439.) E. Chlorine and Nitrogen, when placed in contact, have no mutual action on each other, provided that both Gases are perfectly dry. A compound of these Gases may, however, be produced by passing a current of chlorine Gas through a solution of any ammoniacal Salt. The most convenient process for forming the chloride of Nitrogen, (to which the name of Azotane has been sometimes given,) is to fill a clean glass basin with a solution of muriate or nitrate of ammonia, containing about one part of the Salt dissolved in twelve parts of water, at 80° or 90° Fahrenheit. Over this solution let a tall jar of chlorine Gas be inverted. The Gas is gradually absorbed, and a film of an oil-like substance forms on the surface of the Liquid, and when a drop of sufficient size is collected, it sinks down to the bottom of the basin. The best way of removing a globule of this chloride of Nitrogen for any purpose of examination, is by a syringe made of a piece of glass tube, with a piston of tow wrapped round a wire.

Scarcely any known substance requires such care in its management as this Fluid; for it is the most violently detonating body known. It is not safe to make experiments on more than a single small globule not larger than a grain of mustard seed. M. Dulong, who discovered it, received a severe injury on the occasion; (b.) and Sir H. Davy did not fare better in repeating Dulong's experiments. (c.) A heat something below 212° Fahrenheit causes it to explode; also the contact of oil, phosphorus, and numerous other bodies; but the metals, alcohol, resins, sugar, or camphor, do not cause its explosion. Its Specific Gravity = 1.653, and it is supposed to contain Nitrogen one atom + chlorine four atoms. (d.)

(440.) F. Unknown.

(441.) G. Iodine and Nitrogen do not unite by mere contact; but when iodine is placed in a solution of ammonia in water, a brownish black iodide of Nitrogen is formed. This compound, like the chloride of Nitrogen, evaporates spontaneously in the open air, and detonates violently when heated or touched.

(442.) Of these substances, hydrogen and carbon unite with Nitrogen, the former producing ammonia, see subsect. 7; the latter producing cyanogen, see subsect. 8.

(443.) I. Of the metals it would seem that potassium and sodium may be considered as uniting in some manner with Nitrogen.

(444.) K. None.

(445.) L. Nitrogen is best recognised by its negative properties when in the gaseous state: that it is not combustible, nor does it support combustion.

(446.) M. None.

Subsect 1.—The Atmosphere.

(447.) "The Atmosphere is a collection of elastic Fluids, retained on the surface of the Earth by their gravitation. Its weight was first ascertained by Galileo, and applied by Toricelli to explain the height of water in pumps, and of mercury in barometrical tubes; and by Pascal to the mensuration of the heights of mountains. At the level of the Ocean it is adequate to sustain a column of water having the altitude of 34 feet, or one of mercury of the height of 30 inches, and it presses with the weight of about 15 pounds on every square inch of surface. As we ascend, the Atmosphere decreases in density in a geometrical proportion to..."
Chemistry, equal ascents. Thus, at three miles in height, the density of the Atmosphere is one-half what it is at the Earth's surface; or equal to a column of 15 inches of mercury; at six miles, the barometer would stand at one-fourth the usual height; or at 7½ inches; at nine miles of elevation, at 3½ inches; and at 15 miles nearly at one inch. Hence the greatest part of the Atmosphere is always within 15 or 20 miles of the Earth's surface; though from the refraction of the Sun's light, it may be inferred to extend from 40 to 45 miles in height. Beyond the former limit it appears highly probable, indeed, from the recent observations of Dr. Wollaston, (Phil. Trans. 182?) that our Atmosphere does not reach at all; the force of Gravity downwards, upon a single particle, being there equal to the resistance arising from the repulsive force of the medium. We have no evidence, then, of the existence of similar matter round any other Planet; and, on the contrary, it has been ascertained by the observations of Captain Kater, that no retardation of the motion of Venus can be perceived in her progress towards the Sun, as would happen if the latter were encompassed by a refracting Atmosphere. The approach, also, of Jupiter's Satellites to the body of that Planet is uniformly regular, till they appear in actual contact, showing that there is not that extent of Atmosphere, which Jupiter should attract to himself from an infinitely divisible medium filling all space. These observations are favourable, as Dr. Wollaston remarks, to the existence of particles of matter no longer divisible, for if an elastic Fluid like our Atmosphere consist of such particles, we can scarcely doubt that all other bodies are similarly constituted; and may, without hesitation, conclude that those equivalent quantities, which we have learned to appreciate by proportional numbers, do really express the relative weights of elementary atoms, the ultimate objects of Chemical research.

The great body of air constituting our Atmosphere is in a state of constant motion, not only from its accompanying the Earth in its rotation round its axis, but it also from the Equator towards the Poles, and contrariwise. Over the torrid zones the air is expanded by heat, and acquires a tendency to ascend, while the air from the temperate and frigid zones presses forward to supply the vacancy. In the torrid zones, the upper regions of the Atmosphere meet with less lateral pressure than is necessary to support them, and the air, therefore, overflows in both directions, so that currents Northward and Southward are established for supporting a temperature on the Earth's surface, approaching much more nearly to uniformity, than it could have been without such a provision of nature." Henry, Chemistry, vol. i. p. 287.

(446.) We may state in general terms that the mass of the Atmosphere consists of

| Nitrogen Gas | 77.50 | 75.55 |
| Oxygen Gas  | 21.00 | 23.32 |
| Aqueous vapour | 1.42 | 1.03 |
| Carbonic Acid | 0.08 | 0.10 |

*100. 100.*

A small quantity of muriatic Acid is found in the air which is in contact with the sea; and the aqueous vapour is of course variable according to the temperature; but in other respects, a most singular and striking uniformity of composition has been found to pervade all the air hitherto examined, whatsoever may have been the altitude from which it has been taken.

A pressure of 50 inches of Mercury is supported by the ingredients already named in the following proportion, supposing each to act independently of the others.

- Nitrogen Gas: 23.36 inches.
- Oxygen Gas: 6.18 inches.
- Aqueous Vapour: 0.44 inches.
- Carbonic Acid: 0.02 inches.

Two opinions exist as to the mode in which these Gases exist together in the Atmosphere. The one that they are all in Chemical combination with each other; and the other opinion is, that no such combination takes place, but that the Atmosphere is merely a mechanical mixture of its ingredients. The latter opinion is ably supported by Mr. Dalton. (d.)

It is owing to the oxygen Gas in the Atmosphere, that it supports respiration and combustion. When rarefied, the air does not so readily afford the food that is necessary for burning bodies; and this seems to depend upon a want of condensation of that heat which is requisite for keeping up the combustion. Though it appears from Davy's experiments, that artificial condensation does not render it better fitted for that purpose.

(449.) The weight of 100 cubic inches of Atmospheric air at thermometer 60° Fahrenheit, and barometer 30 in, was said by Mr. Kirwan to be 30.92 grains troy. Sir H. Davy states it at 55° Fahrenheit, 31.10 grains. Sir George Shuckburgh at 30.5 grains, which is the estimate generally admitted. But Mr. Brande obtained by experiment 30.199 grains. Dr. Prout, whose accuracy and caution gives his opinions a very great weight, is disposed to think that even Sir G. Shuckburgh's estimate is below the truth; and from him, if from any one living, we may look for a full and satisfactory investigation of this most important element in many of our calculations.

(450.) The determination of the quantity of oxygen Gas existing in a given portion of Atmospheric air, was early considered to be the same thing as ascertaining the purity of the air for respiration, &c. and hence it obtained the name of Eudiometry. (εὐδοιμένη.)

Lavoisier exposed a quantity of mercury to heat in a retort which communicated with a jar of Atmospheric air; it will be obvious that the oxygen was removed, and the residuary Gas was nitrogen.

Berthollet employed a cylinder of phosphorus exposed to a known quantity of Atmospheric air confined in a tube over water. By the slow combustion of the phosphorus the oxygen was abstracted. A vapour of phosphorus, however, remains, forming the first part of the residuary Gas, for which allowance may be made. (f.) Seguin adopted the rapid combustion of phosphorus on similar principles. Several eudiometrical instruments have been constructed for the purpose of exposing a given volume of Atmospheric air to any liquid capable of absorbing and removing its oxygen. Such are Guyton's, (f.) Hope's, (g.) Henry's, (h.) and Pepy's eudiometer. (i.) The Liquid employed is either sulphuret of potash, sulphuret of lime, or a solution of sulphate of iron, saturated with nitrous Gas. But of all eudiometers that of Volta is, perhaps, the most satisfactory. It, with other instruments of the same sort, is described in our introductory Chapter on Apparatus.
CHEMISTRY.

Subsect. 3.—Protoxide of Nitrogen. Nitrous Oxide Gas.

(451.) A. This substance has not been found as a natural production. “Protoxide of azote was discovered by Dr. Priestly about the year 1776, and called by him dephlogisticated Nitrous Gas. He procured it first by keeping iron-filings in Nitrous Gas, and by keeping a mixture of iron and sulphur in the same Gas. (k.) The associated Dutch Chemists examined it in 1793, and demonstrated it to be a compound of azote and oxygen. (l.) But for a fuller account we are indebted to Sir H. Davy, who published an excellent Dissertation on it in the year 1800. He gave it the name of Nitrous Oxide.”—Thomson.

(452.) B. The best process for obtaining this Gas is to expose nitrate of ammonia to heat in a glass retort, connected with a Gasometer. The heat should not exceed 440° Fahrenheit, and may be conveniently produced by a well-regulated Argand's lamp. (m.) Should the air be required for respiration, it is well to let it stand some time in contact with water, which will absorb any Nitrous Gas, though at the same time it dissolves some of the Protoxide of Nitrogen. Carbonic Acid, another impurity, may be removed by a little caustic alkali or quick lime.

Its action with the other ultimate and proximate elements is not sufficiently important to be pursued by us here.

(454.) M. This Gas does not support life, for an animal confined in it dies; but its effect upon Man is so singular, that it frequently forms the subject of experiment. From two quarts to a gallon, or even more, may be breathed from a bladder or oil-silk bag, supplied with a stopcock. It is essential that the aperture be large, so as to supply a rapid torrent upon the lungs. The effects differ in different individuals, but for the most part they consist in a most delightful species of intoxication, which lasts only a few minutes, and goes off again without leaving any unpleasant or debilitating effects. From the excessive tendency to laughter which it produces, it has been sometimes called the Laughing Gas. For this point, see Davy's Researches, 1 vol. 8vo.

Subsect. 4.—Tritoxide of Nitrogen. Hyponitrous Acid Gas.

(456.) If 400 volumes of nitrous Gas and 100 volumes of oxygen Gas be mixed together over a solution of potassa standing over mercury, there result 100 volumes of Tritoxide of Nitrogen. This Acid Gas combines with the potassa, but has not yet been exhibited in an isolated form; for if a stronger Acid be added to disengage it from the potassa, the Acid is resolved into nitrous Gas and nitrous Acid. A crystalline substance is formed by uniting this Acid with the sulphuric. Although the existence of this peculiar compound seems to be tolerably well established, we are not in possession of much information about it. We refer our readers to the writings of Gay Lussac (o.) and Dalton (p.) for further satisfaction.

Subsect. 5.—Telartoxide of Nitrogen. Nitrous Acid Gas.

(457.) According to Sir H. Davy, if two volumes of nitrous Gas are mixed with one volume of oxygen, both being quite dry, the remaining volume is 1.5; but according to Gay Lussac it is only one volume. Thus a deep orange-coloured Gas is formed. It supports the combustion of a taper, of charcoal, and of phosphorus, but not that of sulphur. It is readily absorbable by water, and possesses acid properties. Water saturated with this Gas forms the liquid nitrous Acid of commerce. The solution first becomes green, then blue, and finally orange. Dr. Thomson considers that this Acid is produced by the dry distillation of nitrate of lead; (q.) but Gay Lussac thinks that the Acid so obtained is the hyponitrous. (r.) Berzelius states that liquid nitrous Acid boils at 160° Fahrenheit, and he considers that it unites with bases to form Salts, (s.) but Gay Lussac states positively that it is so readily decomposed by contact with alkaline solutions, as to be quite incapable of forming a class of Salts.

Subsect. 6.—Pemptoxide of Nitrogen. Nitric Acid Gas.

(458.) Liquid nitric Acid, which is a combination of this Gas with water, “seems to have been first obtained in a separate state by Raymond Lully, who was born at Majorca in 1235. He procured it by distilling a mixture of nitre and clay. Basil Valentine, who lived in the XVth century, describes the process minutely, and

4 U 2
with the hydrogen of the latter, in consequence of which water, chlorine, and nitrous Acid are the results. For every 101 parts by weight of real nitric Acid (equivalent to 118 of hydronitric Acid) which are decomposed, 67 parts of chlorine, he calculates, are produced. According to this view, it is not correct to say that aqua regia (the old name of Nitro-Muriatic Acid) oxidates gold or platinum, since it merely causes their combination with chlorine. By long-continued and gentle heat Nitro-Muriatic Acid may be entirely deprived of chlorine, and it then loses its power of acting on gold or platinum.

"The Nitro-Muriatic Acid does not form with alkaline or other bases a distinct genus of Salts, entitled to the name of nitro-muriates; for when combined with an alkali, or an earth, the solution yields on evaporation a mixture of a muriate and a nitrate; and metallic bodies dissolved in it yield muriates only." Henry.

Subject. 7.—Ammonia.

(460.) A. The liquid solution of Ammonia in water was known to the Alchemists, as it is mentioned in the writings of Basil Valentine and Raymond Lully. Dr. Black first pointed out the difference between its pure and its carbonated form, and Priestley first examined it as a Gas, calling it alkaline air. It is found in combination with Acids among volcanic products, and it is disengaged together with other Gases during the spontaneous decomposition of putrescent animal and vegetable matter.

(461.) B. Pure ammoniacal Gas is readily obtained for experiment by applying a lamp-heat to common liquor Ammoniae in a gas bottle with a bent tube. The Gas must be collected over mercury; or it may be produced by mixing equal parts of dry Sal ammoniac (hydrochlorate of Ammonia) with dry quick-lime, both in fine powder, and applying a lamp-heat, collecting the Gas as before. This Gas, which of course is the most pure form of the volatile alkali, consists of nitrogen combined with hydrogen in the proportion of one volume or atom of the former to three volumes or atoms of the latter condensed into two volumes. The synthetic union of these elements has not yet been effected, but the decomposition of Ammonia fully proves the accuracy of such a view of its constitution. It was analysed by A. Berthollet, and most satisfactorily by Dr. Henry, (r.) by detonation with oxygen. For the method of obtaining Ammonia for Medical and Commercial purposes, we must refer to Mr. Richard Phillips's excellent translation of the Pharmacopoeia. (y.)

(462.) C. Ammoniacal Gas has a most pungent odour. It extinguishes flame, and when undiluted, cannot be respired. It is not sufficiently inflammable to burn in atmospheric air; but Dr. Henry found that he could ignite a small jet of it issuing into an atmosphere of oxygen Gas. It is lighter than atmospheric air, as will be seen from the table of Specific Gravity in Part V. Heat is capable of decomposing it when passed through a porcelain tube; so also is a current of electric sparks. Water will absorb 190 per cent. by volumes of this Gas. Its properties are decidedly alkaline, as it turns vegetable blues to green, and saturates Acids so as to form a class of Salts. At 50° Fahrenheit, and under a pressure of 6.5 atmospheres, Ammonia becomes a limpid colourless Liquid.

(463.) D. Oxygen has no immediate action on am-
Chemistry. Ammoniacal Gas, but by explosion in Volta’s eudiometer it combines with the hydrogen, setting free the nitrogen.

(464.) E. Scheele first applied chlorine to Gaseous Ammonia, and thus effected its decomposition; hydrochloric Acid and nitrogen resulting. Professor Thomson has availed himself of this process very successfully in the analysis of Sal Ammoniac. (2.) There can then be no combination of chlorine with Ammonia.

(465.) F. Unknown.

(466.) G. Iodine absorbs dry Ammonial Gas without decomposition: a brownish-red viscid substance results. But if iodine be added to the aqueous solution of Ammonia, decomposition takes place, a part of it unites with the hydrogen to produce hydriodic Acid, while another portion of the iodine unites with nitrogen, and forms a black powder of powerful detonating properties.

(467.) H. Unimportant, or in some cases none at all.

(468.) I. There is some sort of action between Ammonia and the metals, though its nature does not seem to be well understood. Of this we have the most important instance marked in Art. (462.) Theobald ascertained that when iron, copper, silver, gold, or platinum are enclosed in a heated porcelain tube, through which Ammonia is passed for its decomposition, they materially aid the process, and in the order above set down. The iron is rendered brittle, and the copper still more so; but the metals undergo no change of weight.

Iron, however, decomposes a much greater quantity of the Gas than platinum does, and at a much lower temperature. (aa.)

(469.) K. The qualities of Ammonia are so decidedly alkaline, that it never performs the part of an Acid with any base; but it acts extensively as a base, forming numerous and important Salts. With carbonic Acid it unites in three different proportions.

(470.) L. Ammoniacal Salts are readily recognised by the odour they emit when rubbed in a mortar with a small quantity of quick-lime: when the Ammoniacal Gas thus evolved is very minute in quantity, it is rendered very apparent by holding over the powder a glass rod which has been dipped in hydrochloric Acid. White fumes are then seen, consisting of hydrochlorate of Ammonia.

(471.) M. Preparations of Ammonia are of considerable service in Medicine. In small quantities they act as stimulant, rubefacient, and antacid: in larger quantities they are emetic.

Subsect. 8.—Cyanogen. Bicarburet of Nitrogen.

(472.) Cyanogen Gas derives its name from κυανός, blue, and γονιόν, to generate, because of its forming the essential part of Prussian blue. It owes its name and rank, as a proximate element, to the researches of Gay Lussac, made in 1815. (bb.) Scheele had, however, accidentally produced the same substance long before.

To obtain this Gas, the cyanuret of mercury (clim Prussianat) is to be carefully dried, and then exposed in a small retort to the heat of a spirit-lamp. Gaseous Cyanogen is evolved, and the mercury is sublimed. This Gas is without colour, but has a pungent odour. It is a limpid Liquid, at 45° Fahrenheit, under a pressure of 3.6 atmospheres. It extinguishes burning bodies, and is itself combustible, burning with a beautiful purple flame. At 60° Fahrenheit, water absorbs 4.5, and alcohol twenty-three times its volume of this Gas. This Gas has a strong affinity for the metals, thus producing metallic cyanures; but its affinity for oxides is very slight. It does not form stable compounds with bases; and though its aqueous solution reddens litmus-paper, that effect is due to the formation of other Acids by mutual decomposition, so that it cannot be considered as an Acid. (ce.) Cyanogen contains nitrogen Gas one atom or volume + carbon vapour two atoms or volumes condensed into one volume. It may be analysed by detonation with oxygen in Volta’s eudiometer.

The compounds of Cyanogen are highly interesting, forming a class of important proximate elements. The following is a synoptic view of their constitution

Cyanic Acid. . . . . . . . . . . = oxygen one atom + Cyanogen one atom.

Of this Acid there seem to be two varieties, having the same ultimate constitution.

Hydrocyanic Acid . . . . = hydrogen one atom + Cyanogen one atom.

Chlorocyanic Acid. . . . = chlorine one atom + Cyanogen one atom.

Iodide of Cyanogen. . . . = iodine one atom + Cyanogen one atom.

Ferro-hydrocyanic Acid. = iron one atom + hydrogen two atoms + Cyanogen three atoms; or = hydrocyanic Acid two atoms + cyanuret of iron one atom.

Sulpho-hydrocyanic Acid = sulphur two atoms + hydrogen one atom + Cyanogen one atom; or = bisulphuret of Cyanogen one atom + hydrogen one atom.

These compounds we shall briefly notice in succession.

Cyanic Acid.

(473.) That there should be two varieties of Cyanic Acid having the same atomic constitution is a singular fact; but is not, according to the present belief, without parallel.

Cyanic Acid of M. Wöhler.—This Chemist found that when alkaline solutions are saturated with cyanogen Gas, a decomposition takes place, and that Hydrocyanic and Cyanic Acids are both produced, so that the action of alkaline solutions on Cyanogen is similar to that upon iodine, chlorine, or sulphur.

The cyanate of potassa is obtained by exposing to a low red-heat a mixture of equal weights of ferro-hydrocyanate of potassa and finely-powdered peroxide of manganese. The mass that has been heated is then to be boiled in alcohol of eighty-six per cent. strength; and as the solution cools, cyanate of potassa is deposited in small laminary crystals. This Acid forms a soluble Salt with baryta, and insoluble Salts with the oxides of lead, mercury, and silver. (ad.)

Cyanic Acid of M. Liebig.—This Acid was obtained from the fulminating mercury of Mr. Howard, a compound to be hereafter described. (See Mercury.) This substance seems to consist of a true cyanate of mercury. Similar Salts may be formed of silver and other metals; but the Cyanic Acid has not hitherto been obtained from them in a separate state; for in attempting their decomposition by alkalies, double Salts are formed, which also possess detonating properties. (et.)
Hydrocyanic Acid.—Prussic Acid, Scheele.

(474.) Scheele discovered this Acid in 1783; and Berthollet ascertained its ultimate elements to be carbon, nitrogen, and hydrogen. Gay Lussac, by discovering the true nature of cyanogen, showed it to be the base of the Acid, and hydrogen the acidifying principle.

Hydrocyanic Acid is obtained by heating three parts of cyanuret of mercury with two parts by weight of concentrated hydrochloric Acid in a glass retort. A vapour of water, hydrochloric Acid, and Hydrocyanic Acid rises, and is purified from the hydrochloric Acid by being condensed in a vessel surrounded with ice.

Vauquelin, however, recommends in preference, that a narrow horizontal tube should be filled with fragments of the mercurial cyanuret; and that then a current of hydrogusulphuric Acid Gas should be slowly admitted. The instant that Gas comes in contact with the cyanuret, double decomposition ensues; Hydrocyanic Acid and the black sulphuret of mercury being generated. The progress of the hydrogusulphuric Acid along the tube may be distinctly traced by the change of colour, and the experiment may be terminated so soon as the whole of the cyanuret has become black. The Hydrocyanic Acid is then to be expelled by a gentle heat, and collected in a cool receiver.

For Medicinal purposes it is prepared at Apothecaries' Hall, by mixing in a retort one part of cyanuret of mercury, one part of hydrochloric Acid, (Specific Gravity 1.15,) and six parts of water. This is distilled at a gentle heat, giving an Acid of Specific Gravity 0.995. (ff)

Pure condensed Hydrocyanic Acid is a limpid Fluid of Specific Gravity 0.7058. at 45° Fahrenheit. It has a strong odour of the peach blossom, and the vapour, when breathed even with much atmospheric air, produces giddiness and headache. When diluted, it has the taste of bitter almonds. This Acid is extremely volatile, and boils at 79° Fahrenheit; at zero it congeals. Even when closely confined, it most readily undergoes spontaneous decomposition, so that it cannot well be preserved undiluted many days. During decomposition it assumes a brownish tint. It reddens litmus-paper feebly, and combines with bases to form Salts; but it is so feeble as not to decompose the carbonates, nor can it be made to neutralize potassa.

By Voltaic electricity it is decomposed, the hydrogen appearing at the negative pole, the cyanogen at the positive one. It is also partially decomposed by being passed through a red-hot porcelain tube. With oxygen Gas it detonates in Volta's eudiometer. It is best analysed by potassia, as in Gay Lussac's experiments.

Free Hydrocyanic Acid is readily recognised by its odour. A fluid which is supposed to contain it may be agitated with finely-powdered oxide of mercury. By double decomposition water and cyanuret of mercury are produced, and on evaporating the filtered solution, small crystals of the cyanuret are obtained.

Dr. Ure has given the following process for estimating the strength of any solution of Hydrocyanic Acid met with in commerce. "To 100 grains of the Liquid contained in a phial, let small given quantities of the finely-powdered peroxide of mercury successively be added, until it ceases to be dissolved. The weight of peroxide so dissolved, divided by four, gives the quantity of real Hydrocyanic Acid present." (gg.)

The distilled water of the Prunus Lauro-cerasus owes its odour and poisonous properties to this Acid; it exists also in the bitter almond, and in the bird-cherry. The Hydrocyanic Acid, when pure, is so violent a poison, that one drop may be fatal. In a diluted state it is now given Medicinally with much success, chiefly to allay irritation in pulmonic complaints. (hh.)

Chlorocyanic Acid.

(475.) If chlorine Gas be passed through an aqueous solution of hydrocyanic Acid, until the Liquid acquires bleaching properties, and then the redundant chlorine be removed by agitation with mercury, two Acids remain, the hydrochloric, and the Chlorocarbonic, first called the Oxypurassic by Berthollet. This Acid is at present little known, and seems scarcely to have been obtained in a separate state. Its composition, as stated by M. Gay Lussac, has been already mentioned.

Iodide of Cyanogen; or Cyanuret of Iodine.

(476.) Such are the names given to a compound of these elements not possessed of acid properties. It was discovered in 1824 by M. Serullas, and may be obtained by mixing two parts of cyanuret of mercury with one of Iodine, both quite dry, in a glass mortar. This mixture is to be put into a wide-mouthed phial. On the first application of heat, vapours of Iodine appear, but so soon as the Cyanuret undergoes decomposition, white fumes are seen, which will condense on the sides of a cool glass receiver in flocculilike cotton wool. This Iodide of Cyanogen has a caustic taste and acrid odour, exciting tears. It is very volatile, and bears a heat of more than 212° Fahrenheit, without decomposition, but its elements are disunited by a red-heat. It is soluble in water. (ii.)

Ferro-hydrocyanic Acid. Ferruretted Chyazic Acid.

(Porrett.) Ferro-cyanic Acid. Acide Hydro-cynique ferruré. (Thenard.)

(477.) We are disposed to prefer the name standing first among these synonyms, as best expressing the constitution of this Acid; viz. that iron and hydrogen both simultaneously combine in forming an acid compound, having cyanogen for a base. Or it might possibly be said that iron in combination exerts a modifying agency upon what would otherwise be Hydrocyanic Acid. Mr. Porrett, to whom, with Messrs. Wilson and Rupert Kirk, we are much indebted for able researches into the nature of these interesting compounds, proposed the name of Chyazic Acid, forming the word from the initial parts of its elements, carbon, hydrogen, and azote. We object to the name of Ferro-cyanic Acid, because it would seem to express the nature of the substance, and yet omits an important element. By some it is considered that hydrogen acts as the acidifying principle upon a sort of double radical consisting of both cyanogen and cyanuret of iron.

The following are two processes recommended by Mr. Porrett for obtaining this Acid. 1. Let 56 grains of crystallized tartaric Acid be dissolved in alcohol, and...

CHAPTER IV.

The Acid thus proposed is a transparent Liquid, hav
ing sometimes a light pink colour. The greatest den
sity that Mr. Porrett could obtain was 1,022.

General Remarks on the Metals.

It boiled

at 216.5° Fahrenheit, and at 54°.5 Fahrenheit crystal
lized in six-sided prisms. It reddens litmus-paper, and
forms Salts with alkaline bases. Its presence is readily
detected by its giving a white precipitate with a Salt of
the peroxide of copper, and a deep blood-red one with
any persalt of iron. At present we are under some un
certainty about the mode of combination among the

(480.) It may possibly conduce to a clear under-Metals.
standing of the properties of this most interesting class
of bodies, if we take a brief survey of the various arti

ficial divisions or systems of classification which have
been proposed for them. Seven Metals only were
known to the Ancients, gold, silver, iron, copper, lead,

elements of this Acid. It is supposed by some to be a tin, and mercury. These were divided into perfect and
imperfect; gold and silver being considered the per
hydracid, having bisulphuret of cyanogen for its ra fect

Pontin, Bibl. Brit. Nos. 323, 324; Gay Lussac and

Metals into five Orders.

-


CHEMISTRY.

Order 1.—Brittle and Acidifiable.
Arsenic. Molybdenum.
Tungsten. Chromium.

Order 2.—Brittle and simply Oxidizable.
Titanium. Bismuth.
Uranium. Antimony.
Cobalt. Tellurium.
Manganese.

Order 3.—Oxidable and imperfectly Ductile.
Mercury. Zinc.

Order 4.—Easily Oxidizable and Ductile.
Tin. Iron.
Lead. Copper.

Order 5.—Difficult of Oxidation and very Ductile.
Silver. Palladium.
Gold. Platinum.

Another arrangement was proposed by Dr. Thomson in the 3d Edition of his Chemistry, and is employed by Dr. Henry. Here there are four Classes.

Class 1.—Malleable Metals.
Gold. Osmium.
Platinum. Copper.
Silver. Iron.
Mercury. Nickel.
Palladium. Tin.
Rhodium. Lead.
Iridium. Zinc.

Class 2.—Brittle and easily fused.
Bismuth. Tellurium.
Antimony.

Class 3.—Brittle and difficult of Fusion.
Cobalt. Molybdenum.
Manganese. Uranium.
Chromium. Tungsten.

Class 4.—Refractory Metals.
Titanium.
Columbium.
Cerium.

In the most recent edition of Dr. Thomson's Work, arsenic, tellurium, and osmium are removed from the rank of Metals, and fall in with his "acidifiable combustibles," phosphorus, sulphur, &c. Then come 31 Metals, which form "alkalis or bases capable of constituting neutral Salts with Acids, by uniting with the supporters of combustion." These are arranged under five Families.

Family 1. contains those bodies which, "when combined with oxygen, possess the alkaline properties in the greatest perfection. They all convert vegetable blues to green, and are all soluble in water, with the exception of magnesia," which is so to only a very slight extent. Here we have the bases of the alkalies and alkaline earths of former Chemists:
1. Potassium.
2. Sodium.
3. Lithium.
4. Calcium.
5. Borium.
7. Magnesium.

Family 2. The compounds which the elements contained in this Family "form with oxygen are white, and these oxides form colourless solutions in Acids; it has hitherto been impossible to reduce them in any quantity to the Metallic state. They are insoluble in water, and produce no alteration in the colour of vegetable blues. On that account they were formerly distinguished in Chemistry by the name of earths proper:"
1. Yttrium.
2. Glucinum.
3. Thorium.
4. Zirconium.
5. Aluminum.

Family 3. The Metals in this Family "are distinguished by two properties: 1. Their oxides cannot be reduced to the Metallic state by the most violent heat that can be applied. 2. When dissolved in an Acid they cannot be precipitated in the Metallic state by plunging into the solution a rod of any other Metal:"
1. Iron.
2. Nickel.
3. Cobalt.
4. Manganese.
5. Cerium.
6. Uranium.
7. Tin.
8. Silver.

Family 4. The substances belonging to this Family are precipitated from their solutions in Acids, in the Metallic state, in the order of the following Table. Zinc precipitating all the others; but not being itself precipitated by any of them. Lead precipitates all except zinc and cadmium. Tin all except zinc and lead. Copper precipitates only bismuth, mercury, and silver. Silver is precipitated by all the rest, but does not itself precipitate any of the others:"
1. Zinc.
2. Cadmium.
3. Lead.
4. Tin.
5. Copper.
7. Mercury.
8. Silver.

Family 5. In this Family, consisting of five Metals, "they all require a strong heat to fuse them; they are all insoluble in nitric Acid, and their oxides are reducible to the Metallic state by the application of heat alone:"
1. Gold.
2. Platinum.
3. Palladium.
4. Rhodium.
5. Iridium.

The remaining Metals which in Dr. Thomson's system do not enter any of these Families constitute a genus apart. They are described as "bodies producing by their union with the supporters of combustion imperfect Acids, or substances intermediate between Acids and alkalis:"
1. Antimony.
2. Chromium.
3. Molybdenum.
4. Tungsten.
5. Columbium.
6. Titanium.

(481.) We now proceed to that classification of the Metals which we have adopted in this Essay. It is almost identical with that made use of by M. Thenard in former editions of his admirable Traité de Chimie; but it differs in that we have already treated of silicon by removing it from the class of Metals: a measure justified by the opinion of Thomson and Berzelius. In the last edition of M. Thenard's Work (the fifth) he has placed silicon and zirconium in a division by themselves as intermediate between the substances of our third Chapter and the Metals. Berzelius has recently ascertained that thorina, which he had considered a peculiar earth, is a phosphate of yttria. The name, however, still remains in our Synopsis, as the same.
Chemist has discovered another earth which he deems a simple substance, and from a similarity of properties proposes that it should occupy the vacant name. The following forty Metals then will stand in six classes, chiefly dependent for their distinction upon the degree of their affinity for oxygen.

(482.) Class 1.—Those Metals which have not yet been actually obtained by reduction from their oxides, and exhibited in a pure state, though considered Metals on sufficiently strong analogies.

1. Zirconium. 4. Yttrium.
2. Thorium. 5. Glycyanum.

(483.) Class 2.—Metals which instantly decompose water at ordinary temperatures; combine with oxygen at the same temperature, or by the aid of a slight heat; and whose oxides are reducible by Electricity, or by certain very combustible bodies; but cannot be reduced by heat alone.

1. Potassium. 4. Barium.
2. Sodium. 5. Strontium.
3. Lithium. 6. Calcium.

(484.) Class 3.—Metals which are capable of decomposing water but only at a red heat; which combine with oxygen at some temperature; and whose oxides are reducible by electricity, and by different combustible bodies, though not reducible by any heat alone however violent.

1. Manganese. 4. Tin.
3. Iron.

(485.) Class 4.—The Metals of this section are incapable of decomposing water at any temperature; they combine with oxygen upon some elevation of temperature; their oxides are reducible by Electricity, and by different combustible bodies, but not reducible by heat alone.

The Metals of this section are again subdivided into first, those which are capable of becoming Acids; and secondly, those which form oxides only.

Acidifiable.

1. Arsenic. 4. Tungsten.
3. Chromium.

Not Acidifiable.

2. Uranium. 7. Copper.
3. Cerium. 8. Tellurium.
5. Titanium. 10. Lead.

M. Thenard suggests that some of these, especially antimony, titanium, and tellurium, have a claim to be considered acidifiable Metals.

(486.) Class 5.—Metals which do not decompose water at any temperature, but which combine with oxygen at some temperature or other, and whose oxides are reducible by heat alone.

1. Mercury. 2. Osmium.

(487.) Class 6.—Those Metals which do not decompose water at any temperature: do not combine with oxygen at any temperature; and whose oxides formed indirectly are easily reducible by heat alone.

Vol. IV.

METALS. CLASS I.

Sect. I.—Zirconium.

(488.) Of this Metal, the oxide of which forms the earth Zirconia, (see subsect. 1.) we have few details, and for the slender knowledge which we possess, we are entirely indebted to Sir H. Davy. He submitted the earth Zirconia, in contact with potassium and mercury, to the action of Voltaic Electricity, and obtained results which showed that some portion of the earth had undergone decomposition; the metallic amalgam being capable of decomposing water, and the Zircon earth being found as a product after that decomposition. Davy also applied potassium to Zirconia at a white heat: the potassium "was for the most part converted into potash, and dust particles, which, when examined with a magnifying glass, appeared metallic in some parts, and chocolate brown in others, were found diffused through the potash and the undecomposed earth." (a.)

Subsect. 1.—Zirconia.

(489.) A. By analyzing Zircon, a mineral found in the Island of Ceylon, Klaproth, in the year 1789, discovered a new earth, which he named Zirconia. (b.) In 1795 he published his Analysis of the Hyacinth, another mineral from the same island, and found in this also a considerable proportion of the same earth. (c.) Morveau then, in 1796, examined the Hyacinths from Expayill in France, in which he also found Zirconia. (d.) Vauquelin has also given some Memoirs on this subject; (e.) and still more recently, M. Chevreul. (f.) MM. Dubois and Silvier have proposed an improved process for obtaining this earth. (g.)

(490.) B. This process consists in submitting the Zirconis, reduced to a fine powder, and mixed with two parts of pure potash, to a red heat for an hour in a silver crucible. The mass is then treated with distilled water filtered and thoroughly washed. The residuum upon the filter consists of Zirconia, silica, with some potash, and oxide of iron. It is then dissolved in hydrochloric Acid, and evaporated to dryness, for the purpose of separating the silica. Let the muriate of Zirconia and iron be redissolved in water; and to separate a little Zirconia which will adhere to the silica, wash the latter with a little weak hydrochloric Acid, and add this to the solution. After filtering the Liquid, let the Zirconia and iron be precipitated by pure ammonia; wash the precipitate well, and treat it with oxalic Acid, boiling them well together; by this the oxide of iron will be dissolved out, and an insoluble oxalate of Zirconia will be formed. Filter and wash the oxalate until no iron can be detected in the washing. The oxalate of Zirconia well washed and dried is of an opaline colour, and may be decomposed by heat in a platinum crucible.

(491.) C. Zirconia is a fine, white powder without taste or smell, but feeling gritty between the fingers; infusible save by the Gas blowpipe. It is insoluble in water, but has a strong affinity for that Liquid. When slowly dried, after being precipitated from a solution, it retains about one-third its weight of water, and assumes...
who gave to the new earth the name of Yttria. (b.)

These researches were still further extended by Vauquelin in 1800; (e.) and likewise by Klaproth about the same time: (d.) Ekeberg also published a new dissertation on the subject in the Swedish Transactions for 1802. (e.) Since that time Yttria has been repeatedly examined by Berzelius, who has shown (f.) that the earth examined by Ekeberg and Gadolin was not pure. He has himself succeeded in separating it from most of the cerium with which it was contaminated, and has described its properties. (g.)

Yttria has as yet only been found in the Gadolinite above mentioned; in yttro-tantalite another Swedish mineral, where it is combined with tantalum; and in combination with phosphoric Acid, by which it produced the earth to which Berzelius had given the name of Thorina, supposing it to be a new proximate element.

Chemistry.

Chemistry. ask of a greyish colour. Also in grey fuscous by infusion or tincture of galls, but very slightly by pure gallic Acid. Its saline solutions are not affected by hydro-

sulphuric Acid, nor by sulphuret of ammonia. It is also

precipitated by phosphate of soda, carbonate of soda, and oxalate of ammonia.

(506.) M. None.

Sect. III.—Glycynum.

(507.) For the existence of this Metal we have the same evidence as is exhibited in the case of zirconium, and for this knowledge we are also indebted to Sir H. Davy. The process he employed was the same as he made use of for zirconium. (486.) The oxide of Glycynum forms the earth glycyna, which we shall describe in the following subsection.

Subsect. I.—Glycyna.

(508.) A. In the year 1798, the Abbé Haüy requested Vauquelin to analyze the emerald and beryl, in consequence of an inference which he had deduced from their crystalline forms, that the two minerals contained the same chemical elements. Haüy's conjecture was confirmed by the analysis, and Vauquelin was rewarded by the discovery of a new earth, to which the name of Glycynum was given, in consequence of the sweet taste of its Salts. (γλυκός.) Vauquelin's experiments (a.) have been repeated by Klaproth, (b.) and Ekeberg, (c.) and Berzelius. Glycyna is found in the emerald, beryl, and euclase. It has been usual to write this word Glucina, but the ordinary laws of derivation from its Greek source require that it should be Glycina, or even in still greater strictness Glycyna.

(509.) B. To obtain this earth, the mineral containing it is to be finely powdered, and then fused with thrice its weight of potash. To the fused mass add a little water, and then dissolve in hydrochloric Acid; evaporate the solution to dryness. Add then abundance of water, and filter out the silica. The muriates of Glycyna, &c. pass through in solution. Precipitate the earths by carbonate of potash. Wash the precipitate well, and dissolve it in sulphuric Acid. Then to this solution add a solution of sulphate of potash; concentrate by evaporation, and leave the Liquid to crystallize. Crystals of alum are thus removed. When as many of these have been obtained as is possible, add carbonate of ammonia in excess, filter and boil the Liquid for some time. The Glycyna gradually subsides in the form of a white powder.

(510.) C. Glycyna is a soft, white powder, insusceptible save by the Gas blowpipe, causing neither taste nor smell, but adhering to the tongue. It does not affect vegetable colours, is insoluble in water, but forms a paste with that Liquid.

(511.) D. E. F. G. These have no action on Glycyna.

(512.) H. With the simple combustibles it does not combine.

(513.) I. Nor yet with the metals.

(514.) K. Glycyna is soluble in solutions of the fixed alkalis like alumina. It agrees with yttria in being insoluble in ammonia, but soluble in its carbonates, though in a much greater degree. It is soluble also in the other alkaline carbonates. Glycyna readily combines with all the Acids, and even the hydrosulphuric. Its Salts are for the most part soluble in water, but the greater part are not crystallizable. The carbonate, phosphate, seleniate, and succinate are insoluble.

(515.) L. Prussiate of potassa gives a white, and infusion of galls a yellow, precipitate when added to the solution of a salt of Glycyna. In its solubility in potassa and soda, Glycyna resembles alumina; but Vauquelin showed that it would not form alum by adding potassa to its liquid sulphate: and further by the sweet taste of its Salts he considered it clearly distinguished from that earth. It differs also from Yttria in not forming crystallizable Salts, in not being soluble in the fixed alkalis, and in not being precipitated by oxalate of ammonia, nor by tartrate or citrate of potash.

References to § 3.

Sect. IV.—Thorinum.

(516.) At the time of forming the outline of this Treatise, it was believed, on the authority of Berzelius, that a peculiar earth existed, to which he gave the name of Thorina; and from analogy with other cases, it was supposed to have a metallic base, which would of course be Thorinum. Berzelius has, however, subsequently found that this supposed earth, of which he had only a very small quantity, was a phosphate of yttria. Still more recently he has obtained another earth, which he believes to be simple, and proposes that it should still continue the name of Thorina among the earths. At present, however, very little is generally known of this substance.

Sect. V.—Aluminum.

(517.) The experiments of Sir H. Davy on the earth alumina gave sufficient evidence of the existence of this Metal, though they were not so successful as those made on some of the other earths. He submitted alumina fused with potash to the action of Voltaic Electricity, and obtained metallic globules, consisting chiefly of potassium, but which, when carefully separated and again oxidized, afforded both potash and alumina. Results of the same nature were obtained from potassa and from mercury, when acted upon in a state of mixture with alumina. By exposing the earth at a white heat to the vapour of potassium, potash was formed, and among the alumina there appeared small particles of a grey colour and metallic lustre, which again became white on exposure to the air, or if placed in water decomposed, it producing a slight effervescence. Alumina, a well-known earth, the oxide of this Metal, will be described in the following subsection.
Chcmistry.

Subsect. 1.—Alumina.

(518.) A. "Alum is a salt which was known many centuries ago, and employed in dyeing, though its component parts were unknown. The alchemists discovered that it is composed of sulphuric Acid with an earth; but the nature of this earth was long unknown. Stahl and Neuman supposed it to be lime; but in 1728, Geoffroy, jun. proved this to be a mistake, and demonstrated that the earth of alum constitutes a part of clay. (a) In 1754, Margraaf showed that the basis of alum is an earth of a peculiar nature, different from every other; an earth which is an essential ingredient in clays, and gives to them their peculiar properties. (b) Hence this earth was called Argil; but Morveau afterwards gave it the name of Alumina, because it is obtained in the state of greatest purity from alum. The properties of Alumina were still further examined by Macquer in 1758 and 1762, (c) by Bergman in 1767 and 1771, (d) and by Scheele in 1776; (e) not to mention several other Chemists who have contributed to the complete investigation of this substance. A very ingenious Treatise on it was published by Saussure, jun. in 1801." (f) Thomson, Syst. vol. i. p. 373.

Alumina forms a part of many minerals. It exists pure in the corundum genus, of which the sapphire and ruby are species; owing their colours only to very minute portions of metallic oxides. Alumina forms the characteristic ingredient in clays and marls, and it is to this earth that they are indebted for their plastic properties.

(519.) B. To obtain pure Alumina, let alum be dissolved in about twenty times its weight of water, then add a small quantity of carbonate of soda in solution to precipitate a little iron, with which almost all alum is contaminated. After this let the Liquid be filtered into a solution of pure ammonia, being careful to keep the latter alkali in excess. The ammonia unites with the sulphuric Acid, and the Alumina falls down in a white flocculent precipitate, which must be well washed and dried. According to Saussure there is a considerable difference in the appearance of precipitated Alumina, arising from the state of dilution in which it exists in its solution.

(520.) C. Pure Alumina is a white, bland powder, adhering to the tongue, but neither exciting smell nor taste. It forms a paste with water: is insufible, except by the flame of the Gas blow-pipe. There is a peculiar smell excited by breathing upon an argillaceous limestone, but this smell depends upon the simultaneous presence of oxide of iron. The Specific Gravity of Alumina is 2.0, according to Kirwan. When first precipitated, Alumina is a hydrate, but by a red heat the water is driven off, and the chemical properties of the earth itself undergo some change. On this subject consult Saussure's Memoir, and some interesting recent experiments by Thomson. (g)

(521.) D. E. F. G. H. I. With the substances in these classes Alumina does not combine.

(522.) K. In considering the action of Alumina with the bases, we may first notice its ready power of union with other earths by fusion. From this property arises much of its utility in the Arts. Thus it unites with lime, barytes, strontia, magnesia, and silica, and probably would do so with the other similar bodies. With those named it combines both in the humid and dry way. The affinity for barytes is very marked, for it communicates to Alumina a degree of solubility beyond that which is natural to it, so that when equal parts of these earths are boiled in water, both are dissolved. Thomson states that if barytic water be added to a solution of muriate of Alumina a precipitate falls consisting partly of both earths. (h) This, however, is denied by Chenevix and Darques. The effect of strontia is analogous, for if five parts of this earth be boiled with one of Alumina, a portion of Alumina is rendered soluble, while another portion remains in the state of an insoluble compound of strontia and Alumina. Scheele observed, that when Alumina is added to lime-water, an insoluble compound of the two earths is precipitated. Chenevix found that if a solution of potash be boiled on a mixture of lime and Alumina, the latter is dissolved; together with a greater proportion of lime than is due to the solvent power of the water alone: while if the alkaline solution be boiled on lime alone, no more lime is dissolved than is due to the water of the solution; a proof that the solvent power of the water over the lime is promoted by the Alumina.

By the intense heat of the Gas blow-pipe, or of oxygen alone, Alumina and lime may be fused together when the Alumina is in excess: but Alumina and magnesia will not run together at any heat, according to Kirwan and Guyton. There is, however, some affinity between Alumina and magnesia, for magnesia alone cannot be entirely precipitated from any of its solutions by ammonia, while if Alumina be present its precipitation is complete. Thus Chenevix found, that if an excess of Ammonia be added to a solution of muriate of magnesia, mixed with a large proportion of muriate of Alumina, nothing remained in solution but muriate of ammonia; the two earths being precipitated in combination, and their mutual affinity was even sufficient to resist the action which potash exerts on aluminous earth.

The mutual attraction between silica and Alumina is shown by an experiment of Morveau, in which, when a solution of silicate of potash and of Alumina and potash are mixed, the two earths are precipitated in combination, by which the properties of each are modified. So also at a very intense heat this affinity is developed by the earths entering into fusion and forming a milky glass or enamel.

Alumina unites also with some of the metallic oxides by fusion, forming enamel of different colours.

Acids dissolve Alumina with ease, especially when it has been recently precipitated. The Salts thus formed are, for the most part, soluble in water, and, generally speaking, their tendency to crystallization is small. The arseniate, seleniate, tungstate, mallate, urate, sacclactate, are insoluble; but for the properties of these Salts we must refer to the more extended chemical systems.

There is, however, one salt of Alumina of too great commercial importance to be passed by without further notice. Alun is a triple compound of Alumina, sulphuric Acid, and any one of the three alkalis proper, with some water of crystallization. Of this salt there are four varieties. We could have wished here to describe more fully the natural and chemical history of a substance so extensively employed in numerous Arts, but our space not permitting, we refer the reader to an excellent synoptic view of the subject given in Professor Thomson's System, vol. ii. p. 357.
like those of glycyna. They are not precipitated from their solutions by oxalate of ammonia, nor by tartaric Acid, which distinguishes them from those of ytrria. They are precipitated by prussiate of potash, nor by tincture of galls, in which respect they differ from the salts of glycyna and ytrria. If sulphuric Acid and then sulphate of potash be added to a salt of Alumina, and the mixture be left at rest, crystals of alum speedily form therein. Phosphate of ammonia produces a white precipitate; and hydriodate of potash a white flocculent precipitate, which speedily becomes of a permanent yellow colour.

(524.) M. The uses of Alumina and its compounds in the Arts and Manufactures are both numerous and important. Every variety of porcelain consists of some combination of argillaceous and siliceous earths; though in the coarser kinds of pottery, sand and other impurities enter in considerable proportions. Silica, it is true, generally predominates even in the best porcelain clays, yet it is upon the Alumina that the essential properties of the compound depend. It is to this latter earth that the clay owes ductility in working, and tenacity in baking.

Generally speaking, the native porcelain clays increase in value in proportion to their purity. If more than five or six per cent. of lime be present, the clay becomes too fusible; if too great a proportion of oxide of iron be present, the porcelain acquires a red or brown tint when it is baked.

Of the porcelain clays the kaolin and petunze of the Chinese are the most celebrated. According to the analysis of Vauquelin, the former consists of silica 74, Alumina 14.5, lime 5.5. The purest clays that have been discovered in Europe result from the natural decomposition of rocks, containing a large proportion of feldspar. Such is the Cornish clay which is sent to Swansea, Worcester, and Coalbrook Dale. Magnesia seems also to be applicable to the same purpose, for Giobert found that a clay which had long been used with success in the manufacture of porcelain, consisted almost entirely of silica and carbonate of magnesia.

The colours on porcelain result from the fusion of certain metallic oxides; thus the purple precipitate of cassis, a preparation of gold, produces the carmine colour; and with a larger proportion of lead in the flux, the same substance gives a purple. Peroxide of iron produces rose-red; white oxide of antimony mixed with oxide of lead and silica gives a yellow; oxide of cobalt, blue; oxide of copper, green; and various shades of brown arise from using different proportions of the oxides of manganese, copper, and iron. The gilding upon china is performed by laying on the gold ground down to an extremely minute state of division in a varnish of borax and gum-water, which is fixed in burning by the fluxing properties of the borax, and afterwards polished with the burnisher.

Crucibles and retorts are formed from a clay containing much oxide of iron; and the Hessian crucible clay consists, according to Vauquelin, of silica 69, Alumina 14.5, charcoal 1, oxide of iron 8.0. The singular properties of alum are taken advantage of for the following uses. To render wood fire-proof, which it effects to a very considerable extent. It will aid the separation of the serous and watery parts of cream in churning butter. The chandlers add it to tallow, for the purpose of giving hardness. It is used in silvering and lackering on copper and brass. It possesses a singular property in clearing turbid water, by producing a precipitate which settles to the bottom. It is used in tanning and dyeing the finer kinds of morocco leather. In dyeing cotton goods also it is of essential importance, as it both prepares the vegetable fibre for receiving the colours, and aids the formation of an actual chemical combination between its own base, the colouring matter, and the cotton that is to be dyed. In Medicine it is applied both internally and externally as an astringent. It adds to the tenacity of bookbinders' paste, and helps to preserve it.

The last of the uses of alum to which we shall advert, is in the formation of that singular substance Homberg's Pyrophorus.

(525.) "Let three parts of alum and one of flour or sugar be melted together in an iron ladle, and the mixture be dried till it becomes blackish and ceases to swell; if it be then pounded small, put into a glass phial, and placed in a sand-bath, heated till a blue flame issues from the mouth of the phial, and, after burning for a minute or two, be allowed to cool, this substance is obtained. It has the property of catching fire whenever it is exposed to the open air, especially if the air be moist." Such is Dr. Thomson's recipe, and we have frequently followed it, generally with success. Instead of a glass phial we place the mixture in a half-pint cucurbit, with a bit of glass tube luted into the mouth after the cucumber is filled. The whole is submitted to a low red heat in a crucible of sand, placed within a small portable furnace. A blue flame issues from the orifice of the glass tube which may be suffered to burn for a quarter of an hour. The whole should then be withdrawn from the fire, and the tube closed with a piece of lute. When the whole is cool, the pyrophorus, a black pulvulent substance with some lumps, should be rapidly transferred to a dry stoppered bottle, and most carefully preserved from the air. In this manner we have kept it good for years, opening it only occasionally. If the pyrophorus does not ignite speedily when taken from the phial, the mere process of breathing on it will frequently cause a vivid ignition.

Homberg discovered this substance accidentally about the commencement of the XVIIIth century. Its singular properties have excited the attention of many Chemists; and Davy has made it appear that the igniferous property, for inflammable we ought not to say, depends upon a small quantity of potassium which is produced from the decomposition of the potash in making the pyrophorus.

References to § 5.

Sect. VI.—Magnesia.

(526.) For the discovery of this base we are indebted to a set elaborate series of researches made by Sir H. Davy on the earths and alkalies in general.

When Magnesia, the oxide of this Metal, was submitted to galvanic action in its pure state, less effect was
this solvingsulphate was attributedto its very imperfect conducting power, arising out of its insolubility. To avoid this difficulty, solutions of the sulphate, or nitrate of Magnesia, were galvanized in contact with mercury. Decomposition then takes place; an amalgam of mercury and Magnesia was formed. Sir H. Davy experienced, however, some difficulty in attempting to separate the Magnesium from the mercury, by distilling off the latter in a tube filled with the vapour of naphtha. The glass of the tube was acted upon, so that he was obliged at a certain period of the experiment to desist. Davy, however, obtained a Solid, having the same general metallic appearance as the Metals from the other earths had. " It sunk rapidly in water, though surrounded by globules of Gas, producing Magnesia, and quickly changed into a fine powder, which proved to be Magnesia." (a.)

In a subsequent experiment, potassium was passed over Magnesia at a high temperature, and quicksilver introduced into the tube while hot. Thus an amalgam was obtained, from which the potassium was abstracted by the action of water. Thus a solid white metallic mass was obtained, which, by exposure to the air, became covered with a white crust, and falling into a fine powder, which proved to be Magnesia." (b.)

With Magnesium, oxygen combines to form the earth under examination, in the following subsection; and it is supposed to combine also with chlorine, as will then be noticed. It seems to be beyond a doubt, that if obtained in sufficient quantity, it would be found to possess all the ordinary characteristic properties of the metallic bodies.

Subsect. 1.—Magnesia.

A. "About the beginning of the XVIIIth century, a Roman Canon exposed a white powder for sale at Rome, as a cure for all diseases. This powder he called Magnesia Alba. He kept the manner of preparing it a profound secret; but, in 1707, Valentine informed the public that it might be obtained by calcining the lixivium which remains after the preparation of nitre: (b.) and, two years afterwards, Slevogt discovered that it might be precipitated by potash from the mother-lye of nitre. This powder was very generally supposed to be lime, till F. Hoffman observed that it formed very different combinations with other bodies. (c.) But little was known concerning its nature, and it was even confounded with lime by most Chemists, till Dr. Black made his celebrated experiments upon it in 1755. Margraff published a dissertation upon it in 1759: (d.) and Bergman another in 1775, in which he collected the observations of these two Philosophers; and enriched them by adding many observations of his own. (e.) But since Geneva likewise published a valuable dissertation on it in 1779." (Thomson.)

Magnesia exists naturally as a constituent part of several minerals and rocks. It seems to communicate to all the steatite family their peculiar soapy feel. It forms a part of the saline ingredients of sea-water, and its sulphate forms the chief active principle of many of the natural saline springs, so much the resort of invalids.

B. Pure Magnesia may be obtained by dissolving sulphate of Magnesia in hot water, and then adding to the filtered solution, while yet hot, a solution of carbonate of potash or soda, as long as any precipitate appears. The process is aided by gently boiling the Liquid. Thus we obtain a pure carbonate of Magnesia, which may be decomposed by a red heat, leaving pure Magnesia: hence sometimes called Calcined Magnesia.

C. Magnesia is a white, light powder, soft to the touch, without smell, and possessing only a rather bitter taste. It slightly changes the vegetable blues to green. It is, perhaps, the most infusible of the earths. Dr. Clarke succeeded in melting it by the flame of the Gas blowpipe, though with difficulty. Pure Magnesia is only soluble in 1600 times its weight of water, according to Dalton. When precipitated it retains some portion of water by a feeble affinity, thus constituting a hydrate. There is also a native hydrate containing thirty per cent. of water.

D. None.

E. If Magnesia be heated in chlorine Gas, a decomposition takes place, oxygen is evolved, and chloride of Magnesium is formed. The chlorine absorbed is double the volume of the oxygen Gas evolved. When water is added to this compound, we have a well-known salt, which forms a part of the sea and many mineral waters. This salt, long called muriate of Magnesia, is, in fact, a hydrate of the chloride of Magnesium. It is a very deliquescent salt, soluble in twice its weight of alcohol, (0.917,) and in half its weight of water. When strongly heated, the water is dissipated, and in part decomposed. The hydrogen and chlorine escape, while the oxygen remains with the Metal to form Magnesia.

F. Unknown.

G. M. Gay Lussac formed the iodide of Magnesium, but its properties are little known.

H. With the exception of sulphur, it does not appear that any action takes place between the non-metallic electro-positive elements and Magnesia. Sulphur combines, but not very intimately, with Magnesia, when the former is fused in contact with it; or when the two are boiled together in water. Hydro sulphuric Acid Gas when passed through, which has Magnesia suspended in it, dissolves a small portion of the earth; but the properties of this compound are little understood.

I. With this class of bodies Magnesia has no action, save that which has been already mentioned under Magnesium. (526.)

J. With those metallic oxides that perform the part of bases, Magnesia has no action. With the Acids Magnesia readily combines as a base. Its Salts are in general of high solubility in water, and have for the most part a disagreeable, saline-bitter taste. They are crystallizable, but our space will not permit a description of them. The carbonate and sulphate are, however, too important to be altogether passed over in silence.

K. With those metallic oxides that perform the part of bases, Magnesia has no action. With the Acids Magnesia readily combines as a base. Its Salts are in general of high solubility in water, and have for the most part a disagreeable, saline-bitter taste. They are crystallizable, but our space will not permit a description of them. The carbonate and sulphate are, however, too important to be altogether passed over in silence.

L. The Carbonate of Magnesia, for medical use, is prepared as directed in Art. (528.) In this state it is a white powder, but having excess of base, so that it is not neutral. If, however, this powder be diffused through water, and a current of carbonic Acid Gas be passed through the Liquid, saturation is effected, and the powder is dissolved. The neutral salt thus formed, may be obtained by evaporation in the form of transparent hexagonal prisms with plane summits. The carbonate of Magnesia of commerce, consists of the first variety,
Chemistry, and is according to Thomson generally contaminated with some sulphate of lime.

(538.) Sulphate of Magnesia was originally procured by evaporating the mineral spring which rises at Epsom in Surrey; hence it acquired the name of Epsom Salt.

“Some account of it was published by Grew, in 1675; and, in 1723, Mr. Brown published a description of the process employed in extracting it from the mineral water, and in purifying it. (f.) In Italy it is manufactured from schistose minerals, containing sulphur and Magnesia.”

(540.) Magnesia is largely employed in Medicine. The sulphate in a copious quantity in sea-water; and the uncrystallized residuum in the salt pans after all the common salt is crystallized, consists partly of this salt dissolved in water. This residuum is usually called Bittern; and sometimes, in Scotland, Spirit of Salt.

In England that term is applied to hydrochloric Acid.

Sulphate of Magnesia is soluble in its own weight of water at 60° Fahrenheit; and a much less quantity if the water boils. When exposed to the air it is efflorescent; and by heat it is fusible; the water of crystallization is then gradually driven off, but the actual decomposition of the salt cannot be effected by any elevation of temperature. Thomson supposes the crystallized salt to contain seven atoms of water.

(539.) L. The most characteristic property by which the salts of Magnesia are recognised, is that by adding a solution of phosphate of soda; no precipitate is produced; but then if ammonia also be added, a white precipitate falls down, which is a double phosphate of ammonia and Magnesia. The delicacy of this test, which was pointed out by Dr. Wollaston, is so great, that an extremely minute portion of Magnesia may be detected by it.

If the experiment be made in a watch-glass, it is advisable to rub the point of a glass rod against the surface of the glass within the solution. This aids the deposition, and the precipitate appears in white lines wheresoever the rod has passed.

Sulphate of soda occasions no precipitate in a magnesian salt, but the alkalis, or their carbonates, produce a white flocculent precipitate.

Prussiate of potash throws down no precipitate from a solution of any salt of Magnesia; those excepted which are formed by the metallic Acids.

(540.) M. Magnesia is largely employed in Medicine. The sulphate in a copious quantity in sea-water; and the carbonate, or the pure earth, is used as a purgative and antacid.

METALS. CLASS II.

Sect. II.—Calcium.

(541.) A. This metal was one of the discoveries of Davy, made by means of the Voltaic battery.

(542.) B. It may be obtained by forming a paste of lime, or of sulphate of lime mixed with water into a cup, which is then to be placed on a metallic dish. Mercury is poured into the cup, and connected with the negative extremity of the pile; while, at the same time, the positive wire is made to touch the metallic dish. Thus in time an amalgam of mercury and Calcium is formed, and is to be put into a small retort, with a little naphtha to cover it. The retort is to be connected with a tubulated receiver loosely corked. By heat the naphtha rises in vapour so as to fill the vessels; the mercury next comes over; and the Calcium remains within an atmosphere of naphtha.

(543.) C. This Metal appears to have the colour and lustre of silver, but its other physical properties are unknown.

(544.) D. The instant that atmospheric air is admitted to Calcium, the Metal absorbs oxygen, and burns with an intense white light, again returning to the state of lime. Lime is the protoxide of Calcium. See sect. 1.

(545.) A superior oxide of Calcium is formed by passing oxygen Gas over ignited lime; the Gas is absorbed, and this oxide results, but its exact atomic constitution is unknown.

(546.) E. If lime be heated in chlorine Gas, one volume of chlorine is absorbed, and half a volume of oxygen being evolved, the chloride of Calcium is formed. It is also produced by fusing hydrochlorate of lime at a red heat. By addition of water the hydrochlorate is again formed.

(547.) F. The substance to be hereafter mentioned as fluate of lime, is by some Chemists supposed to be a true fluoride of Calcium.

(548.) G. Iodide of Calcium is formed by evaporating hydriodate of Calcium to dryness, and fusing the residuum.

(549.) H. The existence of compounds of sulphur and phosphorus with Calcium seems to be sufficiently well established. The phosphuret is formed by taking a glass tube, fourteen inches in length, and one-third of an inch in diameter, closed at one end, and well coated with clay, excepting an inch at the closed end. Into this is put a drachm or two of phosphorus: the tube is then filled with fragments of fresh burnt lime as large as peas: the mouth of the tube may be loosely stopped with paper, and its body passed through a table furnace, and heated to redness. A spirit-lamp is then applied to the sealed end, so as to fuse and volatilize the phosphorus. The vapour passing over the heated lime decomposes it, and a phosphuret of Calcium results. This substance was long called phosphuret of lime: it forms an amusing experiment by dropping a small piece of it into a glass of water. In a short time, bubbles of phosphuretted hydrogen Gas rise through the water and explode on reaching the surface.

The sulphuret of Calcium was formed by Berzelius, who passed a current of sulphuretted hydrogen over red-hot lime. The hydrogen of the Gas united with the oxygen of the lime to form water, and the sulphur united with the Calcium.

(550.) I. Calcium would doubtless unite with other Metals; but this and many other of its properties have as yet been little studied.

Subsect. 1.—Lime.

(551.) A. The nature of this, the protoxide of Calcium, has been already explained in Art. (542.) It does not exist pure in Nature, from its great affinity for water and carbonic Acid. But, in the state of a carbonate, it forms one of the most abundant and important substances in Nature. Whole mountains and vast tracts
The substances do not contain some Lime.

558. C. Lime is a white pulverulent earth, not fusible, save by the heat of the Voltaic pile, or of the gas blow-pipe. Specific Gravity = 2.3. It is not volatile. With water it presents several singular phenomena. If this fluid be sprinkled on fresh caustic Lime, great heat is produced and the water entirely disappears, entering into combination to form a solid hydrate of Lime. Mr. Dalton estimates the heat produced on such an occasion at 800°Fahrenheit. Pelletier even places that light is evolved, so as to be seen in a dark place. Lime absorbs moisture from the atmosphere and falls to powder. This earth is slightly soluble in water, perhaps to about the extent of 1-700th part; 1-752d according to a careful experiment made by Mr. R. Phillips. Mr. Dalton has shown that in the case of Lime, cold water is capable of taking up more than hot water, as seen by the following Table:

<table>
<thead>
<tr>
<th>Grains of water to dissolve one grain of Lime:</th>
<th>778</th>
<th>972</th>
<th>1270</th>
</tr>
</thead>
<tbody>
<tr>
<td>Grains of water to dissolve one grain of hydrate of ditto:</td>
<td>554</td>
<td>720</td>
<td>952</td>
</tr>
</tbody>
</table>

Lime-water possesses alkaline properties. When exposed to the air, the Lime unites with carbonic Acid and is precipitated. Gay Lussac, however, procured crystals of pure Lime, by placing a vessel of Lime-water with sulphuric Acid under an exhausted receiver. The crystals contained one atom of Lime + one atom of water. (a.)

554. D. None.

555. E. The combination of chlorine with Lime is one of great importance from its extensive application in the process of bleaching. If slaked Lime (the prot-hydrate) be passed through a sieve in the state of fine powder, and then placed in contact with chlorine Gas, the Gas is absorbed with great avidity, much heat being evolved. When the Lime has taken up all the chlorine that it is capable of, it appears a dry white powder, known in commerce by the name of bleaching powder, or oxymuriate of Lime.

It consists, in fact, of Lime, chlorine, and water; and probably in the proportions of 1, 2, and 6 atoms of these elements. This powder is, in fact, a subchloride of hydrate of Lime. Dr. Thomson calls it dichloride of Lime, but no one name has met with universal adoption. This substance is soluble in water to a considerable extent. By heat it is decomposed; the water first passing off; then decomposition of the Lime takes place, oxygen Gas is evolved, and chloride of calcium is formed. The purity of this substance being of great importance, has engaged the attention of our most eminent Chemists, as will be seen from the reference. (b.)

556. F. G. Unknown or not existent.

557. H. With some of these substances Lime may be united, but the combinations are not of general importance.

558. I. It is scarcely probable that any combination with these substances can be effected.

559. K. The Salts of Lime are numerous and important. Of these we can only name the sulphate, phosphate, and carbonate.

The sulphate is rapidly formed by art, and exists abundantly in Nature, known by the name of gypsum or plaster of Paris. By calcination it loses water, and the reabsorption, or addition of that Liquid, enables it to form an useful and cheap cement, or to take casts of gems and metals.

The phosphate forms to the amount of eighty-six per cent. of the bones of animals. The bisphosphate, ter-phosphate, and quater-phosphate of Lime also exist, but Mr. Dalton considers the last an octo-phosphate.

The carbonate is the most abundant of the Salts of Lime. As chalk, limestone, and marble it must be familiar to every one. Although the affinity of carbonic Acid for Lime is very great, the substances do not readily combine, unless moisture be present. By a red heat the carbonic Acid is driven off from this salt in the Gaseous state; but if the escape of the Gas be prevented, Sir James Hall found that the limestone was fused by a heat of about 22° of Wedgewood's pyrometer. (c.)

This salt contains one atom of each of its proximate elements. A very elegant experiment by the late Professor Tenant of Cambridge, (d.) exhibits its ultimate decomposition. Carbonate of Lime is soluble in water, having an excess of carbonic Acid; hence arises the extensive calcareous deposit from the water of some springs. In these cases there exists in the water, carbonate of Lime dissolved in excess of carbonic Acid; by exposure to the atmosphere, the excess of carbonic Acid escapes, and the earthy salt is deposited.

560. L. Some of the Salts of Lime are soluble in water, others are not so. In such solutions no precipitate is produced by addition of pure ammonia; but potash and soda throw down caustic Lime. Upon solutions of Lime, the citrate or tartrate of ammonia produces no effect; but oxalate of ammonia exhibits a dense white precipitation. If an insoluble salt of Lime be boiled for some time in a solution of carbonate of potash, a white powder remains, consisting of carbonate of Lime, soluble with effervescence in nitric or muriatic Acid.

561. M. The uses of Lime are very various and important. The nitrate, when fused, forms Baldens' phosphorus. (d) The chloride mentioned in Art. (555.) is now sold, when formed into an aqueous solution, under the name of Labaraq's Disinfecting Liquid; and
CHEMISTRY.

37—properties of chlorine for removing dangerous or disagreeable miasmas, in fever hospitals, or the chambers of the sick.

The use of gypsum in taking casts, and as a cement for marble or stone, has been already noticed. Caustic Lime is of great service in Agriculture when spread upon some kinds of land, as it ameliorates the stiff clays, and powerfully assists the solution of vegetable matters to form the food of growing plants. The formation of mortar from caustic, or quick Lime as it is called, for building, must be within the observation of every one. The mode of its operation is this. When fresh burned Lime is mixed with water, a paste is first formed, but, in a short time, the fluidity entirely disappears, by the passage of the water into the solid form to constitute dry hydrate of Lime. Some combination of carbonic Acid also takes place, but this is for the most part superficial. Lime made from the chalk or limestone of different strata, varies considerably in goodness. Such variations depend on the admixture of small proportions of certain other earths and oxides. The Roman cement, as it is called, contains a proportion of aluminas and oxide of iron. On the subject of mortar there is a valuable Work by M. Vicat, in French.

References to § 1.

(a) Gay Lussac, An. de Ch. et Ph. vol. i. p. 334.

Sect. II.—Strontium.

(562.) Strontium was first obtained by Sir H. Davy. Native carbonate of strontia was formed into a paste with water, and placed on a small platinum tray. A globule of mercury was then placed within a cavity made in the surface of the paste. The platinum was connected with the positive pole, and the mercury with the negative pole of a pile of about 100 double plates. Thus an amalgam of mercury and Strontium was shortly produced The amalgam was introduced into a tube of glass made without lead, which was then filled with the vapour of naphtha, bent into the form of a retort, hermetically sealed. The mercury was then driven from the amalgam by heat, and the Strontium remained.

The lustre of Strontium is not considerable; it is difficult of fusion, and not volatile. It decomposes water with evolution of hydrogen Gas; and if exposed to atmospheric air, it again becomes strontia. This earth is then proved to be the oxide of Strontium; its properties will more fully be stated in the ensuing subsection.

Subsect. I.—Strontia.

(563.) A. About the year 1787, a mineral was brought to Edinburgh by a dealer in fossils, from the lead mine of Strontian in Argyleshire, where it is found imbedded in the ore, mixed with several other substances. It is sometimes transparent and colourless, but generally has a tinge of yellow or green. It is soft. Its Specific Gravity varies from 3.4 to 3.726. Its texture is generally fibrous; and sometimes it is found crystallized in slender prismatic columns of various lengths.

"This mineral was generally considered as a carbonate of barytes; but Dr. Crawford having observed some differences between its solution in muriatic Acid, and that of barytes, mentioned in his Treatise on Muriate of Barytes, published in 1790, that it probably contained a new earth, and sent a specimen to Mr. Kirwan that he might examine its properties. Dr. Hope made a set of experiments on it in 1791, which were read to the Royal Society of Edinburgh in 1793, and published in the Transactions about the beginning of 1794. These experiments demonstrate, that the mineral is a compound of carbonic Acid and a peculiar earth, whose properties are described. To this earth Dr. Hope gave the name of Strontites. (a.) Klaproth analyzed it also in 1793, and drew the same conclusions as Dr. Hope, though he was ignorant of the experiments of the latter, which remained still unpublished. Klaproth's experiments were published in Crelle's Annals for 1793 (b.) and 1794. (c.) Kirwan also discovered the more interesting particulars of this new earth in 1793, as appears by his letter to Crel, though his dissertation on it, which was read to the Irish Academy in 1794, was not published till 1795. The experiments of these Philosophers were repeated and confirmed in 1797 by Pelletier, Fourcroy, and Vauquelin, (d.) and several of the properties of the earth still further investigated. To the earth thus detected, Klaproth gave the name of Strontian from the place where it was first found; and this name, with the omission of the final n, "is now generally adopted. Strontia is found abundantly in different parts of the World, and always combined with carbonic or sulphuric Acid." Thomson's Syst.

(564.) B. Pure Strontia is readily obtained by dissolving the native carbonate in nitric Acid, evaporating the solution till it crystallizes, selecting pure crystals, and driving off the nitric Acid by heat in a platinum crucible. Strontia contains strontium one atom + oxygen one atom.

(565.) C. Strontia thus obtained is a grey, pulverulent mass, having a violent affinity for water. By affusion of this Liquid, heat is evolved, and so much earth is dissolved that crystals separate on cooling. Dalton considers that these crystals contain twelve atoms of water + one Strontia. Strontia has alkaline properties but, unlike barytes, it is not poisonous. (e.) The crystals of Strontia, when dissolved in alcohol, cause it to burn with a bright red flame.

(566.) D. By pouring an aqueous solution of Strontia into the deutoxide of hydrogen, a deutoxide of Strontia is formed.

(567.) E. If Strontia be heated in chlorine Gas, oxygen Gas is expelled, and a chloride of strontium is formed. The same takes place if hydrochlorate of Strontia be heated to redness.

(568.) F. G. Unknown, save that iodine decomposes Strontia, as chlorine does.

(569.) H. Action none very important, save that some of these bodies by aid of heat decompose the earth, and form sulphurets, phosphurets, &c. with its metallic base.
Chemistry.

(570.) I. Not considerable.

(571.) K. Strontia never performs the part of an Acid; but with Acids it universally acts as a base. Its Salts are more soluble than those of baryta, but less so than those of lime. The greater part are capable of crystallization.

(572.) L. A solution of these Salts affords precipitates with the sulphates, phosphates, and oxalates; but not with ferro-hydrocyanate of potassa. Succinate of ammonia gives a precipitate in solutions of baryta salts, but none in those of Strontia. The colour of its flame in alcohol forms also a good test.

(573.) M. None, save to give colour in pyrotechnics. Strontia is not poisonous.

References to § 2.

Sect. III.—Baryum.

(574.) Such should be the spelling of this word, derived from Bap. (heavy), though we have at times inadvertently spelled it Barium, as is frequently done. This Metal was obtained by Davy in 1808, from the carbonate of baryta, by a process which we have already described in Art. (562.) with reference to strontium. The Metal has a dark grey colour, with a lustre inferior to that of cast iron. It is fused at a heat below redness; though solid at all ordinary temperatures. It did not rise in vapour till nearly a red heat, and then acted violently on the glass of the tube which contained it. By admission of atmospheric air or oxygen, it is converted into the earth baryta. (See subsect. 1.) It has been proved by Gay Lussac and Thenard to be capable also of uniting with an additional proportion of oxygen, so as to form a deutoxide, by passing oxygen over pure baryta at a red heat. (g.) In the very curious experiments made with the Gas blow-pipe, by Professor Edward Daniel Clarke of Cambridge, he frequently reduced pure baryta earth to an appearance which himself and many Chemists regarded as the Metal Baryum. The quantities, however, so obtained were very small, and apparently superficial; insomuch that, beyond the appearance, no fully conclusive evidence of the reduction was afforded.

Subsect. I.—Baryta.

(575.) A. "Barytes was discovered by Scheele in 1774; and the first account of its properties published by him in his Dissertation on manganese. (a.) There is a very heavy mineral most frequently of a flesh-colour, of a foliated texture and brittle, very common in Britain, and most other Countries, especially in copper-mines. It was known by the name of ponderous spar, and was supposed to be a compound of sulphuric Acid and lime. Gahn analyzed this mineral in 1775, and discovered that it is composed of sulphuric Acid and the new earth discovered by Scheele. (b.) Scheele published an account of the method of obtaining this earth from ponderous spar. (c.) The experiments of these Chemists were confirmed by Bergman, (d.) who gave it the earth the name of terra ponderosa. Moreau gave it the name of Barote, and Kirwan of Barytes; which last was approved of by Bergman, and is now" (with little change) "universally adopted. Different processes for obtaining Barytes were published by Scheele, Bergman, Weigleb, and Azelius; but little addition was made to the properties ascertained by the original discoverer, till Dr. Hope published his experiments in 1793. (c.) In 1797, our knowledge of its nature was still further extended by the experiments of Pelletier, Fourcroy, and Vauquelin." (f.) Thomson's System.

(576.) B. Pure Baryta is best obtained by dissolving the native carbonate in diluted nitric Acid. This solution is to be evaporated so as to obtain crystals of the nitrate. These are decomposed by a red heat, leaving pure barytic earth. The atomic constitution of this oxide will be seen from the general Table in Part V.; and it may be well here to state, that from a wish to economize space, many statements of the same nature are not made under this reference, as they will all be found in the above-named Table.

(577.) C. Pure Baryta has a caustic taste; changes vegetable bluses to green; and is capable of forming a soap with oils. As generally seen, it is fusible by a moderate heat, being a hydrate; but when obtained pure from the nitrate, it is so only under the most intense heat of furnaces or the Gas blow-pipe. Pure caustic Baryta is slaked by water, forming a hydrate with evolution of very great heat. If a solution of this earth be made in boiling water, and then allowed to cool slowly, regular crystals are produced. These contain Baryta one atom + water twenty atoms, according to Mr. Dalton.

(578.) D. When pure Baryta is heated to redness in oxygen Gas, a deutoxide of baryum is formed.

(579.) E. If pure Baryta be heated in chlorine Gas, a chloride of baryum is formed with evolution of half a volume of oxygen Gas for every volume of chlorine taken up. A similar substance is produced by heating hydrochlorate of Baryta to redness.

(580.) F. Unknown.

(581.) G. If the hydroiodate of Baryta be heated to redness, an iodide of baryum is produced.

(582.) H. No combination is known, or very probable, between Baryta and these substances, but in some cases, Baryta, if heated with them, produces such union with its metallic base.

(583.) I. It is not probable that the Metals can combine with Baryta, neither has it been found that even those which have the most powerful affinity for oxygen decompose it.

(584.) K. With Acids, Baryta combines as a base, forming an extensive class of Salts. Its sulphate and carbonate exist naturally among mineral bodies. The Salts of Barytes have, generally speaking, less tendency to dissolve in water than the Salts of lime have. The affinity between sulphuric Acid and Baryta, is extremely powerful, but the sulphate is decomposed by boiling it with solutions of the alkaline carbonates, or by fusion with them; but the former process is attended with some singularities. This Salt is also decomposed by heating it strongly with one-sixth of its weight of powdered charcoal. With phosphoric Acid, Baryta forms a phosphoate and a biphasphate. For a good detailed description of the Barytic Salts, we must refer our readers to Thomson's System, vol. ii. p. 497.
CHEMISTRY.

(585.) L. The properties by which solutions of Baryta are recognised, are chiefly these. A solution of any sulphate produces a white precipitate insoluble in nitric Acid. Heat applied to one of its crystalline Salts, converts it into a carbonate, if the Acid be of a vegetable nature, but produces no change if the Acid be incombustible; or converts an hydrochlorate or iodate into a chloride or iodide of the metallic base. Prussiate of potash produces no precipitate in a Salt of Barytes, unless the Acid be one of the metallic class.

(586.) M. Baryta, or its Salts, may be considered at present useless, either in Medicine or in the Arts. Its action is, however, most powerful on the animal economy, as it is one of the most virulent poisons known.

Sect. IV.—Lithium.

(587.) This Metal was obtained by Sir H. Davy, and subsequently by Gmelin, from the newly discovered alkali, Lithia. (See subsect. 1.) It has never yet been seen in any considerable mass, partly from its rarity, and partly from the very great rapidity with which it returns to an oxidised state as fast as it is formed by the action of the pile.

Subsect. 1.—Lithia.

(588.) A. This alkali was discovered in 1818, by M. Arfwedson, a Swedish Chemist, engaged in the analysis of petalite, a mineral from the mine of Uto in Sweden. It has been subsequently discovered in spodumene, lepidolite, and in several sorts of mica. Its name, Lithia, is derived from Lithos, (stony,) marking its origin as distinguished from that of the other two fixed alkalis, potash and soda.

(589.) B. Berzelius has suggested the nearest process for the separation of Lithium from earthy minerals. One part of the mineral finely powdered is to be intimately mixed with powdered fluorspar, and this mixture heated with three or four times its weight of sulphuric Acid, as long as any acid vapours are discerned. Thus the silica unites with fluoric Acid, and passes off in the state of silico-fluoric Acid Gas, whilst the alumina and Lithia unite with the sulphuric Acid. These Salts are to be dissolved in water, and then pure ammonia is to be added, and boiled in the solution to precipitate the alumina. The Liquid is to be filtered and evaporated to dryness, and then the sulphate of ammonia may be expelled by a red heat. Sulphate of Lithia remains. This alkali is supposed to contain one atom of oxygen + one atom of Lithium.

(590.) C. Lithia has a white colour; is fused by a red heat, and in that state is transparent; it changes vegetable blues to green. It is not deliquescent when exposed to the air; is not so soluble in water as potassa or soda; and scarcely at all soluble in alcohol.

(591.) D. Unexamined.

(592.) E. Chloride of Lithium is formed when hydrochlorate of Lithia is heated to redness, and is a very deliquescent substance, and readily soluble in alcohol.

(593.) F. G. Unascertained.

(594.) H. Sulphur may be combined with Lithia, as with potassa and soda.

(595.) I. It would seem that Lithia is not entirely without action on the Metals, seeing that it corrodes a platinum crucible in which it may be heated.

(596.) K. With Acids, Lithia forms Salts like the other alkalis: but these have as yet been little examined. Its saturating power is higher than that of either potassa or soda. The Salts of Lithia are soluble in water, but the carbonate much less so than the other alkaline carbonates.

(597.) L. Hydrochlorate of platinum, ferro-hydrocyanate of potassa, and infusion of galls, produce no precipitate in Salts of Lithia. But a solution of carbonate of potash, added to a concentrated solution of a Salt of Lithia, produces a white precipitate. The phosphate of Lithia is also rather an insoluble Salt, in which respect it is distinguished from potassa and soda.

(598.) M. None at present known.

References to § 4.

Sect. V.—Sodium.

(599.) This Metal was discovered by Sir H. Davy in 1807; and his experiments were detailed in the Philosophical Transactions of 1808. He found that if pure caustic soda, a substance to be described in the following subsection, were just moistened by merely breathing on it, and placed on a disc of platinum; the disc being connected with the negative pole of a powerful Voltaic battery, and a wire from the positive pole being brought in contact with the upper surface of the soda; decomposition gradually took place; Oxygen Gas was evolved at the positive wire, and globules of metallic Sodium appeared at the parts in contact with the platinum. (a.) MM. Gay Lussae and Thenard subsequently discovered a process more purely Chemical, by which this alkali might be obtained (b.) in greater quantity. This is performed by heating soda and iron turnings to whiteness in a coated gun-barrel. The process has been slightly modified and improved by others, and full instructions may be obtained by consulting the Memoirs quoted in reference (c.)

(600.) Sodium at our ordinary temperatures is an opaque, metallic-looking Solid, having the lustre and nearly the whiteness of silver; but it is necessary to examine it when covered with a film of naphtha for the exclusion of atmospheric air. It is extremely malleable and ductile. It is lighter than water, having a Specific Gravity about .97. It is less fusible than potassium, but begins to lose its solid form at 120° Fahrenheit, and becomes fluid at 180° or 190°. It is not volatile even at the fusing heat of plate-glass. On being exposed to atmospheric air it soon unites with oxygen, and its surface becomes a stratum of soda; but in perfectly dry air it remains unchanged. It combines with oxygen Gas at ordinary temperatures slowly, and without ignition; at its fusing point the action is more energetic,
but light is not evolved, unless the metal itself be about
red-hot. It decomposes water with effervescence and
a hissing noise. In hot water this action is still more
violent, but no flame is produced except from small
particles, which may be driven off and ignited in their
passage through the air.

Two or more oxides of this metal are at present
admitted by some. The first formed by fusing soda
and sodium together; in which case the oxygen seems
to be shared between all the atoms of sodium, and
from this very circumstance it seems doubtful whether
the grey substance so produced be a true definite
compound or not. The next oxide, soda, is formed when
sodium is burned, a volume of air affording just oxygen
enough to convert the metal into an alkali. This seems
to contain one atom of each of its elements; and in
the state we usually possess it, there is also an atom of
water which it retains with great obstinacy. But if the
metal be burned in excess of oxygen, another oxide is
formed which appears to contain sodium two atoms+
oxgen three atoms. This substance is very fusible,
and of a deep orange colour. When placed in water the
excess of oxygen separates, and a solution of soda
remains.

(601.) The chloride of sodium is formed by burning
the metal in chlorine gas; or by heating it in hydro-
chloric acid gas, in which case the hydrogen is set at
liberty;—or by evaporating a solution of common salt,
which in its crystalline form is a pure chloride of sodium,
having only a little water mechanically existent among
its molecules. But when this substance (which is
times called a salt inadvertently) exists dissolved
in water, it is generally believed to be a hydrochlorate
of soda; and then is truly a salt.

The chloride of sodium, a most important and
abundant substance, crystallizes in regular cubes: its
varieties have been ably described by Dr. Henry. (d.)
By heat it decrepitates, and then fuses into a solid
mass. It dissolves in two and a half times its weight
of water at 60° Fahrenheit, and hot water takes up very
little more. Hence, as Dr. Henry well remarks, its
solution crystallizes, not like that of niter by cooling,
but by evaporation. (e.)

(602.) Iodide of sodium may probably be formed by
a direct process, but it is certainly obtained by applying
heat to the hydroiodate of soda.

(603.) By heating sodium in ammoniacal gas, the
hydrogen is disengaged, and an iodide of nitrogen is
formed. It unites also with sulphur, selenium, and
phosphorus; but not with hydrogen.

(604.) Sodium may form alloys with all the metals.
Its reagent action and useful applications, can only
be sought for among the description of its oxides and
salts; save that the chloride (common salt) is a whole-
some condiment to food, and a powerful antiseptic.

Subsect. 1.—Soda.

(605.) A. "Soda, called also fossil or mineral
alkali; because it was thought peculiar to the mineral
kingdom, was known to the ancients (though not in a
state of purity) under the names of νεροφ, and nitrum.
It is found in large quantities combined with carbonic
acid, in different parts of the earth, especially in Egypt.
But the soda of commerce is obtained from the ashes
of different species of the salsola, a genus of plants
growing on the sea-shore; especially from the sal-
sola soda, from which the alkali has obtained its
name. The soda of commerce is also called barilla,
because the plant from which it is obtained bears that
name in Spain. Almost all the algae also, especially
the fucii, contain a considerable quantity of soda. The
ashes of these plants are known in this country by
the name of kelp, in France by that of varée.

"Soda and potash resemble each other so nearly,
that they were confounded together, till Du Hamel
published his dissertation on common salt, in the
Memoirs of the French Academy for 1736. He first
proved that the base of common salt is soda, and that
soda is different from potash. His conclusions were
objected to by Pott, but finally confirmed by Margraff
in 1758. Thomson's system.

(606.) B. It would occupy more space than we can
here afford, to describe fully the processes for obtaining
pure soda from barilla; but an excellent abstract is
given in Thomson's system, vol. i. p. 326. The general
features of it, however, may be collected from the pro-
cess for potassa. (Art. 626.)

(607.) C. Soda when pure is a greyish white mass;
highly attractive of moisture, and sufficiently caustic to
corrode and dissolve the skin, or other animal matters.
By exposure to air, however, it does not deliquece like
potassa, but absorbing water and carbonic acid, it
crumbles into a white powder.

(608.) D. None. E. See Art. (601.) F. Unknown.
G. Unknown.

(609.) H. More remains to be discovered respecting
the combinations of soda with some of these bodies;
that with sulphur has been examined, but its real
nature is not very manifest. (c.)

(610.) I. Unimportant, though not absolutely non-
existent.

(611.) K. The salts containing soda as a base are
numerous and important. The carbonate, bicarbon-
ate, borate, (borax,) phosphate, and sulphate, are em-
ployed in medicine and the useful arts.

(612.) L. The solutions of salts of soda may be
recognised by the following properties; they are all
soluble in water, and in a higher degree than those of
potassa. Their base is not precipitated by any reagent
whatever. The form of the crystals will serve to dis-
tinguish them from those of a salt of potassa. This is
especially remarkable in the sulphate. By fusion in
platinum-wire with the blow-pipe, a rich yellow colour
is communicated to the flame.

(613.) M. Soda is largely employed in the very im-
portant arts of soap-boiling and glass-making.

Sect. VI.—Potassium.

(614.) A. This metal was discovered by sir H.
Davy in 1807, and from its nature can only exist under
peculiar artificial circumstances, or in combination with
other elements.
B. To the process by which Potassium was obtained we have already adverted in the mention made of Sodium; (599.) for the same measures must be taken in procuring both Metals. As before, we must on this point refer our readers to the more ample details of original Memoirs. (a.)

C. At about 32° Fahrenheit it is hard and brittle, exhibiting a crystalline structure. At about 50° Fahrenheit it is a soft malleable solid, having the lustre of polished silver. At 70° Fahrenheit it is a semi-fluid substance, having in small globules a resemblance to mercury; but at 150° Fahrenheit it becomes quite fluid. At a heat about redness it may be volatilized unchanged. It is a conductor of heat and electricity. Its Specific Gravity has been variously stated from .8 to .9 referred to water as unity.

D. Potassium unites with oxygen, even though the Gas be dry, at ordinary temperatures; but by the aid of heat it burns therein with brilliancy. When the Metal is brought in contact with water, a violent action ensues; the water is decomposed with evolution of flame, and the protoxide of Potassium remains in solution. This protoxide is potassa. (See sect. 1.) But when Potassium is burned in the open air, or in oxygen Gas, it is converted into an orange-coloured substance, which is a superior oxide of the Metal. This is by some called the peroxide; we venture, in adherence to our system, to call it the trioxide, to mark that it contains oxygen three atoms + Potassium one atom. The same substance is formed by passing oxygen Gas over potassa at a red heat. Potassa has a very strong affinity for water, so that even fused caustic potassa is a hydrate, containing potassa one atom + water one atom. But anhydrous potassa may be obtained by fusing nitrate of potassa in a crucible of gold. Mr. Dalton has given a Table showing the proportion of real alkali in solutions of potassa of different Specific Gravities. (b.)

E. If Potassium be heated in chlorine Gas, its combustion is more vivid than in oxygen; and a chloride of the Metal is formed. The same substance results from heating to redness hydrochlorate of potassa formed by dissolving carbonate of potassa in hydrochloric Acid; the hydrogen of the Acid uniting with the oxygen of the potassa to form water, which is dissipated by the heat.

F. Uncertained.

G. Iodide of Potassium may be formed by heating Potassium with iodine in a green glass tube. Light is evolved during the combination. This iodide is volatilized by heat; and by solution in water its elements take to themselves hydrogen and oxygen respectively from the water, and a solution of hydriodate of potash results.

H. With hydrogen, Potassium forms two compounds, the one gaseous, the other solid. The former is produced simply by heating Potassium in hydrogen Gas. The latter by a similar process, but at a very moderate heat. Potassium unites also with sulphur, selenious, and phosphorus.

I. Potassium has a great tendency to unite with many of the other Metals, especially with mercury; and the amalgam so formed is capable of dissolving all other metallic bodies.

J. In consequence of the strong affinity which this Metal bears for oxygen, it reduces the oxides of all other Metals when heated with them. When added to the mineral acids, Potassium decomposes water, becomes oxidized, and a salt of potassa remains in the solution.

L. M. All action to which this head refers, will more properly appear in the corresponding part of the subsection on potassa.

Subsect. 1.—Potassa.

A. "If a sufficient quantity of wood be burned to ashes, and these ashes be afterwards washed repeatedly with water till it come off free from any taste, and if this Liquid be filtered and evaporated to dryness, the substance which remains behind is Potash: not, however, in a state of purity, for it is contaminated with several other substances, but sufficiently pure to exhibit many of its properties. In this state it occurs in Commerce under the name of Potash. When heated to redness many of its impurities are burned off; it becomes much whiter than before; and is then known in Commerce by the name of Pearlash. Still, however, it is contaminated with many foreign bodies, and is itself combined with carbo-acid Gas, which greatly modifies its properties.

That Potash was known to the ancient Gauls and Germans cannot be doubted, as they were the inventors of soap, which Pliny informs us they composed of ashes and tallow. These ashes (for he mentions the ashes of the beech-tree particularly) were nothing else but Potash: not, however, in a state of purity. (c.) The novia, too, mentioned by Aristophanes and Plato, appears to have been a lie made of the same kind of ashes. The Alchemists were well acquainted with it; and it has been in every period very much employed in Chemical researches. It may be said, however, with justice, that till Berthollet published his process in the year 1786, Chemists had never examined Potash in a state of complete purity." Thomson's System, vol. i. p. 328.

Besides forming a part of many vegetable substances, Potassa is found in several animal fluids. Also in some minerals, as the leucite, lava, pumice, and felspar and zeolites, sometimes to the amount of eighteen per cent.

B. To obtain pure Potassa, take pearlash and dissolve it in twice its weight of hot water. To the solution add an equal weight of fresh-burned quicklime, slaked, and then formed into a cream with water. Boil these together in an iron kettle, for half an hour, continually stirring. Then filter out, or pour off the clear alkaline solution, and evaporate it to dryness in a silver capsule. Put the dry mass into a bottle, and add pure alcohol so as to dissolve out as much alkali as possible. Then separate again the alcohol by distilling it over from the Potassa in a silver alembic with a glass head. Pour the fused residuum upon a silver capsule, and as soon as it is cool enough, let the cake be broken up and kept in well-closed phials. Potassa thus prepared is still a hydride containing alkali one atom + water one atom.

C. Pure Potassa is a white, solid substance, highly caustic, fusible by a heat rather above redness, but not volatile. The solid hydrate has its apparent properties greatly similar. When quite dry it is a non-conductor of electricity.

D. If oxygen Gas be passed over Potassa in a closed tube at a red heat, an additional proportion of that element enters into combination, and the tritoxide
METALS. CLASS III.

Sect. I.—Manganese.

(637.) A. The most abundant ore of Manganese, the black oxide, has long been known; and very soon after the study of minerals assumed a scientific form, it was seen that a heavy, black, earthy substance, which had formerly been classed with iron-ores, must be separated from that genus. After several dissertations on this mineral, Bergman suspected it to be the oxide of a peculiar Metal, and at his desire Scheele undertook the examination of the substance, and by his Essay, published in 1774, and Bergman's of the same period, the metallic nature of its basis was established. This oxide is abundantly found in Devonshire and other parts of England; its other ores are the sulphuret, and a phosphate, wherein it is combined with iron, but these are rare.

(638.) B. From the great tendency of this oxide to vitrification, fluxes must not be employed for its reduction, an operation of great difficulty in consequence of the strong affinity of Manganese for oxygen. The only process by which the Metal has been obtained, is to submit oxide of Manganese, mingled with charcoal powder and a little oil, to a most intense heat in a wind furnace. The Metal is fused in small globules, or in an imperfect button at the bottom of the crucible.

(639.) C. Manganese is of a greyish colour, and finely granular texture; softer than cast iron; Specific Gravity 8.013. (John.) It is very brittle, and of different fusibility. According to Morveau it melts at 160° Wedgewood, or at a point somewhat above iron.

(640.) D. Pure Manganese, being exposed to the air, gradually oxidizes and crumbles into powder. If heated in oxygen Gas it undergoes combustion, and decomposes the vapour of water at a red heat. Perhaps there are few subjects of greater difficulty than the determination of the number of oxides which this Metal produces. We have on this subject valuable observations by Sir H. Davy, Chem. Phil. p. 387; John, An. Phil. vol. iii.; Berzelius, An. de Ch. vol. lxxxiii. and lxxxvii.; Arfvedson, An. de Ch. et de Ph. vol. vi.; Davy admits only two oxides, John three, Berzelius five, which number he has subsequently reduced to four; (An. Phil. vol. iii.) and according to Chevillot and Edwards, there is another degree of oxidation still higher than the peroxide of all former Chemists, and possessed of acid properties. (An. de Ch. et de Ph. vol. viii.) Thenard is inclined to admit four oxides including the one last mentioned, which exists in the chameleon mineral. In this state of uncertainty it is impossible in a sketch like the present to give even an outline of the processes or reasonings of these Chemists, we therefore must confine ourselves to the two oxides the existence of which is well established. The first is precipitated from the Salts of Manganese, in the state of a white hydrate, containing, according to Davy, about twenty-four per cent of water; when this water is driven off by a red heat the oxide assumes an olive-green colour.

The native black oxide, hitherto called the peroxide, which must be abandoned, should Chevillot and Edwards's experiments be verified, is familiar to every tyro in Chemistry, as the substance from which oxygen
CHEMISTRY.

Chemistry, as principally procured. It is formed gradually by exposure of the olive 9 to the action of the air.

(641.) E. If metallic Manganese be exposed to heat in chlorine Gas their union is immediately effected, and light and heat are evolved. This chlorine is a light, pink-coloured, flaky substance, and is obtained also by submitting hydrochloride of Manganese to heat.

(642.) F. G. Unexamined.

H. Boron and silicon have not been united to Manganese. The phosphuret is easily obtained; a coloured, flaky substance, and is obtained also by submitting a native compound of the same elements. With nitrogen it constitutes a peculiar substance filling small cavities in cast iron, and known in the foundries by the name of kreach.

Bergman was able only to form a sulphuret of Manganese; but Vauquelin (An. de Mus. vol. xviii.) obtained the true sulphuret; and Proust has described a native compound of the same elements. With nitrogen and hydrogen no combination has been formed.

(614.) I. Many of the probable alloys of Manganese have not yet been examined. It has, however, been united with most of the elements, viz., tin, zinc, gold, and arsenic. It refuses to combine with silver, mercury, or lead.

(615.) K. Until the number and composition of the oxides of Manganese shall be finally settled, our knowledge of the Salts of Manganese must remain in a state of great imperfection. It has been the opinion of Chemists that all the Salts which contain Manganese as a base, contain the green oxide; recent experiments, however, seem to prove that this is not the case; but it frequently happens that in processes wherein the solution of the black oxide is effected, certain phenomena occur which prove that the Metal, as it dissolves, is reduced to a lower degree of oxidation.

Nitric Acid dissolves Manganese with evolution of nitric oxide Gas. But on the black oxide, its action is extremely feeble. If, however, sugar, or any substance absorbing carbon, be added, solution takes place with evolution of carbonic Acid Gas; thus the excess of oxygen is disposed of, and a Salt containing the green oxide is formed. Nitrous Acid acts more readily, because the oxygen which the Metal loses, goes to form nitric Acid, and the same Salt is produced as in the former case.

Potassium. Sulphuric Acid has but little action on Manganese, but this Salt is readily formed by dissolving the carbonate in sulphuric Acid. It crystallizes in rhomboidal prisms which are soluble in alcohol.

Some other sulphates are mentioned by Arfwedson: one has been long known to be obtained by distilling sulphuric Acid off black oxide of Manganese, and lixiviating the residuum; the oxide contained in this reddish-coloured solution of the Salt is not well ascertained.

Scheele, by dissolving peroxide of Manganese in sulphuric Acid, found that some oxygen quitted the Metal and, uniting to the Acid, converted it into the sulphuric, and thus the protosulphate was formed. The true sulphate has not been obtained.

The hyposulphite remains in solution when hyposulphite of lime is precipitated by sulphate of Manganese.

The hyposulphate is an exceedingly soluble Salt, remaining in solution after the sulphate has been obtained by evaporation from the Liquid wherein sulphuric Acid has acted upon oxide of Manganese.

Hydrochloric Acid dissolves Manganese with evolution of hydrogen Gas; with the green oxide no Gas is evolved, but by its action upon the black oxide, chlorine is evolved. A solution thus formed contains hydrochlorate of Manganese, and this, by a proper heat, may be brought to the state of a chlorate of the Metal.

Carbonate. A white powder precipitated from solutions of Manganese, by the addition of carbonate of potash.

Phosphate. This Salt occurs native, and, being scarcely soluble in water, is readily obtained artificially, by adding any alkaline phosphate to a solution of Manganese.

Seleniate. A soft, white, insoluble powder, fusible, and having the power of corroding glass. The biselenate is soluble in water and crystallizable.

Arseniate. Formed by dissolving protoxide of Manganese in arsenic Acid. The Salt separates in a crystalline form. The addition of an alkaline arseniate to a solution of the Metal, produces the same effect. A double Salt may be formed by dissolving these crystals in sulphuric Acid. (John, Gehl. Jour. vol. iv. p. 448.)

Antimoniate. A white, insoluble powder, produced by adding an alkaline antimoniate to a neutral solution of Manganese. (Berzelius, Nich. Jour. vol. xxxv.)

Chromate. Chronic Acid acts slightly on Manganese, but this Salt is best obtained by dissolving the metallic carbonate in the Acid. A brown solution is formed which is not capable of crystallization. (John.)

Tungstate. This Salt is an insoluble, infusible, white powder, formed by adding tungstate of potash to a solution of Manganese. (John.)

Acetate. Acetic Acid acts feebly on Manganese and its carbonate. The acetate may be obtained by evaporation in pink crystals, soluble in water and alcohol. (John.)

Benzoate, or Benzoic Acid, has a similar action, and the Salt produced is in the form of slender, colourless, prismatic crystals, soluble in twenty times their weight of water, and also in alcohol. This Salt contains no water of crystallization.

Succinate. Manganese and its carbonate are readily soluble in succinie Acid. The crystals produced have different forms, and though singly they are transparent, yet a number of them together have a pink hue. They are insoluble in alcohol, but water dissolves eighteen percent.

Oxalate. Oxalic Acid dissolves Manganese or its oxide with effervescence, and a white powder is precipitated. The same Salt is produced by adding oxalic Acid to a solution of the Metal in any Acid. (Bergman.)

Tartrate. An insoluble Salt, which is formed by adding a neutral tartrate to a solution of barytes. The Acid dissolves oxide of Manganese.

Citrate. The citric Acid dissolves Manganese, forming a Salt of moderate solubility.

Silicate. A beautiful rose-red ore of Manganese well-known to Mineralogists, is, according to Berzelius, a combination of silica and the metallic oxide, wherein the former earth performs the part of an Acid. (Afhamdar, vol. i. p. 105.)

Double Salts.

Tartrate of potash and Manganese. By mixing tartrate of potash with a solution of Manganese; after some time has elapsed, small prismatic reddish brown crystals are deposited, consisting of this double Salt, which is sparingly soluble in water.

(616.) L. In neutral solutions of Manganese the
Chemistry. Following effects are produced. Fixed alkalis produce a white precipitate, which gradually blackens by exposure to the air. Potassium bicarbonate produces a white precipitate. Hydrosulphuric Acid whitens the solution, but produces no precipitate. Gallic acid, infusion of galls, succinate and benzoate of ammonia, produce no effect; no other metal throws down Manganese in the metallic state.

(647.) M. The common black oxide of Manganese is of great service to the Chemist for procuring oxygen, and it materially assists the glass-manufacturer in depriving glass of the green colour, which the iron present in the sand, or the flux, is liable to give to it. Bergman thus explains the theory of its action. Manganese in the state of black oxide produces a purple colour, but as a protoxide it gives no colour at all; iron, on the contrary, in a low state of oxygenation, gives a green tinge; but at a higher degree of oxidation it either remains infusible, or does not communicate colour. Hence it is evident that the two oxides being present in proper proportions, each metal passes to that state which is requisite for the formation of colourless glass. If the Manganese be in excess, the glass assumes a violet hue of any requisite intensity. Possibly, also, the oxygen of the Manganese may tend to the combustion of any carbonaceous matter present in the fused glass.

The black oxide of Manganese is largely employed in the preparation of chloride of lime for the bleachers. For more ample details consult the references. (a.)

References to § 1.

Sect. II.—Iron.

(648.) A. This Metal, although the most abundant and useful of all with which we are acquainted, was probably not the earliest known to the inhabitants of the Earth. Gold, silver, and copper, frequently occurring native, would soon attract attention from their properties, and become valuable auxiliaries to the artificer; but with the exception of those rare masses which seem to be of meteoric production, iron must have remained unknown until accident, or a suspicion of their nature, led to the reduction of its ores. This knowledge, however, the Israelites possessed in the time of Moses; but how or whence they obtained it we know not. History informs us that about 200 years afterward, its use was introduced into Greece; but two facts tend to prove that even after another period of two centuries, it was extremely rare in that Country. The first, that the weapons of war were formed of a hard alloy of copper and tin, or ancient bronze; and the second, that a ball of iron formed a prize given by Achilles during the Trojan war. Throughout Europe, indeed, bronze probably preceded iron in the fabrication of swords and the heads of spears. The Celtic inhabitants of Britain have left durable memorials of their workmanship in this beautiful alloy, and similar specimens have at different times been found in many of the Northern parts of Europe.

Some of the Salt of iron occur native, but it is from the oxides that the Iron of Commerce is principally obtained; the sulphures are also frequent. As a genuine mineral production, native iron is of great rarity. (649.) B. The reduction of the ores of this Metal on the large scale will come under consideration elsewhere, and for Chemical purposes the best soft Iron is to be selected, which is nearly pure, but may contain a little carbon, from which indeed this metal is seldom entirely free. (650.) C. The bluish-white colour of iron is familiar to every one. Its hardness when pure is not very great; but when converted into steel, it may be rendered superior in hardness to almost every other substance. It is malleable when cold, and more so when hot, but in this respect it is inferior to gold and silver, though much superior to either in ductility. Its tenacity is great, and its Specific Gravity is stated from 7.6 to 7.87. Its fusing point is about 1550° Wedgewood. (M'Kenzie.) It is capable of permanent magnetism; but when pure it does not long retain this property. When iron is violently heated its surface softens, and if two pieces in this state be hammered together a perfect union is effected. This property is common only to this Metal and platinum: it is of great utility, and known to artificers by the term welding. (651.) D. Iron has an exceedingly strong affinity for oxygen; it rusts, that is, oxidizes, by free exposure to the atmosphere, and this effect is greatly accelerated by moisture. It gradually decomposes water also at ordinary temperatures; but some recent experiments of Dr. Hall (Brande's Journal) render it probable that this effect will not take place in pure water when the access of air is prevented. At a red heat it decomposes water with great rapidity; at a very intense heat it decomposes the fixed alkalis; but it is a singular circumstance, that though in the first case it takes oxygen from hydrogen, and in the second from the metallic bases, yet hydrogen and these bases are also capable of decomposing the oxides of iron. Thus a curious problem in affinity is presented.

Two distinct oxides of iron are recognised by all Chemists, the black and the red. The first has long been known as the *Martial athiope* of the Materia Medica. It is best formed by exposing a paste of iron filings and water to the action of the air, moistening it repeatedly till the whole is oxidised, and then drying the powder by a gentle heat in an iron vessel. (De Roever, *An. de Ch.* vol. xiv.) The same oxide is precipitated from recently prepared sulphate of iron, by the addition of pure potash; and also by the combustion of iron wire in oxygen gas. The red (per) oxide is formed by exposing iron filings to a red heat in an open vessel; a deep-red powder is produced, formerly termed *Saffron of Mars.*

Thenard and Gay Lussac have described other oxides of iron, but at present considerable uncertainty exists on this subject. The atomic constitution of the oxides of iron presents difficulties which have not yet been satisfactorily removed. (652.) E. The chloride of iron was discovered by Dr. J. Davy; it is obtained by dissolving the metal in hydrochloric acid, evaporating and exposing the residue to a red heat, carefully excluding atmospheric air.
Thus obtained, the protochloride is of a grey colour and metallic lustre, fusible, but not volatile, and imperfectly soluble in water. (Phil. Trans. 1812.)

The deutochloride is obtained by burning Iron wire in chlorine gas, or by evaporating a hydrochloric solution of the red oxide of Iron to dryness, with exclusion of atmospheric air. The substance is fusible, volatile, and may be condensed in minute crystals. It is soluble in water. (Sir H. Davy, Phil. Trans. 1811, and Dr. J. Davy, Phil. Trans. 1812.)

No analysis of these two compounds has a very strict agreement with the theoretical composition, supposing the latter to consist of an atom of each substance, and the latter of one atom of Iron and two atoms of chlorine.

(653.) F. Unknown.
(654.) G. The only iodide of this Metal at present known, is formed by heating Iron in the vapour of iodine. It is a brown, fusible substance, soluble in water, producing a light green solution.

(655.) H. Of the combinations of Iron with combustibles, the carbures are by far the most important. When the metal is in excess, steel is formed of different kinds, in proportion to the quantity of carbon; and it is stated by Mr. Mushet that no good steel contains more than one-sixtieth of carbon. In cast Iron, however, a greater proportion is found, the maximum of which is stated at one-fifteenth. For further particulars on this branch of manufacture, see reference (b.) Carbon, combined with a very small proportion of about one-twentieth, is the native plumbago, formerly called black lead. With regard to all the combinations of carbon and Iron, no satisfactory attempt can be made to bring them under the law of the theory; true Chemical combinations they nevertheless appear to be; and if so, the atom of one element must be united to more atoms of the other than we are in the habit of considering probable from the known constitution of other bodies.

The phosphuret of Iron may be formed artificially, and also enters into the composition of what is termed cold short Iron. According to Berzelius the silicuret and seleniumuret exist, and the boruret has been described by Gmelin. Two definite sulphurets exist native, the one known as magnetic pyrites, the other having so much sulphur, that the magnetic property is destroyed. According to Mr. Hatchett, whose experiments are highly interesting, the carbures, sulphures, and phosphurets of Iron have each some particular properties of combination, at which magnetism is most powerfully and permanently developed. Pure Iron being capable of little permanency in its magnetism, and again, when combined with too great a proportion of the nonmetallic combustible, losing the property altogether.

(656.) I. Strictly speaking, Iron may be considered capable of uniting with all the other Metals, though some of these combinations are of difficult formation; thus the great infusibility of both the Metals renders it difficult to form an alloy of platinum and Iron; and the volatility of mercury at a comparatively low temperature presented an obstacle to its union with Iron. This difficulty, however, Mr. Aikin indirectly surmounted.

(657.) K. The black oxide is soluble in most Acids forming light green solutions. The red oxide gives also, with most Acids, solutions of a reddish-brown colour; but it is not so readily soluble as the black oxide. There exist these two distinct series of the Salts of Iron, viz. the proto salts and the persalts, as for the present we may continue to call them.

Nitric Acid (Specific Gravity 1.16) acts gently upon Iron with very slight evolution of Gas, and a solution of protonitrate of Iron remains, darkly coloured by the nitrous gas, which the Liquid at first retains, but which by combining with oxygen is gradually converted into nitric Acid, and becomes transparent.

If the above protonitrate be exposed to the air, or heated, it passes into the pernitrate, which is also the Salt obtained by the action of strong Acid upon the Metal; in this case a rapid decomposition takes place, and the protoxide and deutoxides of azote are abundantly evolved. This Salt is decomposed by a gentle red heat, the red oxide remaining no longer soluble in nitric Acid. Hence, in analysis, if it be desirable to estimate the Iron in the state of protoxide, a few drops of nitric Acid are added previous to exposure to a red heat; but if the protoxide be required, the residuum is mixed with a little tallow or wax, and by exposure to a gentle red heat, a definite protoxide is obtained.

It is well to remember that the protoxide is soluble in nitric, but not in hydrochloric Acid. The peroxide is soluble in hydrochloric Acid, but not in nitric. The crystals of the pernitrate can be obtained by evaporation, but Vauquelin is said to have formed them indirectly.

Sulphuric Acid dissolves Iron and both its oxides. By the action of dilute Acid upon the Metal, hydrogen is evolved, and the proto sulphate is produced. It is readily crystallized, but both in this state and in solution, if exposed to the air, the Metal proceeds to a higher degree of oxidation. This Salt is well known by the name of green vitriol or copperas, the which is met with in Commerce is chiefly produced by moistening native pyrites, with exposure to air and subsequent washing, evaporation, and crystallization. In the crystalline state, this Salt contains about forty-five per cent of water.

There are, according to Thomson, three subspecies of persulphate of Iron, but want of room will compel us here to refer to his system for a more particular account of them. The red persulphate of Iron being soluble in alcohol, which the green protosulphate is not, affords a ready mode of separating these Salts if mixed. The sulphite of the protoxide only is known, and may be formed by direct solution of the base in the Acid.

By the action of sulphurous Acid on Iron, the hyposulphite is produced, and its formation, as explained by Berthollet, is exceedingly instructive. The mutual action is violent, but no Gas is evolved. The Iron is oxidized at the expense of the Acid; half its oxygen combining with the Iron to form the black oxide, while the remaining sulphur and oxygen form hypsulphurous Acid, which unites with the base. (c.) Mr. Herschel obtained the same Salt by dissolving carbonate of Iron in sulphurous Acid, and boiling the solution upon sulphur. (f) The protoxumurate is formed by the action of muriatic Acid upon metallic Iron, but the protoxide is insoluble in this Acid, while by its action upon the peroxide the soluble permurate is readily obtained.

A solution of fluoric Acid in water dissolves Iron; the solution does not crystallize by evaporation, but only becomes gelatinous.

A solution of carbonic Acid in water acts feebly upon Iron; with excess of Acid the Salt remains dissolved, but by boiling, or by long exposure to air, the Iron falls...
Chemistry. down in the state of red oxide, still retaining some Acid; this process is daily seen in mineral waters. The carbonate has recently been found native, (c.) and may also be obtained by precipitating a solution of the sulphate by an alkaline carbonate. The rust which collects on exposed surfaces of Iron, especially if moist, is this carbonate more or less perfect.

The phosphate is produced by mixing solutions of phosphate of soda and sulphate of Iron, the perphosphate by mixing those of permuriate of Iron and phosphate of soda; it exists also native. (d.)

The borate precipitates, by the addition of solution of borate of soda to that of sulphate of Iron. Berzelius has described (An. de Ch. et de Ph. vol. ix.) the protoselenate and biperphosphatite, the perselenate and biperphosphatite. (e.)

The protarseniate and perrarseniate of Iron exist native in Cornwall; the former may be produced by adding arseniate of ammonia to a solution of sulphate of Iron, and the latter by adding the same arsenical Salt to a solution of permuriate of Iron. Antimonic acid of potash precipitates a white antimoniate of Iron from the sulphate. Chromate of potash produces from sulphate of Iron a tawny-coloured precipitate, consisting of oxide of chromium. Hence Vauquelin observes, that as the black oxide of Iron decomposes chromic Acid, protochromate of Iron does not exist. (Vauquelin, An. de Ch. vol. ixxx.) He suggests that we might probably form a perchromate by employing some persalt of Iron instead of the protosulphate.

Alkaline molybdates, according to Scheele, produce a brown precipitate in the Salts of Iron. The tungstate exists native. (Walbr.) and may be formed by adding an alkaline tungstate to a solution of sulphate of Iron. Acetic Acid readily dissolves Iron, and appears to form distinct Salts with the two oxides. The acetate is crystallizable, but the peracetate by evaporation is only gelatinized. The benzoate of Iron is a yellow, insoluble Salt, obtained by precipitation. The succinate is a crystallizable Salt, obtained by dissolving oxide of Iron in succinic Acid. But by adding succinate of ammonia to solutions of the persalts of Iron, a reddish, insoluble persuccinate is thrown down. On this property is founded the method of separating Iron from manganese. Thus by taking care to have the mixed solution of the Metals neutral, and the Iron in the state of a persalt, and then adding succinate of soda, the Iron may be entirely precipitated. By adding boleate of ammonia to a protosulphate of Iron no precipitate is produced; a solution of persulphate is entirely decomposed by these means, and the Iron thrown down in the form of a red powder. According to Braconnet, by this means Iron may be separated from manganese, lime, or alumina.

Sulphuric Acid gives a deep yellow colour to sulphate of Iron, but causes no precipitate. Oxalate Acid dissolves both Iron and its oxides; the protocitrate is soluble and crystallizes; the peroxalate has the contrary properties. The superoxalate of potash is, therefore, sold under the name of Salt of lemons, for the purpose of removing spots of ink from linen. From a persalt of Iron, mellite acid produces a yellow precipitate. Iron and its oxides are soluble in tartaric Acid; the prototaartrate is soluble and crystalizable; the parataartrate has not these properties. Citric Acid dissolves Iron, and gradually deposits a white powder, which is stated to consist of a citrate and a bicitrate of Iron: the former readily passing, if exposed, to the state of percitrate, which is a deliquescent and soluble Salt.

According to Scheele, the saccharic Acid does not throw down Iron from its sulphate. Malic Acid gives, according to Scheele, a brown, uncrystallizable solution. Lactic Acid dissolves Iron, depositing delicate crystals, scarcely soluble in water. With protosalts of Iron, gallic Acid produces no precipitate, but with the persalts it forms the well-known black of our writing-ink; and this, though in reality a true precipitate of pergallic of Iron, is in so minute a state of division, as to remain suspended in the Liquid, especially if its consistency be increased by the presence of any mucilaginous substance.

Double sulphates of potash and Iron, and potash and ammonia exist. (Link, An. de Ch. vol. i.) The well-known tartarized tincture of Iron of the Materia Medica, is a double tartrate of potash and Iron. And the Ferrum Ammoniaceum of the Pharmacopoeia, is a double muriate of ammonia and Iron formed by sublimation. In this case the ammonia and the Acid are capable of carrying the oxide of Iron along with them in the volatile state, and the same property enables the muriatic Acid to carry over with it Iron in the process of distillation, which is the cause of the yellow colour in the common Acid of Commerce.

On a review of the above Salts of Iron it will appear, that for the most part the protosalts are crystallizable, and that the greater part of them are so soluble as not to be obtained by precipitation; that is supposing the formation of a protosalt to take place when a neutral solution of any Salt is added to a protosalt of Iron, the newly-formed Salt remains in solution; but whether this is the case, or whether no decomposition is effected, we have not at present any means of determining.

The persalts, on the contrary, rarely crystallize, and generally fall down in an insoluble state.

(655.) L. Much of the effects of reagents on the solutions of Iron, may be gathered from the preceding section. The most common tests of Iron are the infusion of galls, which gives no precipitate until the Iron is peroxidized by a few drops of nitric Acid, or by exposure to the air. The ferro-hydroxyanate of potassa giving a white precipitate with the persalts, and a deep blue on with the persalts, is a most delicate test. Sulphuric hydrogen produces no precipitate with the protosalts, but with the persalts gives a precipitate consisting of sulphur, because in this case the sulphuric hydrogen is decomposed, and also the peroxide of Iron, which passes to the state of protoxide. "This Gas likewise precipitates Iron from its solution in some of the weaker vegetable Acids." Hydrosulphuric of potash gives a black precipitate with the persalts.

(659.) M. The countless uses of metallic Iron and steel need no enumeration; two of its Salts have been mentioned as employed in Medicine, and formerly it was given in several other states of combination. The peracetate is of great use to dyers, and considerable quantities of the sulphate are employed by hatters.

References to § 2.

Sect. III.—Tin.

(660.) A. Pliny begins his chapter upon Tin thus, "Stannum illitum ancia vasa, saporem grationem facit, et compsect cruguris viris; mirurque, pondus nil auget. (Mirm! truly.) He describes it as coming from Spain and Britain, and mentions its great abundance in the latter. (a.) Moses mentions Tin as one of the Metals that may "abide the fire" for purification. (b))

(661.) B. The common process for smelting Tin in Cornwall is fully described in Aikin’s Dictionary; it consists in pulverizing the ore, and washing it so as to remove the lighter rocky particles. The heavy metallic ones which remain, are then roasted to drain off arsenic and sulphur, and to oxidize some other metallic impurities. By a subsequent washing, the oxide of Tin remains in tolerable purity; it is now mixed with charcoal, and subjected to a violent furnace heat, by which the reduction is effected, and metallic Tin sub-sides to the bottom of the furnace, from which it is run off into pigs for sale.

(662.) C. Tin is of a brilliant white colour; it has a slight but disagreeable taste, and emits a smell when rubbed. In hardness it is superior to lead, but inferior to gold; Specific Gravity 7.291 to 7.299. "It is very malleable: Tin-foil, as it is called, is about one-thousandth of an inch thick, and it might be beaten out into leaves as thin again if wanted for purposes of Art. Its ductility and tenacity are much inferior to that of most of the Metals known to the Ancients." When dissolved in concentrated nitric Acid, with aid of heat, and precipitating the solution by ammonia. Thus an hydrate of the protoxide is obtained. By heat it is not decomposed, but passes to a higher degree of oxidation; it is soluble in alkalis and Acids.

The deutoxide is obtained by acting upon Tin with concentrated nitric Acid; so solution is effected, but a white powder is formed, which is a hydrate of the deutoxide. By heat, the water is driven off, and the pure yellow deutoxide remains. Berzelius obtained the same substance by heating Tin filings in contact with peroxide of mercury. (f)

This oxide may, by digestion, be united to the sulphuric and muriatic Acids; but though in both cases the compound remains insoluble in the Acid, yet in the former it becomes soluble in water. In the same manner, by digestion with alkalis, compounds soluble in water are similarly produced.

The two oxides of Tin are easily distinguished from each other by their properties: the protoxide undergoes evident combustion, at a red-heat; the deutoxide does not so. The former is soluble in dilute nitric Acid; the latter does not so. Solutions of the protoxide gives black precipitates with corrosive sublimate.

(664.) E. Two chlorides of Tin are described by Dr. J. Davy. (f) They are formed by heating protomuriate of Tin in a retort, till a fused, grey, resinous substance remains.

The deutilchloride may be formed by heating Tin, or its protochloride, in chlorine Gas; but it is most readily formed by heating 6 parts of Tin, 1 of mercury, and 33 of corrosive sublimate, together in a retort. At first, water is disengaged, but afterwards a white vapour is rapidly produced, and condensed in a receiver, forming a colourless Liquid. This has long been known by the name of the fuming liquor of Libavius, from its discoverer.

(665.) F. Unexamined.

(666.) G. Tin in fusion readily combines with the vapour of iodine, and a fusible, orange-coloured iodide is the result. Water converts it into hydriodic Acid and oxide of Tin.

(667.) H. Tin, in all probability, does not combine with hydrogen nor azote; neither has its union with carbon, boron, or silicon been effected. The phosphuret may be formed by dropping pieces of phosphorus into melted Tin, or by fusing in a crucible equal parts of glacial phosphoric Acid and Tin-filings.

Three sulphurets of Tin are known to Chemists. The proto-sulphuret is formed by fusing Tin and sulphur together, pulverizing the compound, again mixing it with sulphur, and subjecting it to a sufficient heat to volatilize all the superabundant sulphur. This compound has metallic lustre with the colour of lead, and is capable of crystallization. "When dissolved in concentrated muriatic Acid it is entirely converted into oxide of Tin and sulphuretted hydrogen Gas," Thomson.

A substance, long known to Chemists under the name of Aurum Mosaicum, is the deuto-sulphuret of this Metal. The best process for obtaining it appears to be as follows. Amalgamate 8 oz. of Tin with an equal quantity of mercury, mix this with 6 oz. of sulphur and 4 of muriate of ammonia. Expose this compound to a violent...
Hydrochloric Acid readily dissolves Tin, with evolution of a fetid hydrogen Gas. In this solution the Metal is in the state of protoxide, and from the strong tendency which Tin has to pass to the higher degree of oxidation, this solution produces marked effects in many metallic solutions, wherein the oxygen is combined with the Metal by a feeble degree of affinity. Thus by protohydrochlorate of Tin, solutions of zinc, antimony, silver, and mercury, are precipitated in the metallic state, either pure or mixed with some portion of Tin. With gold a purple precipitate is produced, containing both gold and Tin in some state of combination, not at present clearly understood. The persalts of iron are reduced to the state of protosalts. For many more of these important properties we must refer to the Memoirs of Pelletier and Proust. This protohydrochlorate may be crystallized, but readily changes to the state of deuthydrochlorate, if great care be not taken to preserve it from oxygen. The deuthydrochlorate may be formed by dissolving the deutoxide of Tin in muriatic Acid, or by the process before given for obtaining Libavius's liquor, in which state it has been already described.

From the failures of Bergman (i.) and Proust (k.) it would appear that no carbonate of Tin can exist.

Phosphate of Tin being insoluble in water, is formed by adding hydrochlorate of Tin to an alkaline phosphate, but liquid phosphoric Acid has scarcely any action on metallic Tin.

Precisely similar properties mark the action of boracic Acid. Arsenic Acid is slowly decomposed if digested upon Tin; but by adding this Acid to acetate of Tin, or by mixing alkaline arsenautes with muriate of Tin, an insoluble arseniate of Tin is precipitated.

With the assistance of heat, acetic Acid acts slowly upon Tin; and both the protocate and deucrandeacte seem to have been formed; the first capable of crystallization; the second only capable of gelatinization.

Benzoic Acid does not dissolve Tin or its oxides, but by adding benzoate of potash to a solution of Tin a benzoate of Tin is precipitated. It is soluble in hot water, but insoluble in alcohol.

Succinate of Tin is a crystalline Salt in tables, produced by dissolving the oxide in the Acid and slow evaporation.

By the aid of heat, oxalic Acid first blackens Tin, and then incrusts its surface with a white oxide, of which a portion is taken up. Prismatic crystals may be obtained by slow evaporation.

Tartrate of Tin is formed by dissolving the metallic oxide in tartaric Acid. By boiling oxide of Tin in a solution of tartrate of potash, a very soluble, but crystallizable, double Salt is formed, from which the alkalies and their carbonates produce no precipitate. (m.)

Deutoxide of Tin appears also to dissolve in nitrate of ammonia, producing a double Salt in solution. (i.)

(670.) L. The effects of reagents upon solutions of Tin are as follows. Gallic Acid and infusion of galls, no precipitate. Prussiate of potash, a white one. Hydrosulphuret of potash, a dark brown one in Salts of the protoxide, and a deep yellow precipitate in those of the deutoxide. Corrosive sublimate produces in the former Salts black, in the latter white precipitates. Lead precipitates Tin from some of its Salts in the metallic state. With the protosalts a solution of gold produces a purple precipitate.

(671.) M. Tin is of importance in the Arts for the
Chemistry.

formation of several alloys. The bronze of the Ancients, a very beautiful compound, sufficiently hard for the formation of swords and spear-heads, consisted of 88 parts of copper and 12 of Tin. Gun-metal is of about the same composition. (a.) (o.) In bell-metal the Tin is from one-fifth to one-third of the weight of the copper. The Chinese gong is formed of 80 of copper and 20 of Tin. (p.) For the specula of telescopes, Mudge recommends 1 part of Tin to 2 of copper; but Mr. Edwards's experiments are in favour of a more complex material, consisting of 32 of copper, 15 or 16 of Tin, with brass, arsenic, and silver, each 1 part. (q.) The surface of copper-vessels for culinary purposes is often covered with a film of Tin, which prevents the poisonous effects produced by solution of the former Metal. The process is extremely simple: the copper being first polished, and then covered with a coating of sal ammoniac or pitch, to prevent oxidation, and the vessel being heated, the Tin is applied hot, and readily adheres to the surface of the copper. On similar principles the manufacture of Tin-plate is effected; thin sheets of polished iron are dipped into a vat of melted Tin, having a coat of tallow floating upon its surface. The Tin unites with the surfaces of the iron forming with it an alloy of slight depth. Pewter is of very variable composition, but most is formed from Tin and lead; the best, however, contains only Tin with a little antimony. This compound may safely be used even for vinegar; for unless the lead be in improper excess, none of it is taken up by the Acid; but if any solution takes place, it is only of a small quantity of Tin. Nitric Acid, on the contrary, takes up more of the lead than of Tin. Plumbers' solder contains equal parts of Tin and lead. In silvering mirrors, Tin-foil is spread on flat stones, and then covered with a coating of salammoniac, which is heated, the Tin is applied hot, and readily adheres to the surface of the glass. The oxides of Tin are the principal basis of white enamel; and some of its Salts are of great use as mordants in dyeing. (r.)

References to § 3.

Sect. IV.—Zinc.

(672.) A. Metallic Zinc was unknown to the Ancients, though they were well acquainted with its ore, and used it largely in the formation of brass. Owing to its volatile nature and strong affinity for oxygen they never obtained it in the reduced form, though its oxide formed some of their medicinal preparations. Pliny says, Pluta autem genera sunt, nambque ipse laquis ex quo sit as, cadmia vocatur. (a.) Henckel first mentions its reduction in 1721. Zinc has never been found in the metallic state, but exists abundantly as a sulphuret and carbonate: sometimes also combined with oxygen and silica.

(673.) B. The reduction of Zinc is performed on a large scale in Britain, principally from the sulphuret; the ore is roasted, and then reduced to powder, mixed with charcoal, and violently heated in earthen meltung-pots. It either passes in fusion through an iron tube from the bottom of these crucibles, or is volatilized; and in both cases, the tube terminating in a vessel of water, the Metal is condensed, and subsequently fused into convenient masses for market. (b.)

To obtain pure Zinc for Chemical purposes, let the Metal be dissolved in sulphuric Acid to saturation, leaving a plate of the Metal a short time in the solution, by which all impurity of foreign Metals will be precipitated. Decompose the filtered solution by an alkaline carbonate, and reduce the powder produced; by mixing it with half its weight of charcoal, and submitting it to a strong heat in a retort, the pure Zinc will condense in the beak of the vessel, which is to be kept cool.

(674.) C. Zinc is of a bluish-white colour, of a laminated structure, and fine granular fracture. Specific Gravity 6.5 to 7.1, more malleable than antimony, but less so than copper or lead; rather ductile, but at ordinary temperatures not very elastic. At a temperature from 212° to 310° it becomes very malleable, and may be formed into thin sheets by passing it between steel rollers; at 400° it becomes again quite brittle, and may be pulverized, and at about 480° Fahrenheit it fuses. (Black.) By higher temperatures it is capable of distillation in close vessels.

(675.) D. Though the surface of Zinc becomes tarnished, it can scarcely be said to undergo oxidation by exposure to the air. At ordinary temperatures it very slowly decomposes water; but if wet zinc wire be passed over Zinc made red hot, a most rapid decomposition is effected, the Metal becomes oxidated, and hydrogen is evolved. If Zinc be fused in an open vessel, it forms a greyish oxide. But if an earthen crucible be heated red hot, and small pieces of Zinc be projected into it, a most intense white light marks rapid combustion, and an abundance of white flakes are carried up by the current of heated air. This delicate white powder, the nihil album, lana philosophica of the Alchemists, Flowers of Zinc of the early medical writers, is the pure white oxide of this Metal. This substance is not volatile, and very difficult of fusion; insoluble in water, it absorbs carbonic Acid from the atmosphere, is not decomposed by heat, but reducible by the Voltaic pile; and by heat, if in contact with charcoal, the Metal distils over in closed vessels. It is the only oxide which Chemists have been able to procure from this Metal.

(676.) E. Zinc readily takes fire in chlorine Gas, and a chloride of Zinc is formed. By evaporating a solution of hydrochlorate of Zinc to dryness, and subsequent exposure to a red heat in a glass tube with a minute orifice, the same substance is produced. In this state, according to Dr. John Davy, (c.) it is not capable of being subdued by a low red heat.

(677.) F. Zinc is soluble in fluoric Acid, and it seems very probable that by exposure to heat the Salt so formed would be converted into a fluoride of Zinc.

(678.) G. If iodine and Zinc be fused together, iodide of Zinc is formed. It is a volatile compound, which on condensation crystallizes in small quadrangular prisms, which deliquesce by exposure to air, and are
Chemistry. soluble in water. In this state it becomes, in fact, a solution of hydriodate of Zinc.

(679.) H. Zinc unites with phosphorus, forming a metallic-looking compound. The sulphuret of this Metal cannot be directly formed by melting the two substances together, but if, instead of metallic Zinc, its oxide is fused with sulphur, a true sulphuret is formed. The same substance is precipitated by dropping an alkaline hydro-sulphuret into a solution of Zinc. According to Mr. E. Davy, if the vapour of sulphur is passed over Zinc in fusion, a yellowish compound, similar to blende, is produced. The properties of Zinc and selenium are precisely similar to those just described. Direct union is impossible, but when volatilized selenium comes in contact with fused Zinc red-hot, an instantaneous combination takes places with such violence, as to produce a sort of detonation. (d.) Zinc has not been united to boron or silicon, and it is stated not to combine with hydrogen or azote. It must, however, be remembered that most Chemists are of opinion, that in the common process of obtaining hydrogen by the action of sulphuric Acid and Zinc upon water, some portion of the Metal is carried up along with the Gas.

(680.) I. Zinc has been alloyed with potassium, sodium, (c.) iron, antimony, copper, gold, silver, lead, tin, and mercury. It is said that it refuses to unite with nickel and cobalt.

(681.) K. Nitric Acid readily dissolves Zinc or its oxide; and in operating upon the Metal it is advisable to moderate the action, by using the Acid in a dilute state. By evaporation, this nitrate is said to crystallize in " flat, striated, tetrahedral prisms, terminated by four-sided pyramids." These crystals are soluble in water and alcohol. They are entirely decomposed by a sufficient heat.

Concentrated sulphuric Acid has little action upon Zinc without heat, but if diluted, dissolves it with rapidity. By evaporation, the sulphate of Zinc crystallizes in four-sided, rectangular prisms, terminated by tetrahedral pyramids. In this state it is the white nitrate of Commerce. By a strong and continued heat, it is entirely decomposed, leaving oxide of Zinc in great purity.

Sulphurous Acid dissolves oxide of Zinc, forming a crystallizable sulphite which is not soluble in alcohol.

On metallic Zinc, sulphurous Acid exerts a considerable violence of action, and hydro-sulphurous Acid Gas is given out, the water undergoes an entire, and the Acid a partial, decomposition; oxygen goes to the Zinc, and part of the sulphur escapes in combination with the hydrogen; thus the Acid becomes the hyposulphurous, and being neutralized by the oxide, hyposulphite of Zinc remains. By spontaneous evaporation, slender, four-sided crystals, with pyramidal summits, are produced. These are soluble in water and alcohol. (Fourcroy.)

The carbonate of Zinc occurs native, and is known by the name calamine; it exists both as an hydrous and as an ahydrous Salt. A solution of carbonic Acid dissolves both Zinc and its oxide, but the carbonate is more readily formed by adding an alkaline carbonate to a solution of Zinc. The Salt precipitates in the form of a white powder; but is again dissolved by excess of the precipitating Acid.

Borate of soda in solution, added to sulphate of Zinc in the same state, throws down a white powder, consisting of borate of Zinc, which heat fuses, but does not decompose.

Phosphoric Acid dissolves Zinc, but ceases to act when the Salt has arrived at the state of a biphosphate, which may be evaporated just to dryness without crystallization or decomposition. If, however, such a saturated solution be boiled upon carbonate of Zinc, a true insoluble phosphate of Zinc is formed.

Berzelius has described the seleniate and biseleniate of Zinc; (f.) the former is insoluble, the latter soluble in water.

The arsenate, antimoniate, tungstate, molybdate, and chromate of Zinc, are formed by adding their alkaline Salts to a solution of sulphate of Zinc; in all cases a white, insoluble powder is precipitated, the chromate excepted, which is of an orange-red colour.

Acetic Acid dissolves Zinc; and by evaporation a crystalline acetate is obtained, readily soluble in water.

The benzoic, succinic, maleic, and lactic Acids, dissolve Zinc, and form crystallizable Salts, which are again soluble in water.

The oxalic, citric, and tartaric Acids also attack Zinc, but the Salts which are thus formed, immediately separate from being insoluble in water.

A double tartrate of potash and Zinc may be formed by boiling tartaric Acid and Zinc filings in water. (g.)

A double sulphate of Zinc and iron is formed by mixing a solution of sulphate of iron with that of sulphate of Zinc; the Salt is soluble, and may be obtained in crystals by evaporation. Sulphate of Zinc and cobalt may be formed by digesting zaffre in a solution of sulphate of Zinc. It crystallizes in large, four-sided prisms. (A.)

A mineral substance, known by the name of electric calamine, consists of silica and oxide of Zinc; and here the former substance is considered to perform the part of an Acid; it is therefore called silicate of Zinc. The crystalline forms are numerous; a small hexagonal prism or an acute octahedron is the most common.

Caustic ammonia is capable of dissolving the oxide of Zinc, and has even some action on the Metal; after which a mass of plumose crystals may be obtained by evaporation. From such a solution copper precipitates Zinc, but Zinc precipitates copper from an Acid. May not this tend to prove that the oxide of Zinc here acts the part of an Acid?

(682.) L. Many of the instances in which saline solutions form reagents for the separation of Zinc, may be collected from the preceding section. Its Salts, when in solution, are always colourless. Alkalis produce a white precipitate, soluble in sulphuric or hydrochloric Acid. Prussiate of potash, hydriodate of potash, hydro-sulphate of potash, and hydro-sulphuric Acid Gas, produce white precipitates. Gallic Acid and infusions of galls give no precipitate. Zinc is not thrown down in the metallic state from its solution by any other Metal.

(683.) M. The sulphate of Zinc is used as an emetic, and the acetate has recently been recommended by Dr. Henry as an external application to remove inflammation. It has long formed a constituent of some empiric eye-waters.

Zinc is principally obtained on the large scale for the formation of brass. This useful and beautiful alloy commonly consists of about 62 to 66 of copper, with from 32 to 35 of Zinc; (Chaudet;) the more valuable kind, known by the name of Dutch brass, was found by Thomson to contain 70 of copper and 30 of Zinc, but he considers that much of its superiority consists in the greater purity of the Metals, which in common brass
Chemistry are contaminated with lead. (i.) When the copper is in greater proportion, other Metals are formed, known in Commerce by the names of pinchbeck, Prince's metal, etc. A considerable quantity of Zinc is employed for the plates of galvanic batteries. Its white oxide forms a pure and delicate white paint. Recently it has been much employed for making the shoots carried round the eaves of houses to collect rain-water.

Sect. V. — Cadmium.

(684.) A. In the year 1817, Professor Stromeyer of Gottingen discovered the oxide of a peculiar Metal as an impurity in oxide of zinc, sold for medicinal purposes; while at the same time a peculiarity in a preparation of zinc, from the manufacture of M. Herman in Silesia, led to the observation of the same metallic oxide. The oxide of zinc had been condemned on the supposition that it contained arsenic, because it produced an orange precipitate with hydrosulphuric Acid Gas. On more accurate investigation, this suspicion was found to be without foundation; and some of the orange precipitate having been transmitted to Stromeyer, he recognised in it the same metallic oxide, to the Metal from which he gave the name of Cadmium. (a.) This Metal has since been found in some of the English ores of zinc by Professor Clarke of Cambridge; (b.) but its most abundant ore is the brown fibrous blende of Bohemia. Mr. Herapath has pointed out an abundance of the oxide in sublimate from zinc furnaces. (c.)

(685.) B. Stromeyer's process for obtaining the Metal is as follows. A solution of the ore or oxide is made in sulphuric Acid, by passing a current of hydrosulphuric Acid Gas through the Liquid; the Cadmium, zinc, and copper, if present, are precipitated. Redissolve in concentrated hydrochloric Acid, and evaporate to dryness, to get rid of the excess of Acid. Dissolve in water, and add excess of carbonate of ammonia, by which the zinc and copper are dissolved, but the carbonate of Cadmium remains in the state of a white powder, zinc in the state of crystalline carbonate. If a red heat the Acid is driven off, and oxide of Cadmium remains. This oxide may be reduced to the metallic state by mixing it with lamp-black, and exposure to a low red heat in a glass tube or small retort.

The following elegant process for obtaining Cadmium is from Dr. Wollaston. From the solution of the ore, precipitate all other metallic impurities by a plate of iron; filter, and immerse a plate of zinc in the clear solution: if Cadmium be present, it will be precipitated in the metallic state, and may be reduced in hydrochloric Acid, for the exhibition of appropriate tests. (686.) C. Cadmium is of a bluish-white colour, and, much like tin, susceptible of a fine polish. Its texture is compact, and Specific Gravity 8.604–8.694. It fuses, and is volatilized below a red heat; in fact, at a heat rather above that of boiling mercury. It crystalizes in octahedrals, is flexible, and gives, on bending, the same sound as tin does. It is ductile and malleable, yielding readily to the knife; but exceeds tin in hardness and tenacity.

(687.) D. When Cadmium is heated with access of air, it burns, and the smoke condenses in the form of a brown powder, its only known oxide. In this state it is readily soluble in nitric Acid, and feebly so in dilute hydrochloric, sulphuric, and acetic Acids. Oxide of Cadmium is soluble in ammonia, but not in the fixed alkalis.

(688.) E. If oxide of Cadmium be dissolved in hydrochloric Acid, small rectangular crystals of hydrochlorate of Cadmium are obtained by evaporation. By heat these are converted into chloride of Cadmium, and are even capable of volatilization unaltered.

(689.) F. Unknown.

(690.) G. Iodine and Cadmium, if heated together, readily unite. Or if water be boiled upon the two substances in contact, a solution is obtained, which by evaporation may be crystallized in the form of hexagonal plates. These crystals are decomposed by heat, and are soluble in water and alcohol.

(691.) H. The combinations which ought to fall under this head are at present little investigated. Cadmium and sulphur do not unite readily by fusion, but the sulphuret is easily formed by passing a current of hydrosulphuric Acid Gas through a solution of a Salt of Cadmium. The yellow sulphuret thus produced, forms, according to Stromeyer, an excellent paint. By the action of nitric Acid, the sulphuret is converted into a neutral sulphate. The phosphuret of Cadmium is a grey, metallic-looking, brittle substance, easily fusible; placed on burning coals it ignites, and is converted into the phosphate.

(692.) I. As yet Cadmium has been alloyed only with copper, mercury, cobalt, platinum, and zinc.

(693.) K. The Salts of Cadmium are at present little known. The nitrate, sulphate, and acetate are soluble in water. The carbonate, phosphate, and oxalate are insoluble in water. The borate, tartrate, and citrate are very slightly soluble.

(694.) L. In solutions of Cadmium the fixed alkalis produce permanent precipitates, but ammonia produces a precipitate which excess of the alkali again dissolves. "The alkaline carbonates throw down Cadmium in the state of a white carbonate. This carbonate does not form an hydrate, as is the case with carbonate of zinc. Neither is it redissolved by adding excess of carbonate of ammonia, as is the case with carbonate of zinc, unless there previously existed a notable excess of Acid in the solution." "Phosphate of soda throws down Cadmium in the state of a white powder, zinc in the state of crystalline scales." Thomson.

Hydrosulphuric Acid Gas and the hydrosulphurets produce a yellow precipitate, easily soluble in hydrochloric Acid, and unaltered by a low red heat; in which two points it differs from orpiment. Prussiate of potassa precipitates solution of Cadmium white.

Infusion of gall gives no precipitate.

Cadmium is precipitated by zinc in the metallic state.

(695.) M. None at present.

METALS. CLASS IV

Sect. I.—Arsenic.

(696.) A. "The word Arsenic (ἀρσενίκος) occurs first in the Works of Dioscorides, and some authors who wrote about the beginning of the Christian era. It denotes in their works the same substance which Aristotle had called σάραπασσάς; and his disciple Theophrastus ἀρσενίκος, which is a reddish-coloured mineral, composed of Arsenic and sulphur, used by the Ancients in painting, and as a medicine. (a.)" "The white oxide of Arsenic, or what is known in Commerce by the same name of Arsenic, is mentioned by Avicenna, in the XIth century; but at what period the metal called Arsenic was first extracted from that oxide is unknown. Paracelsus seems to have known it; and a process for obtaining it is described by Schroeder in his Pharmacopia, published in 1649. But it was only in the year 1733, that this metal was examined with Chemical precision. This examination, which was performed by Mr. Brandt, (b.) demonstrated its peculiar nature; and since that time it has been always considered as a distinct Metal, to which the term Arsenic has been appropriated. Its properties were still further investigated by Macquer, in 1746, (c.) by Monnet, in 1773, (d.) by Bergman, in 1777. (e.) To the labours of these Philosophers, and those of Mr. Scheele, (f.) we are indebted for almost every thing known about the properties of this Metal. Its combinations with oxygen have been carefully examined by Proust, (g.) Bucholz, (h.) Berzelius, (i.) and some other Chemists." (k.) Thomson. (l.)" Arsenic exists native, in the state of an oxide; and as a constituent part of many metalliferous ores.

(697.) B. To obtain metallic Arsenic, let the white oxide of Arsenic be mixed with half its weight of black flux; (made by deflagrating two parts of crystals of tartar with one part of nitre in a crucible.) Put the mixture into a crucible; and invert over this another crucible, and let the two be luted together with sand and clay. Expose the lower crucible to a red heat, and let the upper one be kept as cool as possible. Brilliant metallic Arsenic will be found sublimed into the upper crucible. A wide earthen tube-retort, divided into two parts, would be more convenient.

(698.) C. Arsenic is so brittle and soft that it may easily be pulverized. It is readily fusible, and rises in vapour at about 356° Fahrenheit. When thrown on a red-hot iron, it burns with a blue flame and a white smoke, having a strong alliaceous odour. This odour is not present when only the oxides of Arsenic are volatilized.

(699.) D. If Arsenic be moderately heated with free access of atmospheric air, sublimation takes place, and a white powder is condensed, which is Arsenious Acid. See subsect 1.

Besides this oxide another exists having also acid properties. This was discovered by Scheele; and the process recommended by Bucholz for obtaining it is as follows. Mix two parts of hydrochloric Acid, Specific Gravity 1.2; eight parts of Arsenious Acid; and twenty-four parts of nitric Acid. (Specific Gravity 1.25.) Evaporate the mixture to dryness, giving at last a low red heat. (m.) The same Acid is still more readily obtained by dissolving Arsenic in nitric Acid, and evaporating to dryness. See subsect 2.

As far as at present known, the following is the composition of these two oxides:

<table>
<thead>
<tr>
<th>Arsenious Acid</th>
<th>One atom + two atoms</th>
</tr>
</thead>
<tbody>
<tr>
<td>Arsenic Acid</td>
<td>One atom + three atoms</td>
</tr>
</tbody>
</table>

In this and all such cases it is surely more easy to speak of the deutoxide and tritoxide of Arsenic, and to remember that the protoxide has not yet been exhibited, than it is to speak of the protoxide, and to remember that it contains an atom more oxygen than protoxides in general; and of the deutoxide, having also to remember that it is similarly circumstanced.

(700.) E. Arsenic undergoes combustion in chlorine Gas, and a true chloride of Arsenic is formed. It is most fully described by Dr. Davy. (n.)

(701.) F. Unknown.

(702.) G. Iodine and Arsenic unite to form a deep red iodide, which is capable of decomposing water and affords Arsenic and hydriodic Acids.

(703.) H. Arsenic unites with hydrogen to form a gaseous substance; (o.) but there is considerable danger in making experiments upon it, as the mere inhaling a small quantity killed M. Gehlen. (p.)

Arsenic unites with sulphur in two proportions, and both compounds are found native: these are realger and orpiment. (q.) It combines also with phosphorus and selenion.

(704.) I. This Metal combines to form alloys with all the other Metals; and has even in very small quantity the property of rendering them quite brittle.

(705.) K. The oxides of Arsenic seem to possess little power of performing the parts of a base in the formation of Salts. The sulphate, borate, phosphate, nitrate, and hydrochlorate of Arsenic, have been described. In these Salts, the Acid and base are held by very feeble affinities.

But the oxides of Arsenic are capable of more important effects in performing the part of Acids with certain bases; and hence has been called Arsenious and Arsenic Acids.

(706.) L. In Medical Jurisprudence, a decisive test of Arsenic is a matter of great importance; as upon it the life of an accused person must frequently depend. Several tests have been proposed for this purpose, but, as it would seem, all are more or less uncertain. For an able investigation of this point we are indebted to Dr. Christieon; and from his Memoirs we give the following summary of what he considers a faultless process for the purpose. Let the mass of fluids suspected of containing Arsenic, suppose for instance the contents of the stomach of a deceased person, be well agitated and boiled with water, and thrown on a filter. Be careful to acidulate the clear Liquid with hydrochloric or acetic Acid. Through this Liquid pass a current of hydrosulphuric Acid Gas. (sulphuretted hydrogen.) Suppose a yellow precipitate to be formed. It may be the sulphurets of Arsenic, cadmium, tin, antimony, or selenium. But the sulphuret of Arsenic will easily be recognised by the following properties. Let a portion of it be dried; mixed with a little black flax, (697.) placed in a dry glass-tube, and raised to a red heat in the flame of a spirit-lamp. The Arsenic is reduced, rises in vapour,
and is condensed in the form of a bright iron-grey crust lining the cooler part of the tube. The inner surface presents also a crystalline appearance. By vaporizing a little of this Metal, the allaceous odour of garlic is instantly perceptible. This evidence is quite conclusive. But it is easy also to revert the Metal into Arsenious Acid. For this purpose hold the part of the tube to which the Arsenic adheres about three-fourths of an inch above the flame of a very small spirit-lamp, so that the Metal may rise in vapour very gradually. In so doing it combines with oxygen, and is deposited in well-characterized crystals of Arsenious Acid, on the cooler parts of the tube. It is essential that the tube be quite dry. The volatility, form, transparency, and adamantine lustre are so characteristic, that Dr. Christison considers that one-hundredth of a grain is sufficient to satisfy an experienced eye. This gentleman states that he has been able by these processes to separate and exhibit in two instances so small a quantity as the twentieth of a grain from the stomachs of people who had been poisoned with Arsenic.

(707.) M. Arsenic, in the form of its yellow sulphuret, forms a pigment, being the colouring principle of King's yellow. The sulphures of Arsenic are poisonous, but not to such an extent as the Metal or its oxides. Preparations of Arsenic have been employed in Medicine, and form the active ingredient in Fowler's Ague-drops.

Subsect. 1.—Arsenious Acid.

(708.) Having previously stated the formation and constitution of Arsenious Acid, (699.) we may here note a few of its principal properties, though in so doing we must be as brief as possible. According to Klapproth and Bucholz, cold water dissolves only .25 per cent. of its own weight of white Arsenic; whilst boiling water takes up 7.775 per cent. A part was again deposited on cooling, but 4.775 per cent. remained in solution. This oxide is soluble also in alcohol and oils. Arsenious Acid is capable of neutralizing the alkaline bases; and thus forms a class of Salts called Arseniates. It unites in a similar manner with several metallic oxides.

Subsect. 2.—Arsenic Acid.

(709.) The formation of this Acid has been noticed in Art. 699. It reddens vegetable blues; attracts with solution of alkaline carbonates. By evaporation it gelatinizes, but does not crystallize. It unites also with bases, forming a class of Salts called Arseniates.

Part II.

Sect. II.—Molybdenum.

(710.) A. This, which is now the name of a peculiar Metal, was used by Pliny (lib. xxi. ch. xiii.) for plum-bago, genus herba, &c. &c. quod plumbum, id est occultum vitium, commanducata tollit; also, in lib. xxxiv. ch. xviii. it is explained as vena communis plumbi et argenti.

In 1778, Scheele analyzed this substance and obtained sulphur, and a white powder possessed of Acid properties, to which he gave the name of "Acid of Molybdena." Hjelm, in 1782, succeeded in reducing it to the metallic state; his process depended upon subjecting the oxide to intense heat after it had been mixed up with linseed-oil, but according to Bucholz, the addition of carbonaceous matter is unnecessary.

(711.) B. This Metal has hitherto resisted all efforts to reduce it to a metallic button, as the most successful experimenters have but produced a porous mass of adhering particles.

(712.) C. Its colour is silvery-white, and the highest Specific Gravity to which Bucholz could bring it was 8.61. It appears as if under all states it would prove brittle.

(713.) D. If Molybdenum be heated in an open vessel, it undergoes oxidation, producing small, bright, needle-formed crystals, and, according to Bucholz, it is capable of forming three oxides. Mr. Hatchett is disposed to admit four.

The protoxide is said to be formed by dissolving Molybdic Acid in ammonia, and evaporating the clear solution to dryness; the residuum is exposed to a white heat with charcoal in a crucible. A brown oxide is formed at the bottom of the crucible, having a crystaline appearance, but incapable of forming Salts with Acids.

The deutoxide, or Molybdous Acid, (subsect. 1.) is to be formed, by mixing one part of Molybdenum with two parts of Molybdic Acid in a state of powder; the mass is to be mixed with hot water, and triturated till it becomes blue: eight or ten parts of water are added, and boiled for a few minutes. The solution is then filtered and evaporated at a temperature of 120°. The blue oxide remains in the state of a fine powder, soluble in water, which is strongly acid, converting vegetable blues to red, and saturating bases so as to form Salts.

The white oxide, or Molybic Acid, is prepared from Molybdena, (the native sulphuret of the Metal,) by the following process of Bucholz. Expose the mineral, finely pulverized, to heat, in an open crucible, stirring it with an iron rod till the whole is of an ash-grey colour. The sulphur is driven off, and by a moderate but continued heat the Molybdenum is oxidated. It is then pulverized, and digested in a solution of ammonia in water, by which the Molybdic Acid is taken up. After this solution has remained in a close vessel to deposit its sediment, it is decanted off, and, by dropping in nitric Acid, the Molybic Acid is precipitated in a fine white powder. See subsect. 2.
716 CHEMISTRY.

Chemistry.  [714.] E. F. G. The first of these combinations has been formed, and it is not improbable that the others may be so hereafter.

(715.) H. Molybdenum unites with phosphorus and sulphur.

(716.) I. It may be combined also with all the Metals, those only excepted the volatility of which does not allow of their being exposed to a sufficient degree of heat.

(717.) K. Both the Molybdous and Molybdc Acids are capable of neutralizing bases and forming Salts; but Salts, in which an oxide of Molybdenum serves as a base, have not been recognised; in fact, as these two higher oxides are precipitated by Acids, no such combination with them is to be expected.

(718.) L. An excellent Synoptic Table of the effect of reagents on solutions of Molybdenum is given by Professor Thomson, (a) which we regret we have not space to insert. Perhaps the most marked test is that a drop of muriatic Acid, and a piece of metallic tin, being placed in such a solution, produce a blue colour, and a blue, pulverulent precipitate.

(719.) M. None.

Subsect. 1.—Molybdous Acid.

(720.) For this, not very important, compound we must refer to Bucholz’s Memoir. (b)

Subsect. 2.—Molybdic Acid.

(721.) In a close vessel it fuses and crystallizes, but in an open one it is sublimed, and when again condensed has the form of glittering, yellow scales. It is soluble in 960 parts of boiling water, and the solution reddens litmus. The mineral Acids reproduce the white precipitate. By heat, the Molybdic Acid is soluble in sulphuric Acid, giving a colourless solution, which, however, becomes blue when cold; and this colour is increased by saturating the Acid with soda. It is also soluble in muriatic Acid, but not in the nitric. If to a base, have not been recognised: in fact, as these two higheroxides are precipitated by Acids, no such combination with them is to be expected.

(722.) B. The Metal is obtained by submitting the oxide, mixed with charcoal, to an intense heat. According to Richter, the charcoal from sugar answers best.

(724.) C. Chromium is white, very brittle, capable of a high polish, and, according to Richter, slightly magnetic. Specific Gravity 5.9. Fusible only at very high temperatures.

(725.) D. Chromium is not altered by exposure to the air, but if heated, it is gradually converted into a green oxide. At the three degrees of oxidation with which we are acquainted, it is green, brown, and yellow, or red; in the last state it becomes an Acid.

The green oxide may also be obtained by submitting Chromic Acid to heat, by which it is partly decomposed. When this oxide is precipitated from its solution in Acids, it is of a deep green colour, and contains water, which may be driven off by heat. In its first state it is soluble in Acids, but if subjected to a heat rather below redness, it becomes of a lighter green, and insoluble; yet without losing any of its weight.

The brown oxide may be obtained by dissolving the green oxide in nitric Acid, then evaporate and heat the dry mass until it ceases to give out nitrous fumes. A brown powder remains, which is scarcely soluble in alkalies, and not at all in Acids. If heated with hydrochloric Acid, chlorine is evolved, and the green oxide is produced; which proves that the brown powder was the Metal in a higher degree of oxidation. Chromium, in its third degree of oxidation, forms Chromic Acid, which will be found in subsect. 1.

(726.) E. If metallic Chromium be dissolved in nitro-muriatic Acid, a hydrochlorate of Chromium results; and by desiccation this is converted into a true chloride of Chromium.

(727.) F. G. It is pretty well established that both these elements form Gaseous combinations with Chromium.

(728.) H. In this department few experiments have been made; but Chromium is known to unite with sulphur and phosphorus.

(729.) I. With some of the Metals Chromium has been combined, but with some it seems unwilling to unite.

(730.) K. Chromium is not soluble in the mineral Acids, the nitro-muriatic excepted. In these Acids the green oxide is soluble with difficulty. It is soluble also in the alkalies.

(731.) L. Solutions of Chromium produce a green precipitate with prussiate of Potash; a brown one with infusion of galls; and a green one with hydrosulphurate of potassa.

(732.) M. Perhaps the most beautiful fixed pigments with which we are acquainted, arise from the oxides of this Metal. In miniature-painting, the chromate of lead is highly esteemed; the oxide gives a bright green to porcelain, and imparts the same hue to the glass or paste by which the emerald is imitated. M. Lassaigne has shown that Chromium might be applied with advantage to dyeing and calico-printing. (a) A red subchromate of lead, formed by Dulong, (b) has been proposed by Mr. Badams as a die for cotton. (c)
Subsect. 1.—Chromic Acid.

(733.) Chromic Acid is obtained by the decomposition of either the chromate of lead or of iron. If the former, let it be reduced to a fine powder, and boiled in a fixed alkaline solution, which thus becomes an orange-coloured solution of the alkaline chromate. Add sulphuric Acid and evaporate. The crystals of Chromic Acid may then be separated from the alkaline sulphates. As the chromate of iron is more abundant of the two, it is generally employed for obtaining the Acid, for which the following process is employed. Let the ore be reduced to a fine powder, and mingled with an equal weight of sulphuric Acid and evaporate. The Acid may then be separated from the alkaline sulphates.

The following process is employed. Let the ore be reduced to a fine powder, and boiled in a solution of either the chromate of lead or of iron. If the chromate of iron is more abundant of the two, it is generally employed for obtaining the Acid, for which the following process is employed. Let the ore be reduced to a fine powder, and mingled with an equal weight of sulphuric Acid and evaporate. The Acid may then be separated from the alkaline sulphates.

The Salts formed by Chromic Acid with alkaline, earthy, and metallic bases are highly interesting. All so formed from white oxides are yellow when neutral, or in the state of subsalts, and are reddish yellow when acid. Chromate of lead is yellow; of protoxide of mercury, red; of silver, purple. The chromates of the first and last four classes of Metals are decomposed at high temperatures, leaving oxide of chromium and the base. By great heat, with aid of charcoal, a perfect reduction may be obtained.

The chromates of potassa, soda, ammonia, glycyna, yttria, lime, magnesia, protoxide of nickel and of cobalt, are soluble.

The insoluble chromates with their colours are barytes and strontia, white or yellow; of silver, crimson; of mercury, red; of lead, orange or yellow; of copper, apple green; of iron, brown; of uranium, zine, and bismuth, yellow; of antimony, brown.

With solutions of nickel, zinc, tin, cobalt, gold, or platinum, no precipitate is produced.

References to § 3.

Sect. IV.—Tungsten.

(734.) A. Scheelium, or Wolframium, the Swedish mineral Tungsten, (heavy stone,) was analyzed by Scheele in 1781, who obtained lime and a white pulverulent substance, which he considered a peculiar Acid, and which Bergman supposed to be a metallic oxide. The D'Elhuyarts obtained it also from the mineral Wolfram, and succeeded in reducing it to the metallic state.

(736.) B. The best method for procuring the Metal is that of Allen and Aikin, subjecting tungstate of ammonia to an intense heat. The oxide is reducible by charcoal.

(737.) C. The Metal, from its extreme infusibility, has only been seen in a mass consisting of small agglutinated grains of a greyish-white colour, and some brilliancy. It is so hard as scarcely to be affected by the file. Its Specific Gravity, according to Bucholz, 17.4. It seems to assume a crystalline form on cooling, and not to be affected by the magnet.

(739.) H. The sulphuret has been formed and examined by Berzelius.

(741.) K. Tungstic Acid, as will be seen hereafter, forms Salts by uniting with bases; but Salts, in which any oxide of Tungsten performs the part of a base, have not been recognised.

(742.) L. An ore of Tungsten is recognised by calcining it with its own weight of nitre; a portion of the frit is soluble in water, forming a colourless solution. Nitric Acid throws down a white precipitate, which, by being well washed in boiling water, becomes yellow, and has the properties of Tungstic Acid.

(743.) M. None.

Subsect. 1.—Tungstic Acid.

(744.) The Tungstic Acid of Scheele was in fact a triple Salt, but the true yellow oxide, which appears to possess acid properties, may be thus obtained. Let three parts of Hydrochloric Acid be boiled on one part of Wolfram. The clear Liquid is to be decanted off and left at rest. A yellow powder gradually separates, which is to be redissolved in ammonia; the clear solution, evaporated to dryness, leaves the yellow oxide in a state of purity. It is insoluble in water, and though it does not exert any action upon vegetable colours, it is capable of saturating bases. Good analyses have given such approximations to the theoretical numbers of the Table, that no others need here be given.

Tungstate of lime is found native. The tungstates of ammonia, potassa, soda, and magnesia are soluble, those of lime, barytes, strontia, manganese, and iron are not so.

CHEMISTRY

Sect. V.—Columbium.

(745.) A. In the year 1801 Mr. Hatchett obtained from the analysis of a mineral in the British Museum, similar in appearance to chromate of iron, a new metallic oxide, possessed of acid properties. It had been sent from America, and, therefore, to the inferred metallic base of the oxide, he gave the name of Columbium. Ekeberg soon after discovered in a Swedish mineral a metallic oxide which he considered new, and called Tantalum, from the name of the mineral itself. Dr. Wollaston having examined the substance, found it identical with the Columbium of Hatchett. Columbium occurs in the mineral from Massachusetts, and in the tantalite and yttro-tantalite of Sweden.

(746.) B. Dr. Wollaston’s method for obtaining this oxide from the mineral tantalite is as follows. Mix one part of tantalite with five of carbonate of potash and two of borax, and fuse in a platinum crucible. Soften the mass with water, and digest it in hydrochloric Acid. The iron and manganese are dissolved, and a white powder remains, which is the oxide of Columbium. By subjecting this oxide, mixed with charcoal, to an intense heat, Berzelius reduced it, although unable to produce a bead of fused Metal.

(747.) C. Columbium has a dark-grey colour, is capable of metallic lustre, hard enough to scratch glass, and may be reduced to a dark-brown powder. Its Specific Gravity can scarcely be said to be accurately known.

(748.) D. When heated, Columbium takes fire, and burns feebly to an imperfect-grey oxide. It detones slightly with nitre in a red-hot crucible. The white mass produced by this deflagration is a mixture of oxide of Columbium and potash. The potash may be separated by hydrochloric Acid, leaving behind a hydrous, white oxide, which has the singularity of being soluble in oxalic, tartaric, and citric Acids. After the water has been driven off by heat, this property disappears, and the pure oxide is insoluble in nitric and sulphuric Acids, but imperfectly so in the muriatic. It is capable of reddening vegetable blues, and with potash as a base it forms a crystallizable Salt. This is Columbic Acid.

(749) E. F. G. H. I. Little known, save that it has been alloyed with some other Metals.

(750.) K. Columbium resists the action of hydrochloric, nitric, and nitro-muriatic Acids.

(751.) L. Columbium must be tested in the state of columbic Acid, or a columbate. See, therefore, subsect. 1.

(752.) M. None.

Subsect. 1.—Columbic Acid.

(753.) On this point we may briefly state that Columbic Acid is scarcely at all soluble in water. Insoluble in Acids, save the fluoric. Soluble in acid tartrate of potassa; also in potassa and soda. For the full action of this substance with tests, we must direct the reader to Dr. Thomson’s First Principles. (a.)

References to § 5.

(754.) A. The Ancients obtained with their silver ores an oxide of this Metal, to which the name στιθίμα, or stibium, was applied. Pliny thus speaks of it. In iisdem argenti metallis inventur, ut proprié dicamus, spumæ lapsis candide nitentesq; non tamen transcen
tenta, stimmi appellant, aliī stibium, aliī alabastrum, aliī larbasen.” Lib. xxxii. ch. vi. He enumerates its medicinal virtues, and particularly its application to the eyes. Thus employed as an ornamental pigment, its use is of high antiquity; at least that such a custom prevailed we learn from Ezekiel, ch. xlvii. v. 40., and among the Eastern ladies it is continued to this day. They colour the eyelids black with a substance of which the Arabic name is Kohol, this being some preparation of Antimony. Dr. Thomson has shown, by a singular quotation from Thallinus, that its use was continued in Spain during the Middle Ages, under the name of “piedra de alcohol.” The Alche

mists were well acquainted with the substance, and doubtless received from Arabia or Egypt the name kohol, with the article al prefixed; hence their usual term alcohol, though many other names were given to it from its properties. In 1624, the Currus Triumphalis Antimonii of Basil Valentine, a Monk of Erfurt, appeared. As the title implies, the virtues of this mineral form the subject of the Work. It is not improbable that through him, or some one in his time, the word Antimony came into use. Legends tell that the Monkish experimentalist, who practised as a Physician, made trial of its virtues upon the hogs of the Convent. The medicine acted as a brisk cathartic, and the pigs speedily fattened. Encouraged by this happy result, he administered it to some of his brother Monks; but the dose being too violent it proved fatal, and hence the name āvit mortuos, or “Anti-moine.” It is found but sparingly in the state of an oxide, but very abundantly as a sulphuret, which ore is the crude Antimony of Commerce; also in native crystals of considerable purity.

(755.) B. Antimony may be obtained from its sulphuret for the purposes of the laboratory by mixing three parts of the ore with two of tartar and one of nitre; this powder is to be gradually projected into a hot crucible, which is then exposed for three-quarters of an hour to a furnace or forge-heat. On cooling, the button of Antimony is found at the bottom of the crucible. By this process the Metal is not obtained in a state of great purity; for delicate purposes it must be revivied from the oxide. Thenard suggests the passing a current of hydrogen over the oxide in a heated porcelain tube, as the most unobjectionable method.

(756.) C. In colour, Antimony is greyish-white, with considerable brilliancy. Its texture is laminated and
Chemistry. imperfectly crystalline. According to Haüy, (a.) the primary form is an octahedron. By friction it communicates to the fingers a peculiar taste and smell. Its hardness nearly equals gold. Its Specific Gravity, according to Hatchett, is 6.71. It is so brittle as to be easily pulverized. According to Muschenbroeck, a wire one-tenth in diameter supports a weight of about ten pounds. It fuses at about 810° of Fahrenheit, and is volatilized by greatly increased heat; but from the experiments of Thenard it would appear that the Metal is fixed if air be excluded, and that the volatilization which takes place is that of the oxide.

(757.) D. There is considerable difference of opinion as to the number of oxides which Antimony is capable of forming, but of three at least there is good evidence. By exposure to air or water, the Metal undergoes no alteration, but at a red heat it decomposes steam with such rapidity as to produce a violent explosion.

1. The protoxide is a white or grey powder, easily fusible. It may be obtained by dissolving the Metal in hydrochloric Acid, and diluting the solution largely with water; a white precipitate is obtained; which, after being well washed, is to be boiled in a solution of carbonate of potassa, to remove an adhering portion of hydrochloric Acid. This powder, when again washed and dried, is the protoxide.

2. The hemidioxide (deutoxide of some) is a fine white powder, not so fusible as the former, nor so easily soluble in Acids, and insoluble in water; it is obtained by heating the protoxide in an open vessel nearly to redness. It takes fire, when heated, and is converted into the oxide. It is produced also by the action of hot nitric Acid upon Antimony. By heating the Metal in a furnace with free access of air, a white oxide is sublimed, (argentine flowers of Antimony,) which Thomson considers to be this, while Thenard asserts that it is the former oxide.

This oxide possesses acid properties, and combines with bases producing the Antimonites. It has been called Antimonious Acid. See subsect. 1.

3. The remaining known oxide, the deutoxide, (peroxide of some,) is also an Acid, and called the Antimonic. See subsect. 2. It may be formed by mixing six parts of nitre and one of Antimony in a silver crucible, and exposing it to a low red heat for an hour. The excess of alkali is to be washed off with a little cold water. Digest the remaining powder in hot water, which will dissolve a part. From this solution, acetic Acid precipitates a hydrate of antimonous Acid. The water may be driven off by a gentle heat, and the powder thus obtained is incapable of combining with Acids, but readily combines with bases to form Salts; by a red-heat it is converted into the preceding oxide.

Of the constitution of these oxides no very decided account can be given, the reader is therefore referred to the Table for the nearest theoretical assumption.

The antimoniate of potassa is formed in the above process, and many metallic antimonianes exist, but have not yet been made the subject of investigation.

(758.) E. The action of chlorine upon this Metal produces the following beautiful experiment. Into a stopped glass jar containing chlorine, pour, by means of a funnel, some finely powdered Antimony, which has been previously warmed. The rapid combination produces a beautiful shower of fire within the jar.

(759.) F. Unexamined.

(760.) G. Iodine combines with Antimony, but by water is again separated into hydriodic Acid, and the white oxide.

(761.) H. With carbon, boron, silicon, azote, and hydrogen, we know of no compound, but with phosphorus, sulphur, and selenium, it readily unites.

(762.) I. With the Metals it readily unites, and generally to the destruction of their ductility.

(763.) K. Boiling sulphuric Acid undergoes a violent action upon Antimony; it is decomposed, giving out sulphurous Acid Gas; an imperfect sulphate is produced, which, however, is decomposed by a plentiful effusion of water, and the white oxide of the Metal subsides to the bottom.

The sulphurous Acid has no action upon Antimony, but it decomposes many of its Salts. From the hydrochlorate, a white precipitate is produced, which, according to Aikin, is a true sulphate of Antimony.

Upon this Metal, nitric Acid, even when cold, undergoes rapid decomposition; nitrous Gas is evolved, and a white oxide is produced. If the Antimony be reduced to fine powder, and mingled with just Acid enough to form a paste, the action is so violent as to cause inflammation. Another singular consequence of the partial decomposition of the water, together with that of the Acid, is that the liberated hydrogen of the former unites with the azote of the latter, and ammonia is produced. The addition of a small quantity of fixed alkali or caustic lime will disengage the Ammonia, which may be recognised by its pungency, or by the fumes of hydrochloric Acid.

The hydrochloric Acid dissolves Antimony, but in very small quantity; on the oxide its action is much greater; a thick, honey-like substance is the result, which formerly went by the name of Butter of Antimony, and is a highly corrosive substance.

Strong nitromuriatic Acid dissolves this Metal in considerable quantity, but the whole is again precipitated in the state of an oxide by water.

From all these instances we may fairly conclude that Antimony, when oxidated in the higher degrees, can no longer as a base unite with Acids to form Salts; but it may assist in the formation of Salts with certain bases, to which it performs the part of an Acid.

The only true Salts of Antimony then contain the protoxide; of the mineral Acids there probably are few if any, as their own decomposition furnishes oxygen for the formation of the insoluble white oxide. From the vegetable Acids, the acetate, succinate, benzoate, oxalate, and tartrate have been described. One triple Salt, however, claims peculiar notice, as the Tartar Emetic of Medical writers. It consists of tartaric Acid, potash, and protoxide of Antimony. Alkalies, alkaline earths, sulphurets, several metals, and astringent vegetable decoctions, decompose it. With any of these, therefore, it ought never to be conjoined in a prescription.

The solutions of the Salts of this Metal are generally yellow, and precipitable by water. Prussiate of potassa and tincture of galls give a white precipitate, but only from their water determining the deposition of the white oxide. From hydrosulphurets, a yellow precipitate is produced. A plate of iron or zinc throws down the Metal in the state of a black powder, especially if the solution be acidulated.

(764.) L. In the Arts an alloy of this Metal with lead is used for the plates upon which music is
Chemistry, engraved; and with tin it forms one kind of pewter. It enters also with lead and copper into the composition of printers' types. Its oxide assists in the vitrification of earths, and gives to glass an amethystine hue. Combined with oxide of lead, it forms a paint called Naples yellow, and enters into some enamels. Of its application to medicinal purposes the tartrate has been noticed. The Glass of Antimony of the old Pharmacopoeia is a fused sulphuret. The Kermes Mineral is an hydroxysulphuretted oxide. The celebrated Fever-powder of Dr. James appears, from the analysis of Dr. Pearson, (b) to be a combination of phosphate of lime with oxide of Antimony, which is imitated in the Pato. Antimonialis of the Materia Medica.

Subsect. 1.—Antimonious Acid.

(765.) If Antimony be burned or strongly heated in an open vessel, an oxide is formed, the constitution of which is at once expressed by our term of the hemideutoxide; it is condensed upon any cold surface in the form of shining, white, acicular crystals. This substance was formerly called Argentine flowers of Antimony. It unites with alkalis to form a class of Salts.

Subsect. 2.—Antimonic Acid.

(766.) Dr. Thomson obtained this Acid by dissolving pure metallic antimony with nitric Acid in a platinum crucible. The solution was evaporated to dryness, and exposed for some hours to a heat of 500° Fahrenheit. This acid oxide is a yellow powder, and is converted by a red heat into the oxide preceding. The same able Chemist has suggested, and with great probability, that the hemideutoxide is a compound of one atom of the protoxide—one atom of the deutoxide. Berzelius formed and described the Antimoniate of potassa.

References to § 6.

Sect. VII.—Uranium.

(767.) A. On examining a Saxon mineral called Pechblende, Klaproth, in 1789, discovered that it was the sulphuret of a new Metal. Herschel had just discovered his new Planet, and as the German Astronomers gave to it the name of Uranus, the Chemist gave to his new Metal the name of Uranium. The beautiful green uranite of Cornwall is an hydrated oxide of this Metal.

(768.) B. To obtain the Metal from pechblende by digestion in nitric Acid, the Uranium, iron, copper, and lime are taken up. Evaporate to dryness, and redissolve in water, which will leave the peroxide of iron. By digestion in ammonia the Uranium is precipitated, and the copper retained in solution. The precipitate is to be again dissolved in nitric Acid, evaporated and crystallized. The green crystals are picked out, slightly washed, dissolved in water, and, by a second crystallization, they are supposed to be obtained free from the lime. By exposure to a red heat a yellow, pulverulent oxide remains. This oxide, mixed with one-twentieth of charcoal powder, and exposed to intense heat, is reduced. In this, and probably in many other cases, too much charcoal should not be employed.

(769.) C. Thus obtained, Uranium is not a very compact button, as a much greater heat is required for its perfect fusion than our furnaces can produce. Its physical properties are little known; it yields to the file; and, according to Professor Clarke, of Cambridge, a pure bead, produced by acting upon the nitric green oxide with the Gas blowpipe, was brittle.

(770.) D. At a red heat, in an open vessel, Uranium is converted into a greyish-black powder, which, by continued heat, is unaltered, and is the protoxide. The yellow powder, above described, is the deutoxide, which is also obtained by precipitation from the nitrate by an alkali.

It would appear from recent experiments, especially those of Dr. Thomson (a.) and Arfwedson, (b.) that the higher oxide of Uranium is, in fact, possessed of acid properties, and can neutralize bases. The constitution of the oxides of Uranium is by no means well settled; for, supposing the dark-green oxide to be a protoxide, it remains doubtful whether the yellow oxide is a hemideutoxide, or a deutoxide: Thomson is of the latter opinion.

(771.) E. F. G. Little studied, or unknown.

(772.) H. Bucholz succeeded in forming an artificial sulphuret of Uranium.

(773.) I. Nitric Acid readily dissolves Uranium, or its oxide; and by evaporation, a crystallized nitrate, of a lemon-yellow colour, is obtained. It is deliquescent, very soluble in water, and moderately so in ether, but shortly undergoes decomposition. A sulphuric acid, insoluble in water, is described by Bucholz. Sulphuric Acid has very little action on Uranium. But it dissolves, with some difficulty, the oxide, if assisted by heat, and a crystallized sulphate may be obtained. Berzelius describes a seleniate and biseleniate. The phosphate, arseniate, tungstate, molybdate, and tartrate may be found by precipitation from a Salt of Uranium with Salts of these Acids. Richter obtained also the borate, oxalate, citrate, malate, benzoate, and succinate. Acetic Acid dissolves the oxide, and forms a crystallizable salt soluble in water.

Besides these Salts, in which oxides of Uranium constitute the base, it is quite well established that the yellow oxide of Uranium performs the part of an Acid also to certain bases. See subsect. 1.

(774.) K. For the reagent effects of Uranium, consult a valuable series of facts given in Thomson's First Principles, vol. ii. Generally speaking, the caustic alkalis give yellow precipitates with Salts of Uranium not soluble in excess of alkali; with their carbonates a white one, which is soluble in excess. Prussian of potassa a dark, red-brown precipitate.

(775.) L. With proper fluxes the oxide of Uranium gives an orange colour to porcelain.

Subsect. 1.—Uranic Acid.

(776.) To preserve the uniformity of our plan we introduce this name. Uranate of barytes is described
Sect. VIII.—Cerium.

A. In the year 1750, a mineral, having considerable resemblance to tungsten, was found in the copper-mine of Bastnäs in Sweden. Bergman published an attempt at its analysis by MM. D’Elhuyart, by which it was proved not to be tungsten. Klaproth afterwards declared it to contain a new earth, which he called Ochrolia. Hissinger and Berzelius made a more complete examination of the substance, and, considering it a metallic oxide, they gave it the name of Cerium, from the coincidence of the discovery of the Planet Ceres about the same time. It has subsequently engaged the attention of Vauquelin, Thomson, and Laugier. Three minerals contain this substance, two from Sweden, and one from Greenland.

B. Cerium is best obtained by the process of Laugier. The mineral Cerite is dissolved in nitric acid; a precipitate is produced by ammonia, which is washed and, while still moist, is treated with a solution of oxalic acid, which dissolves out the oxide of iron which had been thrown down; the remaining powder is, after calcination at a red heat, pure oxide of Cerium. Several attempts have been made to reduce this oxide to the metallic state, but with partial success; for though a metallic powder has been produced, it has never been formed into a mass, so that its physical properties are almost unknown. Sir H. Davy effected the decomposition of the oxide of Cerium by the action of potassium.

C. M. Vauquelin obtained some small grains of metallic Cerium, which were brittle and of a white colour. According to Messrs. Children and Thomson, Cerium may be volatilized by a very intense heat. Lehman, Christopher Schurer, a glass-maker at Platten, was the first to use it thus in about 1540. Cobalt is found in several states of mineral combination, and is almost constantly attended by arsenic.

D. If Cerium be dissolved in nitric acid; the solution neutralized with caustic potassa; then precipitated by tartarate of potassa; and lastly, after washing, be calcined, oxide of Cerium is obtained. This is Cerium in its highest degree of oxygenation. The two oxides of this metal would seem to be a protoxide and a hemideutoxide.

E. F. G. Unknown.

H. Laugier obtained a carburet of Cerium; and there is reason to suppose that a phosphuret may be formed. Also a sulphuret by indirect processes.

I. According to Gahn, Cerium would not unite with lead; but Vauquelin succeeded in forming an alloy with iron.

K. According to Vauquelin, the reduced metallic powder is insoluble in all unmixed Acids, and not easily so in even the nitro-muriatic. The oxides are soluble in most Acids. The Salts of the protoxide at present known are the protonitrate, protosulphate, protocarbonate, protoselenate, and protoxalate. Those of the red oxide are, the nitrate, sulphate, seleniate, and oxalate. There also exist combinations of oxide of Cerium with the phosphoric, arsenic, molybdic, acetic, benzoic, succinic, tartaric, and citric Acids; but of the state of oxidation of the Metal in these cases we are not well assured; for the most part they seem to contain the protoxide. A double Salt of sulphuric acid with potassa and oxide of Cerium, is described by the Swedish Chemists.

L. Of the protoxide, the Salts are colourless, or white; and of the peroxide they are yellow. Their solutions in water have a sweet taste. Gallic acid and hydrosulphuric acid gas give no precipitate. Hydro-sulphuret of potash and prussiate of potassa give a white precipitate. Oxalate of ammonia produces a white precipitate soluble in nitric and hydrochloric Acids. Tartrate of potash gives no precipitate, but arseniate of potash gives a white precipitate. "Succinate of ammonia does not precipitate Cerium from the acetate, which furnishes a ready means of separating iron from Cerium."

References to § 8.

Sect. IX.—Cobalt.

A. Cobalt was recognised as a distinct metallic substance by Brandt in 1733, but had long been used to give a blue colour to glass. According to Lehman, Christopher Schurer, a glass-maker at Platten, was the first to use it thus in about 1540. Cobalt is found in several states of mineral combination, and is almost constantly attended by arsenic.

B. For commercial purposes, the Cobalt ore is roasted; by which volatile and fusible substances are removed, and some silica within an impure oxide remains, which is called zaffire. Many processes have been recommended for obtaining pure Cobalt; one of the best is as follows. Reduce zaffre to the metallic state, by mixing it with thrice its weight of black flux, a little oil, and a little salt; expose this mixture to a strong heat in a crucible for some hours, and a button of Cobalt will be found at the bottom of the crucible. In this state it is usually alloyed with iron, copper, nickel, and arsenic. Pulverize the metallic button, and calcine with four parts of nitre; after which hot water will remove the arseniate of potassa. Dissolve the residuum in dilute nitric acid, and precipitate the copper by a plate of iron. By filtering, evaporation to dryness, and digestion in hydrate of ammonia, the oxides of nickel and Cobalt will alone be taken up. Expel the excess of ammonia by heat, and add dilute hydrate of potassa, which will precipitate the nickel. By immediately filtering and boiling the clear liquor the oxide of Cobalt is precipitated, and may be reduced by subjecting it to a strong heat with charcoal and a little oil.

C. Thus obtained, Cobalt is of a reddish-grey colour, of a fibrous or laminated texture. Brittle, but said to be malleable when heated. Its Specific Gravity has been stated at from 7.7 to 5.7. It is not
**Chemistry**

and, after fusion, may, by care, be obtained in a crystalline form. Like iron and nickel, it possesses permanent Magnetic properties.

(790.) D. Cobalt at a red heat in an open vessel undergoes oxidation. The protoxide is however best obtained by dissolving the Metal in nitric Acid, and precipitating by hydrate of potassa: the precipitate is at first blue, but becomes black, and is the higher oxide of this Metal. By exposing this oxide to a low red heat, one portion of oxygen is driven off, and protoxide, which has a beautiful blue colour, is produced.

(791.) E. The chloride may be formed by gently heating filings of the Metal in chlorine; it is also formed by evaporation of the hydrochlorate, and is a very definite compound.

(792.) F. G. The iodide and fluoride are unknown.

H. The phosphauret, sulphurauret, and sele- niuret, have been examined, but of any combination with carbon, boron, silicon, hydrogen, or nitrogen, we are ignorant.

(794.) I. Cobalt has been alloyed with gold, platinum, tin, copper, iron, antimony, arsenic, and lead; but it would scarcely, if at all, unite with silver, mercury, bismuth, or zinc.

(795.) K. As we have before seen, Cobalt is soluble in nitric Acid when heated, and red prismatic crystals may be obtained.

The muriatic Acid attacks this Metal but with great difficulty, and the solution was formerly known by the name of Hellot's Sympathetic Ink; a better Salt for this purpose will, however, be described hereafter. The oxide is readily soluble.

At a boiling heat, sulphuric Acid is decomposed upon Cobalt, and a soluble sulphate remains, but the oxide is not very soluble in this Acid. Carbonate, borate, sele- niate, arseniate, antimoniate, antimonite, oxalate, and tartrate of Cobalt, may be formed by precipitation where the Salts are neutral. Oxalate of Cobalt attacks and dissolves metallic Cobalt, but phosphoric, fluoric, tar- tarcic, and acetic Acids, only dissolve the oxide. The Acetate of Cobalt forms an excellent sympathetic ink, by which if anything be written or painted upon paper, it is invisible when cold, but becomes of a fine azure blue when exposed to heat. The most probable cause that has been assigned for this change is, that, when suffered to cool, the muriate or acetate of Cobalt, being very deliquescent, absorbs moisture, and undergoes a sufficient dilution to be colourless; but that by heating they become concentrated, and the green or blue colour is developed. This view of the matter is confirmed by the fact, that the same colour is produced by exposing the washed paper to the absorbent action of quick-lime, or sulphuric Acid in an exhausted receiver.

Neutral solutions of the Salts of Cobalt are generally of a reddish colour.

(796.) L. In neutral solutions of Cobalt the alkalies produce a blue precipitate, prussiate of potassa a light-green one. Hydro sulphuric Acid gas no precipitate; but hydro sulphuret of potassa a black one, soluble in excess of the precipitate. Gallic Acid produces no change, but tincture of gall gives a white precipitate. Metallic zinc produces no precipitate, neither does its hydriodate, nor that of potassa.

(797.) M. Cobalt is employed in the Arts to give a blue colour to glass, enamel, and porcelain. Zaffre has been already described, but as it is found in Com- mence it is always mixed with two parts of powdered flint.

Small is a finely pulverized glass, coloured by oxide of Cobalt. Aikin states that so high is the colouring power of this metallic oxide, that one grain will give a full blue colour to 240 grains of glass.

Sect. X.—Titanium.

(798.) A. In the year 1791, the Rev. Mr. Gregor published the analysis of a black sand found in the parish of Menachan in Cornwall. Finding that it contained the oxide of a new Metal, it received the name of Menachine from Kirwan. Little interest was excited till, four years afterwards, Klaproth discovered that what was called red schorl consisted of the same oxide nearly in a state of purity. To the Metal he gave the name Titanium, which is generally adopted. It has since been found in anatase, iserine, and sphene, and frequently forms those beautiful brown filaments which traverse rock crystal.

(799.) B. The native red oxide is not soluble in Acids, but may be decomposed by fusion with two parts of potash, or six parts of its carbonate. The fused mass is to be digested in dilute hydrochloric Acid, which is to be decanted off when it has removed all the soluble part. To this hydrochloric solution, oxalate of ammonia is to be added; by which, oxalate of Titanium is precipitated, while the iron remains in solution. By calcination, the vegetable Acid is destroyed, and a yellow oxide remains, which becomes white on cooling. The reduction of this oxide has proved of the utmost difficulty, and has been frequently attempted without success. By forming the oxide into a paste with oil, and exposing it to a most intense heat, Laugier appears to have effected it.

(800.) C. The colour of the Metal produced was that of gold; it was brittle, but in a slight degree elastic, having considerable lustre, but highly insusceptible; according to Vauquelin it may be volatilized by an intense heat.

(801.) D. When heated with access of air, it changes its colour and undergoes oxidation, forming a blue powder, which is said to be the first oxide. The native red schorl is the second, and the last is the white powder already described.

This powder has feeble acid properties; hence it has been called Titianic Acid. (Subsect. 1.)

(802.) E. Metallic Titanium unites with chlorine; and it would appear that two chlorides of Titanium exist. (a.)

(803.) F. G. Unknown.

(804.) H. Sulphur was united with Titanium by Rose, and with phosphorus by Chenuoeix.

(805.) I. Vauquelin and Hecht were unable to alloy Titanium with silver, copper, lead, or arsenic; but
CHEMISTRY.

By Dr. Wollaston obtained similar results.

(806) K. Though nitric Acid has little action on either the Metal or the red oxide, it will, if aided by heat, dissolve the carbonate, and a crystallized nitrate may be obtained, provided that the Metal be in its first degree of oxidation. The Metal is soluble (though the red oxide is not) in hydrochloric Acid, and a Salt forming cubic crystals is produced; but according to Vauquelin a gelatinous mass is produced by evaporation, which by increased heat is decomposed, chlorine is liberated, and an oxide precipitates, which is insoluble in hydrochloric Acid, but yields to the nitric. Hence it is inferred that the hydrochlorate contains the white oxide and that no combination can exist between this Acid and the proto-oxide. Boiling sulphuric Acid oxidizes and dissolves the Metal, but affects not the red oxide; it acts readily on the carbonate, but this metallic sulphate has not as yet been seen in a crystalline form. The phosphoric and arsenic Acids, if added to the solutions of this Metal, produce insoluble white precipitates. The carbonate is formed by fusing together six parts of carbonate of potassa and one part of the red oxide; the mass is to be well washed with water, and the insoluble white powder remaining is the Salt. Oxalate and tartaric Acids produce also white precipitates, but these are again redissolved by any excess of Acid.

The Salts are colourless, and have different degrees of solubility.

(807) L. Alkaline carbonates produce a white flaky precipitate, prussiate of potash a grass-green inclining to brown; "but if an alkali is added after the prussiate, the precipitate becomes purple, then blue, and at last white." Hydrosulphuret of potash produces a dirty-green precipitate; sulphuretted hydrogen produces none at all; infusion of galls a bulky reddish-brown precipitate. A rod of tin immersed in a clear solution of Titanium becomes gradually surrounded by a fine red cloud, and a rod of zinc by a blue one.

(808) M. In the Arts, Titanium has been sparingly employed to produce a brown or yellow colour on porcelain.

Subsect. I.—Titanic Acid.

(809) The existence of this Acid is doubtful, for Rose has stated that he could not detect true acid properties in the oxide of Titanium; we leave it, however, for future examination.

Sect. XI.—Bismuth.

(810) A. Bismuth was unknown to the Ancients, but appears to have been early recognised by the German miners. According to their speculations it was an imperfect silver, but by the successive researches of Chemists it was first deemed an alloy, and at length recognised as a peculiar Metal. It is found native, but contaminated with arsenic, as an oxide, and as a sulphuret.

Vol. IV.

(811) B. Being easily fusible, it is separated from its ores by subjecting them to the heat of a furnace in iron tubes, inclined so that the Metal may run out at one end.

(812) C. In colour, Bismuth is reddish-white, and has a laminary structure. In hardness it is inferior to copper. According to Hatchett its Specific Gravity is 9.622. It is not malleable, nor of great tenacity. Its fusing point is 451° according to Berzelius, but Gay Lussac makes it as high as 541. If a mass of Bismuth, fused in a crucible or ladle, be suffered partly to congeal, and the fluid portion be poured off from the other, a very beautiful crystallization is seen in rectangular parallelopipeds. The primary form, according to Hauy, is an octahedron. (Jour. de Mines, An. 5.) It has long been said that, by increased heat, Bismuth may be sublimed; this, however, is denied by Thenard.

(813) D. The action of air or water is not alone sufficient to produce oxidation, but by continuing the Metal in a state of fusion with free access of air, a film of oxide forms upon the surface. At a strong red heat it takes fire, emitting a yellow smoke, which when condensed is no longer volatile, and forms the yellow oxide of Bismuth. It is tasteless, and insoluble in water, but fusible.

(814) E. If Bismuth, finely powdered, be introduced into chlorine it takes fire, and the metallic chloride is produced.

(815) F. Unknown.

(816) G. Iodine, by the aid of heat, enters into combination with Bismuth, and this iodide, though insoluble in water, may be dissolved in caustic potassa without precipitation.

(817) H. Bismuth combines readily with sulphur and selenium, scarcely, if at all, with phosphorus, and not with hydrogen or carbon.

(818) I. All Metals seem capable of uniting with this to form alloys, and in general a great increase of fusibility is the result. Newton's fusible Metal is a striking example, consisting of eight parts of Bismuth, five of tin, and three of lead. It melts at a heat considerably below that of boiling water, and the addition of one part of mercury adds still more to its fusibility.

(819) K. The action of nitric Acid upon Bismuth is very violent, much nitrous Gas is evolved, and the Metal undergoes oxidation. With slightly dilute Acid a soluble nitrate is produced, which on cooling is precipitated in small crystals.

Cold sulphuric Acid exerts no action upon Bismuth, but, by the assistance of heat, the Metal is converted into a white powder, and sulphurous Acid is evolved. By washing with a small quantity of water, a portion of the metallic sulphate is carried off, and may be obtained by evaporation.

Arsenic Acid digested upon this Metal with a moderate heat, converts it into a white powder, which is arsenate of Bismuth.

Hydrochloric Acid, if heated, acts upon Bismuth, and very readily on its oxide, and a crystallizable hydrochlorate is produced, which is, like the nitrate, precipitable by water; by the action of heat the muriate becomes a chloride, which, according to Dr. J. Davy, is not volatile.

The following Acids, though producing little or no effect upon this Metal, combine with its oxide, and produce Salts; viz. the carbonic, boric, phosphoric, sulphurous, molybdic, oxalic, acetic, and tartaric, which
are all scarcely, if at all, soluble in water. The benzoic and succinic form soluble Salts. There is, according to Morveau, this singularity on the part of acetic Acid, that its presence prevents the precipitation of Bismuth from its nitric solution by water. The formation of the above mentioned Salts is best effected by adding a solution of the Salt of potash with the given Acid to the nitric solution of the Metal.

(820.) L. In all the acid solutions of Bismuth, (acetic?) the addition of water produces a white precipitate, consisting of the metallic oxide generally united to a small portion of Acid; thus the white powder falling from the nitrate is an oxide containing a little nitric Acid. Prussiate of potash gives a white precipitate, and infusion of galls a yellowish one. By hydriodic Acid a chocolate precipitate, sulphuretted hydrogen a dark brown. By a plate of copper or tin a precipitate of the pure Metal is produced.

(821.) M. In the Arts, Bismuth enters in the composition of soft solders. An alloy of two bismuth, one lead, one tin, and four mercury, is used for silverting the inside of glass globes. The interior of the globe is well dried, and a small quantity of the alloy introduced; by immersion in hot water it melts, and by turning the globe about, a sufficient coating adheres to its inner surface. The flake white of painters is the precipitate from the nitrate by water, formerly called Magistery of Bismuth, and the pearl-white is said to be a similar precipitate from the hydrochlorate or tartrate. It is proposed to use it instead of lead in assaying.

References to § 11.

Sect. XII.—Copper.

(822.) A. This Metal, occurring frequently in the native state, was one of the earliest known to the Ancients: alloyed with tin it formed the bronze of which ancient weapons were made before iron was obtained in sufficient quantity to be applied to this purpose. The armour of the warrior at the siege of Troy was of bronze, and the knives of the ancient Egyptians were found by Dr. E. D. Clarke to consist of the same alloy.

Copper is found in a state of native purity, as an oxide and sulphuret, and also as a Salt, carbonate, hydrochlorate, phosphate, sulphate, and combined with many other substances.

(823.) B. Various processes are employed for extracting this Metal from its ores. The sulphurets are roasted in reverberatory furnaces, once, or oftener, as the case may require; and, finally, reduced by heating them in an appropriate furnace with small-coal. To render it sufficiently pure for sale, it is remelted, and granulated by falling into cold water several times over; and lastly, refined by again fusing it with charcoal powder. Pure Copper for Chemical purposes is best obtained by placing a plate of iron in a slightly acid solution of Copper; the Metal is deposited in the form of a fine, brown powder, which is to be washed with a little dilute sulphuric Acid, to remove any adhering iron.

(824.) C. Copper has great brilliancy, and a fine red colour. It acts disagreeably on the organs both of smell and taste. Specific Gravity 8.60—8.69, Hatchett. It is harder than silver; has such malleability as to be beaten out into extremely thin leaves. Its tenacity is very great, according to Mr. Rennie: (Phil. Trans. 1818;) a wire of cast Copper, one-tenth of an inch in diameter, is broken by a weight of 190.7 pounds, and one of the same size of hammered Copper would be broken by a weight of 337.9 pounds; these results are calculated from experiments on longer bars. (Thomson.) Copper is calculated to melt at 1450° Fahrenheit, and is volatilized by increased heat. By slowly cooling it, Mongez obtained crystals in the form of quadrangular pyramids.

(825.) D. This Metal does not decompose water at ordinary temperatures, or its vapour at a red heat, but by long exposure to air and moisture a mixture of carbonate and oxide is formed upon its surface, (verdigrise.) By heating a plate of Copper to redness in atmospheric air, a red oxide is formed at the surface, and may be detached in laminae. Two oxides of Copper are well known to Chemists, and a third is admitted by Thenard. To obtain the lowest oxide, dissolve the Metal in hydrochloric Acid by the assistance of heat. Let this green solution be put into a phial with some metallic Copper, and cork it closely. The Liquid gradually acquires a brown colour, and deposits crystals like grains of sand. By adding hydrate of potassa to a solution of these in water, the orange-coloured oxide is precipitated. (Chenevix, Phil. Trans. 1806; Berzelius, An. de Ch. vol. lxxviii.)

The scales above described as forming upon the surface of heated Copper, are composed of the higher oxide, but retain some particles of Metal. By exposure to heat the whole becomes a uniform black powder. The same substance is obtained by precipitating a solution of Copper in nitric Acid, with a caustic, fixed alkali: and exposing the precipitate to a red heat to drive off the water.

The black oxide last described is chiefly found in the Salts of Copper, and was heretofore considered the highest oxide; but Thenard obtained, by means of an oxygenated Acid, a still higher oxide of this Metal. (a.)

If with Thomson, Prout, and Wollaston we consider the atom of Copper = 62, the constitution of these oxides will be,

<table>
<thead>
<tr>
<th>Oxygen</th>
<th>Copper</th>
</tr>
</thead>
<tbody>
<tr>
<td>The red oxide = 8 or one atom + 64 or two atoms,</td>
<td>The black oxide = 8 or one atom + 32 or one atom,</td>
</tr>
<tr>
<td>forming a suboxide, and an oxide.</td>
<td>forming a protoxide and a deutoxide.</td>
</tr>
</tbody>
</table>

But if with Thenard we call the atom of Copper = 64,

<table>
<thead>
<tr>
<th>Oxygen</th>
<th>Copper</th>
</tr>
</thead>
<tbody>
<tr>
<td>The red oxide = 8 or one atom + 64 or two atoms,</td>
<td>The black oxide = 16 or two atoms + 64 or one atom,</td>
</tr>
<tr>
<td>forming a suboxide, and an oxide.</td>
<td>forming a protoxide and a deutoxide.</td>
</tr>
</tbody>
</table>

Thenard could not fix the constitution of his higher oxide.

(826.) E. Chlorine readily combines with Copper-filings, forming a volatile chloride and a fixed subchloride of the Metal. These two compounds may also be obtained by evaporating the sub-hydrochlorate and the hydrochlorate of the Metal respectively.

(827.) F. Unexamined.

(828.) G. The iodide of Copper is a brown, insoluble powder, formed by adding hydriodic Acid to solutions of the Metal, or by heating Copper in contact with iodine.

(829.) H. Copper readily unites with phosphorus.
Tellurium.

Its carburet was not supposed to exist, but Priestley obtained it by passing the vapour of alcohol through a copper tube; the discovery is confirmed by Vau Marum. (b.) Boron, silicon, hydrogen, and nitrogen, do not seem as yet to have been united to this Metal.

I. Alloys of Copper are of frequent occurrence in the Arts. Alloys have also been formed with potassium, sodium, arsenic, iron, (with difficulty,) nickel, cobalt, manganese, zinc, (common brass,) cadmium, tin, bismuth, and lead; but in the last case the union is so imperfect that, by heating the alloy to such a temperature as to fuse the lead, it runs out leaving the Copper nearly pure. This is curiously seen in heating Roman coins.

K. Let it be remembered that almost all the Salts of Copper contain the black oxide of the Metal. The action of nitric Acid on Copper is very violent, nitrous Gas is evolved, and the solution produces a blue crystallizable Salt. No nitrate of the suboxide exists, as by the action of nitric Acid on the suboxide, one portion of Copper falls down in the metallic state, and the other portion receiving its oxygen, a solution of the proto-nitrate remains. Without heat, concentrated sulphuric Acid has no action on Copper, but at a boiling heat the Acid is partly decomposed. Sulphurous Acid Gas escapes, and a soluble sulphate is produced. The common blue vitriol of Commerce is a bisulphate. For a description of the numerous Salts of Copper, we must refer to the more complete Systems of Chemistry.

L. Solutions of Copper are changed to a deep blue colour by addition of ammonia. Prussiate of potassa gives a reddish brown precipitate, the hydro-sulphurets a black, and gallic Acid a brown one. A plate of iron throws down the Copper in the metallic state.

M. A few of the Salts with oxide of Tellurium as a base have been examined by Berzelius; these are the sulphate, hydrochlorate, and nitrate. The same Chemist has also examined the tellurates, and described those of potassa, ammonia, lime, barytes, copper, iron, and lead. Telluric Acid as a Subsection. Hydro-Telluric Acid Gas. It unites also with sulphur and carbon.

Sect. XIV.—Lead.

A. Of the first discovery of Lead we have no record, but it has been known from the very earliest times, as we find it frequently mentioned in the Mosaic writings. The Alchemists found reasons for identifying it with Saturn, under whose name they spoke of it, and by whose symbol they represented it. Lead is rarely found native, but it forms a part of several compound minerals. Its sulphate, carbonate, phosphate, chromate, and molybdate, are found in greater or less abundance; but it is from the sulphuret, (galena,) a very abundant ore, that this useful Metal is principally obtained.

B. The processes for obtaining Lead from its native sulphuret differ in some particulars, which depend upon the nature and richness of the ore. In general, the ore is triturated and washed in running water to remove as much as possible of the earthy impurities. It is then roasted to drive off a part of the sulphur, and subsequently fused with charcoal or lime, for the complete reduction of any oxide that may be formed; or for the final separation of any sulphur which may remain in combination. The galena is however often sufficiently rich in an accompaniment of silver, to make it worth while to submit it to a further process for the extraction of that Metal. It is remarked, that that galena which has a fine-grained fracture, exhibiting small, bright, curvilinear facets, is the richest in precious Metal. (a.) (b.)

C. The colour of Lead is a bluish white.
When in fusion it is bright like quicksilver, but rapidly tarnishes and becomes covered with a crust of oxide. By exposure to air it becomes dim in a few hours, acquiring a thin surface consisting of a carbonated oxide, and then undergoes no further change. Lead can scarcely be said to make any impression on the nerves of taste, but it develops a slight smell upon friction. It produces a bluish streak upon white substances. Few Metals are less hard, for it yields to the nail. Its tenacity is by no means considerable, for, according to Mr. Rennie’s experiments, a wire 25 inches in diameter supported only 114 lbs. (c.) The ductility of Lead is not great, though it may with care be formed into wire; and it scarcely can be said to possess any elasticity; but its malleability is rather considerable. According to Newton, the fusing point of Lead is about 540° Fahrenheit. Irvine found it 594°, (d.) and Clerk of Glasgow, states it to be 612°. (e.) By increased heat, the Metal boils and is volatilized. By slowly cooling, it may be obtained in the crystalline form. Mongez describes these as quadrangular pyramids, and Pajot de Chormes obtained a polyhedron of 82 faces arising from the aggregation of six quadrangular pyramids. (f.)

(848.) D. Chemists have, in general, described Lead as uniting with oxygen in only three proportions. Berzelius, however, describes four oxides of lead.

1. The first, which he terms the suboxide, is the dark powder which gradually forms upon the surface of metallic Lead when left exposed to the air. (g.) Du-long obtained the same oxide by distilling oxalate of Lead to a dry powder in a glass-retort. Carbonic Acid and carbonic oxide Gases are evolved, and the suboxide remains as a dark grey powder.

(849.) 2. The next, or yellow oxide of Lead, is best obtained by precipitation from the addition of carbonate of potassa to a solution of Lead in nitric Acid. The powder as it first falls is white, but being dried, and heated nearly to redness, it takes its true yellow colour. This substance is without taste or smell, is insoluble in water, but soluble in potash or Acids. By heat it easily vitrifies, and by a considerable heat it is capable of volatilization, but if so heated with free exposure to the air the surface passes on to a red colour. (h.) (i.)

The Massicot of commerce, is in fact, the yellow oxide of Lead formed by exposing it to heat and removing the oxide as fast as it forms upon the surface of the fused metal. This powder has at first a dusky-green colour, being a mixture of true oxide and metallic Lead, but by longer exposure to heat in an open vessel more oxygen is absorbed, and complete massicot is formed.

White Lead, so much used as a pigment, is a compound containing the yellow oxide of Lead and carbonic Acid. It is formed by exposing thin plates of Lead to the vapour of hot vinegar.

(850.) 3. The next oxide of Lead is of a bright red colour, and is known in the Arts by the name of Minium, or Red Lead. It is easily formed by exposing finely powdered massicot in such a furnace, that the flame may constantly play upon the powder which is constantly stirred so as to expose fresh surfaces. The process is continued forty-eight hours. (k.)

Minium is a tasteless powder of very high Specific Gravity; by exposure to a red heat it parts with a portion of its oxygen and fuses into a dark brown glass. It is acted upon by Acids, but in every case seems to undergo decomposition, and to be reduced to the state of the yellow oxide. Indeed there is no combination known in which the red oxide of Lead retains its constitution unchanged.

(851.) 4. The highest oxide of Lead is a puce-coloured powder, formed by dispersing the yellow oxide through a mass of water, and then passing a current of chlorine through the Liquid. There results a soluble hydrochlorate of Lead which may be separated by washing, and the peroxide of Lead is an insoluble powder. Such is Proust’s method. It is, however, better to put one part of the red oxide (minium) into a flask with five or six parts of diluted nitric Acid, containing equal proportions of Acid and water. Heat the Liquid almost to ebullition and agitate it from time to time. Thus a soluble nitrate of the yellow oxide is formed, and the peroxide of Lead, insoluble both in water and nitric Acid. That is to say, one portion of the minium takes oxygen from the other portion, and passes to the state of peroxide, while the latter portion, being reduced to the state of massicot, (2 oxides,) forms the soluble nitrate of Lead. The oxide is to be well washed when the process is completed and carefully preserved in an air-tight phial.

The atomic constitution of these oxides of Lead present some difficulties which we have not space to discuss.

(852.) E. When Lead is placed in chlorine Gas, it does not undergo visible combustion, but the Gas is absorbed, and chloride of Lead is formed. This chloride is, however, more easily obtained by precipitation from adding a solution of common salt to a solution of nitrate of Lead. It is then found in the form of delicate, white, plumose crystals, which are, in fact, hexahedral prisms. By heat, these crystals are fused into pure anhydrous chloride of Lead: the plumbum corneum of early authors.

There exists also a subchloride of Lead, a white, insoluble powder, which takes a fine, yellow colour by application of heat. It is formed by decomposing a small quantity of common salt in a great excess of litharge diffused through water.

(853.) F. If hydrofluoric Acid be poured into a solution of acetate of Lead, a precipitation takes place in the form of brilliant laminae insoluble in water, very soluble in nitric and hydrochloric Acids and fusible at a red heat. This is considered, by some, the fluoride of Lead, and not the hydrofluorate, because of its insolubility in water.

(854.) G. By heating iodine and Lead together, the iodide of Lead is readily formed. It is a fine, yellow, waxy-looking substance. The same compound is produced as an insoluble precipitate whenever a solution of any hydriodate is added to a solution of a Salt of Lead. This precipitate is of a beautiful, citron colour.

(855.) H. The combinations of Lead with azote, hydrogen, boron, or silicon, are as yet unknown.

(856.) Carburet of Lead is a black powder, very easy of reduction, formed by heating together a mixture of finely powdered charcoal and oxide of Lead in a closely-luted crucible. It may also be formed by moderately heating a precipitated prussiate of Lead; in this case, nitrogen escapes and carburet of Lead remains.

(857.) Seleniuret of Lead. When selenion and Lead are heated together, an intimate union takes place, and more heat is evolved. A grey, porous mass is formed
Phosphuret of Lead may be formed by dropping bits of phosphorus into melted Lead; or by heating in a crucible equal parts of glass of phosphorus and Lead-filigings. This substance may be cut with a knife, but is not malleable. Its colour is silver-white, inclining to blue, but it tarnishes by exposure to air.

**Chemistry.**

Phosphuret of Lead is easily formed by dropping pieces of sulphur into melted Lead, or by placing alternate layers of the two substances in a crucible in continued proportion, three of Lead to one of sulphur, and giving a moderate heat. Phosphuret of Lead thus formed is of a deep blue-grey colour of considerable brilliancy, less fusible than pure Lead, and very brittle. Heat does not decompose it; oxygen is not acted upon by it at an ordinary temperature; but by a moderate elevation of temperature it passes into sulphate of Lead, and sulphurous Acid, while by a further increase of temperature, a part of the Lead is reduced. This is identical with the mineral galena.

Professor Thomson states, that, “besides the common sulphuret of Lead, there occurs another occasionally, lighter in colour and more brilliant, which burns in the flame of a candle, or when put upon burning coals, emitting a blue flame. It contains at least 25 per cent. of sulphur. It is, therefore, a Bisulphuret of Lead. This variety has not hitherto been noticed by Mineralogists, neither has it been made artificially by Chemists.”

I. Lead combines readily with several other Metals. When fused with gold, it enters into intimate combination, and when even small in quantity, it greatly impairs the colour and ductility of the nobler Metal. With silver it forms a very fusible compound, but of inferior tenacity and hardness. The same is true of the alloy of Lead and platin. The alloy of Lead and copper is a brittle, grey substance. It had been thought that iron could not be combined with Lead, but Muschenbroeck united 184 parts of Lead with 400 of iron, and formed a hard alloy, but inferior to iron in tenacity. Morveau showed, that when the two Metals are heated together, two distinct alloys are formed, the one at the top of the crucible, containing very little Lead, the other a button of iron at the bottom, but combined with a small quantity of Lead. (o.) This Metal readily unites with potassium and sodium. Gmelin also examined carefully the alloys of Lead and zinc; the Metals seem to unite in almost every proportion. (p.) Bismuth was combined with Lead by Muschenbroeck, and formed a brittle alloy. The alloy of Lead and arsenic is brittle, having a foliated structure. Mercury dissolves Lead, and the amalgam seems to retain its physical properties much in proportion to the quantities of its respective ingredients. When the Lead is in such quantity as to produce a mass nearly solid, certain crystalline facettes are perceptible.

K. Acids for the most part act upon Lead or its oxides. The Salts thus formed have a sweet taste. One oxide alone, the yellow, seems to form the base of its Salts; for if the other oxides be employed in solution, oxygen is evolved, and a Salt of the yellow oxide results.
of Lead forming differently-coloured enamels; and of all the metallic oxides, that of Lead forms the strongest flux for promoting the vitrification of earthy substances. So strong is the affinity of oxide of Lead for the Acids, that it will decompose some neutral Salts when dry. Thus if oxide of Lead and muriate of ammonia be triturated together, ammonia is evolved, and by the aid of heat a complete decomposition may be effected. Muriate of soda is capable of a similar decomposition. (689.) L. Numerous characteristics distinguish Lead and its Salts; the latter, if soluble at all, is a colourless Liquid. They have a sweet taste, and are strongly styptic. Hydrosulphuret of potash, sulphuretted hydrogen, and, in short, sulphur in any of its forms, produces a copious black or deep-brown precipitate. Prussiate of potash, gallic Acid, and infusion of galls, all produce white precipitates. Zinc precipitates the Lead in a pure, metallic state. Sulphate of soda is used as a test of Lead producing a white precipitate. Hydrodate of potash produces a beautiful, bright, yellow-coloured precipitate. Vauquelin has shown that the precipitates thrown down from the Salts of Lead by the action of water are not so soluble as the Salts subsaltus. (u.) The most satisfactory proof that a precipitate contains Lead, is obtained by reducing it by the blow-pipe on charcoal. The polyhedral form which the irreducible, enamel-looking globule assumes upon cooling, after it has been fused by the blow-pipe on charcoal, is a good proof of Lead which has been precipitated by a phosphate.

"The uses of Lead are extensive. As it is flexible, easily reduced to thin sheets, and easily united by solder, it is used in making pipes for conveying water, large boilers, and vessels of different kinds. It is cast into thin sheets for covering buildings. Its oxides are used as paints. They are also employed in the manufacture of the finer kinds of glass, to which they communicate density, a higher refractive power, a greater equality of texture, and a greater susceptibility of polish: hence, they enter into the composition of the pastes which imitate gems. They form, in combination with earthy matter, the glazing of the inferior kinds of earthenware. There is some reason to doubt, whether the use of Lead in pipes for conveying water, or in vessels for containing it, be altogether safe; Lead, immersed in water, is covered at length with a white crust of oxide or carbonate; while the Metal is the most insidious, and, at the same time, one of the most destructive of the mineral poisons. In water, however, which has been conveyed through pipes of Lead, no trace of the Metal can be discovered by the most delicate test, sulphuretted hydrogen. Even water kept in cisterns of Lead, where the exposure to the air is more free, seems not to have, in general, any sensible impregnation; this may arise from the deposit of earthy matter from the water covering the Lead. The observations of Guyton too, on the effect of the presence of a little saline matter in preventing its action on Lead, may serve to explain how the practice of keeping water which is used as drink in cisterns of Lead, is not more injurious than it appears to be. Some facts appear to prove, that river water is more liable to receive an impregnation from leaden vessels than spring water is, probably from the Salts in the former being chiefly muriates, while in the latter they are sulphates or carbonates. The use of earthenware glazed with oxide of Lead is hazardous, as the glazing is soon eroded by any acid liquor, and a noxious impregnation communicaled; and many fatal accidents have occurred from the use of Lead in the fabrication of vessels in which wine, cider, and other fermented liquors, are prepared or kept."

Minium and massicot have been already noticed. (D.) Litharge, another common preparation of Lead, is supposed to contain the yellow oxide, with, perhaps, the admixture of some carbonic Acid; it is formed during the process of cupellation by directing a strong current of air upon the surface of the fused Lead which thus carries off the oxide in a semivitrified, or crystalline state, in fine scales as fast as it is formed. If litharge be fused by a stronger heat into a compact mass, it goes by the name of Glass of Lead.

In consequence of the sweet taste of the Salts of Lead, they have at times been employed to correct the flavour of bad wines. This most pernicious adulteration is readily detected by what is generally called Hahnemann's Wine Test, having the advantage of precipitating Lead but not iron. "It is prepared from sulphuret of lime (formed by exposing equal parts of sulphur and oyster shell, or a white heat for 15 minutes) and supertartrate of potash. 120 grams of the sulphuret and 180 of the supertartrate are put into a bottle, which is to be filled with 16 ounces of water that has been previously boiled and suffered to cool. The liquor having been repeatedly shaken, is to be poured off clear into phials which hold about one measured ounce; into each of which about 20 drops of muriatic Acid has been put; and they are well corked. One part of this solution mixed with three parts of the suspected liquor will discover, by a black precipitate, the smallest quantity of Lead, while it does not precipitate iron; the tartaric and muriatic Acids retaining iron in solution when combined with sulphuretted hydrogen." (r.) Burgundy, and all wines which hold tartar in solution, will not retain an adulteration of Lead, as the tartrate is insoluble. Lead taken internally is an active poison. Small quantities of the acetate are sometimes given as a styptic in cases of internal hemorrhage. Its solution is employed as a sedative application to inflamed surfaces and scrofulous sores. When greatly diluted, it forms a good eye-water. Goulard's Extract, the sub-acetate, is indeed a valuable article in Pharmacy. The deleterious effects of Lead may be seen in the specific disease which afflicts house-painters, and has the name of Colica Pictonum. A disease much similar prevailed formerly in the cider Countries, from placing the cider in leaden vats. Its evil effects are chiefly of a paralytic form, when taken for some time in small quantities. A large dose will act as a poison: the best antidote for any one that cannot be ejected from the stomach, is a quantity of sulphate of soda dissolved in water.

Sect. I.—Mercury.

(870.) A. The early history of this Metal is entirely involved in the obscurity of distant Ages. Its uses in the separation of other Metals are among the earliest recorded metallurgical processes. (q.)

(571.) B. The ores of Mercury are numerous. The process by which the pure Metal is chiefly obtained is by putting the richest ore, carefully picked, into retorts with some lime just slaked by exposure to air. Heat is applied, and the Mercury is condensed in a cool receiver.

(872.) C. This is the only Metal permanently fluid at our ordinary atmospheric temperatures. It freezes at — 39°, or — 40° Fahrenheit; at 680° on the common Mercurial scale, or 662° on that scale corrected, it boils, and rapidly distills over. Its vapour has high expansive force.

(873.) D. Mercury undergoes oxidation by agitation in a bottle with atmospheric air. The oxide so formed was called Æthiops per se, by Boerhaave. This black oxide is, however, better obtained by boiling calomel with an excess of caustic alkali in solution.

Another oxide is formed by exposing the Metal, for several days, to a high temperature, in a flat glass-vessel freely exposed. The red oxide so obtained was formerly called Precipitate per se. The oxides of Mercury are reduced by mere exposure to heat in a retort. The two oxides of Mercury are true protiode and deutiodide.

(874.) E. Mercury readily forms two chlorides. Calomel is the protochloride, and Corrosive Sublimate the deutochloride of this Metal.

(875.) F. Unexamined.

(876.) G. There are two iodides of Mercury. The protiodide is formed by mixing a solution of the proto-nitrate of Mercury with the hydriodate of potassa. The deutiodide by mixing the same hydriodate with a solution of any deuto-salt of Mercury.

(877.) H. Mercury combines with sulphur, forming a sulphur and bisulphuret. The latter, known by the name of factitious Cinnabar, is formed by fusing sulphur with six times its weight of mercury, and collecting the sublimate produced in close vessels. When reduced to fine powder, this same substance is Vermilion. Æthiops Mineral is formed by triturating together equal parts of Mercury and sulphur. Mr. Brande has shown that it is a mixture of sulphur and bisulphuret of Mercury.

(878.) I. Of these substances, selenious alone has been combined with Mercury.

(879.) K. The sulphuric, nitric, and some other Acids dissolve Mercury. Two distinct classes of Salts are formed by its respective oxides. In a more extended Treatise these ought all to be described. Here, however, that is not possible; and as it is obvious to the reader, that in thus abbreviating our description of this Metal, we are treating of it far less fully than many of the other Metals, and especially than that described in the last section, we state once for all, in apology to those who may make the remark, and with justice, that the inequalities of that sort, which are considerable in this Treatise, arise from circumstances which the author has not been able to control.

(880.) We must not, however, omit to notice a curious detonating compound of Mercury described by Mr. Howard. (c.) It is formed by dissolving 100 grains of Mercury in a fluid ounce and half of nitric Acid, of Specific Gravity 1.3; and when cold, pouring the solution gradually into two ounces of alcohol. Specific Gravity 0.849. The mixture is then to be gently heated in a flask, or retort, over a lamp, till a brisk effervescence ensues. A dun-coloured precipitate falls down, which is to be most carefully dried over a water-bath; and this is the fulminating Mercury. This compound will bear a heat somewhat above 212° without explosion; but any further elevation of temperature, or friction with hard substances, or percussion, occasions instant and violent explosion. From silver, a similar, but still more violent compound is obtained. See Fulminating Powders in our Miscellaneous Division.

(881.) L. Solutions containing Mercury give a white precipitate with prussiate of potassa, a black one with hydrosulphates; a white one with hydrochloric Acid; orange-yellow with gallic Acid; and a plate of copper throws down the Metal pure. A meattest of Mercury is orange-yellow with gallic Acid; and a plate of copper.

(882.) M. Mercury has many uses in the Arts, in Metallurgical processes, and in Medicine.

References to § 1.

Sect. II.—Nickel.

(883.) A. Nickel was first recognised as a distinct Metal by Cronstadt in 1751, and his experiments were confirmed by Bergman in 1775. Kupfer-nickel, false copper, was the minor term for the ore, and the latter word was retained by Cronstadt as its distinctive name. It is found as a very impure metallic alloy, and in the state of an oxide. It is also considered the colouring matter of Chrysoprase.

(884.) B. The analysis of Kupfer-nickel is complicated, but an easy method of obtaining the pure Metal is proposed by Thomson. Dissolve the Nickel of Com-
merce (speiss) in sulphuric Acid, adding a small quantity of nitric Acid to promote oxidation. By concentration, green crystals of sulphate of Nickel are obtained; and, for further purification, some of the first formed and purest are washed, and again dissolved in water, and submitted to a second crystallization. By adding an alkali to a solution of these in water, pure oxide of Nickel is obtained. Let this be mixed with three per cent. of resin, formed into a paste with oil, and exposed to a forge-heat in a charcoal crucible, a button of pure metallic Nickel is obtained.

(885.) C. Pure Nickel is nearly as white as silver, but with a slight cast of yellow. It is malleable, and rather softer than iron. Its Specific Gravity, when fused, is 8.08, but by hammering it, it is brought to 8.92. Its fusing point is at least 160° of Wedgewood. Nickel possesses permanent magnetic properties, and, according to Lampadius, its energy is to that of iron as 33 to 55.

(886.) By exposure to heat, Nickel tarnishes but does not oxidate. If, however, the Metal is dissolved in nitric Acid, the precipitate given by potassa after exposure to a red heat, is the protoxide and of a bluish-brown colour. Thenard obtained the next, a hemidioxide, by passing a current of chlorine through water holding protoxide of Nickel suspended in it; a portion is dissolved, and the remaining black powder is the hemideoxide of this Metal.

(887.) E. Nickel does not instantly combine with chlorine, but by leaving the substances in contact, a chloride may be formed; a more ready process, however, is to expose the muriate to a red heat.

(888.) F. Unknown.

(889.) G. The iodide of Nickel, a greenish precipitate, is formed by adding hydriodate of potassa to a solution of the sulphate or nitrate of the Metal.

(890.) H. Nickel has been united to sulphur, phosphorus, selenium, and carbon, but does not combine with nitrogen or hydrogen. Of its habituses with boron, or silicon, we are ignorant.

(891.) I. Nickel combines with gold, copper, tin, and arsenic, forming brittle alloys, but its compounds with silver and iron are ductile. Arsenic entirely destroys its magnetic properties, as also does those of iron and cobalt.

(892.) K. Both Nickel and its oxides are readily soluble in nitric Acid with heat, and a nitrate is obtained in rhomboidal prisms, which, according to Bergman, first deliquesce, and finally effloresce, and fail to powder. Proust describes a subnitrate also, and Thenard a double nitrate of Nickel and ammonia.

Sulphuric Acid dissolves the oxide, and also the Metal; if aided by the addition of a few drops of nitric Acid the sulphate readily crystallizes. Sulphate of potash and Nickel, of ammonia and Nickel, and of iron and Nickel, have also been described.

Hydrochloric Acid scarcely attacks the Metal, but dissolves the oxide, and a crystalline hydrochlorate is produced, with properties like those of the nitrate. The following Acids do not attack the Metal, but produce precipitates of insoluble Salts, on the addition of their neutral Salts to neutral solutions of Nickel. Carbonic, phosphoric, (and this has a slight action on the oxide,) boracic, selenic, (but the biseleniate is soluble,) and molybdic.

The oxalic Acid attacks Nickel if slightly heated, and a greenish, insoluble oxalate is deposited. It may also be produced by dropping oxalic Acid into a Salt of Nickel in solution. Acetic Acid also dissolves Nickel, and a very soluble Salt results. No precipitate is produced by adding benzoe or succinate of ammonia to solutions of Nickel; hence these Salts are considered soluble. The arsenate also is soluble; but the chromate, formed by suffering chromic Acid to act upon the carbonate, gradually deposits itself in a pulvulent form.

All the Salts of Nickel are of a green colour, and appear to contain the protoxide, which is also soluble in ammonia. On this property Thenard has founded his process for separating Nickel from cobalt. (An. de Chim. vol. I.) A solution of the two Metals is precipitated by an alkaline carbonate. By the addition of oxymuriate of lime, the cobalt is converted into the peroxide. Ammonia will now take up the oxide of Nickel only, which may be regained by evaporation.

Nickel is soluble also in ammonia.

(893.) L. In neutral solutions of Nickel, hydrosulphuric Acid Gas produces no change, but hydrosulphate of potash gives a black precipitate. Prussiate of potash, a white or greenish one; and infusion of gall gives, with some Salts, a grey precipitate, but, according to Thomson, with the sulphate none at all. The caustic alkalis produce white, and their carbonates apple-green precipitates. No Metal produces one precipitation.

(894.) M. The only purpose to which Nickel has been applied is in the formation of magnetic needles, for which, if plentiful, it might sometimes be useful where steel would rust. From some recent experiments of Stodart and Faraday, Quarterly Journal, vol. ix., the alloy of Nickel and iron would be serviceable in the Arts, being less liable to rust than common iron; but it is singular that Nickel alloyed with steel increases the tendency to rusting. By far the greater part, and, until lately, it was thought that all the meteoric stones which have fallen from the atmosphere contained Nickel. Laugier (Mém. de Muséum, vol. vi.) asserts chromium to be a more constant ingredient; but, be this as it may, several masses of native metallic iron, which from their situation upon the surface of the earth appear to be of meteoric origin, contain more or less Nickel. The blades of the knives used by the Esquimaux tribe, found in the late Northern voyages of discovery, were of this kind.

References to § 2.

Sect. III.—Osmium.
with iridium, chemistry ther. The oxide of Osmium passes over with some
water; metallic mercury is agitated with this solution, and abstracts to Osmium, forming an alloy. By subsequent distillation, the mercury is separated, and the Osmium remains.

(897.) C. Osmium is a dark-grey powder, and as it has never yet undergone sufficient heat to reduce it to a mass, its physical properties are quite unknown.

(898.) D. When Osmium is heated with exposure to air, it oxidates and sublimes, but it is very probable that the pure Metal is not volatile. Oxide of Osmium may be readily procured by mixing the black powder with nitre, and distilling at a low heat. Oxide of Osmium rises into the neck of the retort in the form of an oily fluid, which by cooling becomes a solid, semitransparent mass, soluble in water. According to Vauquelin, pure oxide of Osmium exists in the form of transparent crystals, having a strong and caustic taste. Very soluble in water, and capable of blackening animal and vegetable substances. There is strong reason for suspecting that oxide of Osmium enters into combination with alkalis.

(899.) E. With chlorine, Osmium combines, appearing at first to melt, and assuming a green colour, and, finally, forming a brownish-red liquid.

(900.) F. G. H. Unknown.

(901.) I. Osmium has been alloyed with gold and copper.

(902.) K. On this head also very little is known by direct experiment. According to Tennant, Osmium resists the action of all Acids; but according to Vauquelin, it is soluble in the hydrochloric and nitro-muriatic; but of any Salts with oxide of Osmium as a base, we are as yet ignorant.

(903.) L. Solutions of oxide of Osmium become yellow by the addition of ammonia and carbonate of soda. Magnesia produces no effect, but potassa and lime produce yellow precipitates. The most striking test of Osmium is infusion of galls, which produces a blue colour in solutions of this Metal. If iridium also is present, the infusion of galls first destroys the red colour of the iridium in solution, and then develops the fusible blue of the oxide of Osmium. Copper, tin, zinc, and phosphorus cause a metallic precipitation.

(904.) M. None.

METALS. CLASS VI.

Sect. I.—Silver.

(905.) A. Silver has been known and employed from the very earliest times. There are several ores of Silver in which it is combined with sulphur, with hydrochloric Acid, with antimony, arsenic, and mercury.

It is also found native, but not in a state of perfect purity, and from this source the first knowledge of the Metal would probably arise.

(906.) B. The rich ores of native Silver found at Konigsberg, are fused with an equal weight of lead, by which an alloy is formed, and finely purified by cupellation. The Freyberg ores, which contain but little Silver mixed with much pyrites, are mixed with common salt and roasted in the reverberatory furnace. The frit is then pulverized and washed; and by the addition of mercury an amalgam is formed, which is drained from the earthy and saline matters. It is then submitted to pressure in a bag, by which means the liquid mercury is separated, and the more solid alloy remains for final purification, by distilling off the remaining mercury in heated earthen retorts. In Mexico and Peru the process is nearly the same.

Silver is also obtained in considerable quantities from some varieties of galena, native sulphuret of lead.

For Chemical purposes, pure Silver is best obtained by a process recommended by M. Gay Lussac. (a) Precipitate the Silver from its nitrate by a plate of copper; digest the precipitate in a weak solution of nitrate of Silver; by which any adhering copper is taken up, and pure Silver deposited in its place. (907.) C. Silver is the whitest Metal at present known, and capable of receiving a very high degree of brilliancy from the burnisher. It has neither taste nor smell. Its hardness is superior to that of copper, but inferior to that of gold. Its Specific Gravity 10.39—10.51. Its ductility and tenacity are of the highest order, and in malleability it is inferior to gold only. It may be beaten out into leaves of one hundred-thousandth of an inch in thickness. It fuses at a full red heat, which has been estimated at about 1000° Fahrenheirt, or according to Dr. Kennedy, at 22° Weidgewood. By a greatly increased heat, it is capable of volatilization. This is effected either by the flame of oxygen and hydrogen from the Gas blowpipe, or as Vauquelin found, by a current of oxygen alone upon charcoal. By slow cooling and pouring off some portion while still fluid, four-sided pyramidal crystals may be produced.

(908.) D. By exposure to the air or to water, Silver does not undergo oxidation, but by long continued heat in an open vessel it may be converted into a greenish-brown oxide: Galvanic Electricity and the common Electric discharge produce the same effect. The same oxide is produced by precipitating a solution of Silver in nitric Acid with lime-water. This oxide is insoluble in water, but soluble in several Acids, and in ammonia.

If the ammoniacal solution of this oxide be exposed to the air, a pellicle, consisting of a black powder, forms upon the surface, which Mr. Faraday considered a peculiar oxide; and from a repetition of his experiments, Dr. Thomson coincides with him in opinion.

(909.) E. When Silver is heated in chlorine, the gas is gradually absorbed, and a chloride of Silver is obtained. It is easily formed also by adding any hydrochlorate, or a solution of chlorine, to a solution of nitrate of Silver, in which cases it instantly forms a white, curly precipitate. This substance, formerly called muriate of Silver, is fused into a greyish mass, but undecomposed at a red heat; and this is the true Silver of older Chemists and Mineralogists. It is soluble in ammonia, and decomposed by alkaline carbonates, while the pure alkalis and Acids have no effect upon it. Being a most definite compound, it is

vol. iv.
the usual state in which Silver is separated in analysis; and after a low red heat, its weight affords, by calculation, an accurate estimate of the Silver acted upon. The chloride is easily reduced, by fusion in a crucible with twice its weight of carbonate of potash or soda, a button of pure Silver resulting. It is also decomposed by trituration, or fusion with several of the Metals. (k.)

(910.) F. Unexamined.

(911.) G. By adding hydriodic Acid to a solution of nitrate of Silver, iodide of Silver is precipitated; it is yellow, insoluble in water or ammonia, but is decomposed by heating it with potash.

(912.) H. Silver does not combine with azote, hydrogen, carbon, boron, or silicon. Pelletier formed its phosphuret; and Berzelius is of opinion that two seleniurets exist. Silver appears to have a strong affinity for sulphur; the sulphuret is found native, and forms the tarnish which is so frequently seen upon Silver plate; this arises from the hydro-sulphuric Acid Gas, which is produced by the decomposition of animal and vegetable matter daily going on. The discoloration of a tea-spoon with which an egg has been eaten, arises from the same cause.

(913.) I. Silver is alloyed with copper, for coinage, in England and most other Countries. It unites with iron, but with slight energy, for in cooling rapidly, globules of Silver are forced as it were from pores in the mass; and by slow cooling, the Metals are almost entirely separated in the order of their Specific Gravities, a mass of iron being found at bottom and Silver at the top. The same takes place with cobalt. Silver produces brittle alloys with zinc, arsenic, bismuth, lead, and tin; malleable ones with gold, copper, platinum, and mercury.

With nickel it refuses to unite.

(914.) K. Silver is acted upon by some of the Acids, but not by all. In the nitric, it is readily soluble, with the evolution of nitrous Gas. This solution gives to the skin, and to all animal matter, an indelible black stain. It is capable of crystallization, is soluble in alcohol, and a part of its Silver is reduced by exposure to light. It is decomposed by a red heat, and when fused by a moderate degree of heat, and cast into moulds, forms the common lunar caustic.

Sulphuric Acid acts on Silver only when heated, but at the same time the Metal must be in a minute state of division. Phosphoric Acid does not act on Silver, but the phosphate may be indirectly obtained. For a full description of the Salts of Silver, we must refer to more extended Treatises.

(915.) L. For the most part, the Salts of Silver are very sparingly soluble in water. They may be reduced, before the blowpipe, in charcoal. Solutions of Silver are precipitated by muriatic Acid, or the muriates. By sulphate of iron, the Silver is precipitated in the metallic state. By a plate of copper, the Metal is thrown down nearly pure. Prussiate of potash gives a white, and the alkaline hydro-sulphuric a black precipitate. In some of the saline solutions of Silver, according to Thomson, gallic Acid causes a yellowish-brown precipitate.

(916.) M. The alloy of Silver with copper for coinage in England, is 11.1 of Silver to 9.1 of copper. The best Silver plate is formed by uniting a plate of copper to the surface of a thin plate of Silver, and then extending the mass by passing it between steel rollers, after which it is ready to be worked up into various ornamental and useful forms. Inferior plate is manufactured by applying an amalgam of Silver to the surface of the copper, after some adhesion is effected; the mercury is driven off by heat, and the Silver undergoes the operation of the burnisher. The brass dial of clocks, thermometer and barometer scales, &c. are silvered by rubbing upon them a mixture of whitewash, pearlash, and chlorid of Silver. A similar composition is often sold in small balls in the streets of London for beautifying old brass candlesticks. According to Stodart and Faraday, (Quarterly Jour. vol. ix.) an alloy of one part of Silver with 500 of steel is admirably adapted for the manufacture of cutting instruments. Indelible marking ink is made by dissolving ten grains of lunar caustic in half an ounce of gum-water; with this ink, the linen is to be marked from a common pen, but to prevent the corrosive quality of the salt it is necessary to moisten the linen with a weak solution of pearlash, which is suffered to dry before the ink is applied. It is a singular fact that if, instead of potash, soda be the alkali employed, the ink runs.

The Arbor Diaene, a beautiful experiment of the Alchemists, is formed by putting into a flask six draehms of a saturated solution of nitrate of Silver, and four draehms of a saturated solution of nitrate of mercury diluted with five ounces of distilled water; in this solution place a small lump of amalgam, consisting of seven parts of mercury with one of Silver. The flask is to remain perfectly quiet, and in a few hours a beautiful arborescent precipitate is produced.

Two very violent fulminating compounds of Silver are known to Chemists. The first was discovered by Berthollet, (An. de Chim. vol. i.) and is thus formed. Precipitate a solution of nitrate of Silver by lime-water. Wash the brown oxide thus produced in the open air, and let it be kept dry in a well-closed phial. To prepare the fulminating compound, put ten or twelve grains of this oxide into half an ounce of ammonium perfectly caustic, and moderately dilute. The oxide blackens, and more or less is dissolved. Pour the clear solution into a shallow vessel, and expose it to the action of the air. In ten or twelve hours, the surface becomes covered by a crystalline pellicle, which is the fulminating Silver. This formidable substance is to be removed while still wet, in lumps not exceeding two grains, to bits of blotting-paper, and suffered to dry. Even when wet, it will sometimes explode by a touch; and when dry the touch of a finger or a brass key will ignite it; the black powder which remains in the solution appears to possess the same properties; and so violent and uncertain is the action of this substance, that it is one of the last experiments we should advise a beginner to undertake.

The other fulminating Silver, though of great power, may be procured with more safety. The process for its formation is described in Art. (880.) See also Fulminating Powders, in our Miscellaneous Division.

Sect. II.—Palladium.

(917.) A. Palladium was obtained by Dr. Wollaston in 1803, from crude platinum, with which it exists as a native alloy, and also in separate grains, having a radiated structure.

(918.) B. The most simple process for obtaining it is by the addition of prussiate of mercury to a solution of crude platinum, one thousand parts of crude platinum containing seven of Palladium; a flocculent, yellowish-white precipitate of prussiate of Palladium is formed, which is easily reduced by heat to the metallic state.

(919.) C. This Metal is nearly white, and has much the appearance of platinum. It is harder than wrought iron. Its Specific Gravity has been stated from 11.3 to about 12.14. It is malleable, and not very elastic. By exposure to heat and air, it undergoes no change. Its fusing point is somewhat below that of platinum. When strongly heated, its surface receives a blue tarnish by which it may be distinguished from platinum.

(920.) D. The only known oxide was formed by Berzelius, who heated the filings of the Metal with potash and a little nitre. Its colour was chestnut-brown.

(921.) E. The chloride of this Metal has not been examined.

(922.) F. G. Unknown.

(923.) H. Sulphur unites with Palladium.

(924.) I. Palladium has been alloyed with several other Metals.

(925.) K. Sulphuric Acid does not act freely on this Metal; but when boiled upon it, some little is taken up, and a blue solution formed. Nitric Acid has rather more power, and forms a beautiful, red solution. Hydrochloric Acid, by aid of a boiling heat, produces a fine red solution. But nitro-muriatic Acid is the proper solvent of Palladium.

This Metal unites also with potassa and soda by fusion. Ammonia seems also capable of dissolving a small portion of the Metal.

(926.) L. Solutions of Palladium have usually a red colour. Ferro-hydrocyanate of potassa gives an olive-coloured precipitate. Hydrosulphuret of potassa a dark-brown one. The alkalis an orange precipitate. By mercury and sulphate of iron, the Metal is precipitated in the metallic state. Hydrochlorate of tin changes a very dilute solution to a fine emerald-green colour, but in a concentrated solution produces a brown precipitate. Hydrochlorate of ammonia produces no precipitation; thus distinguishing Palladium from platinum.

(927.) M. The scarcity of Palladium has prevented its general application to any purpose in the Arts; except that Mr. Troughton graduated the celebrated mural circle at Greenwich upon an alloy of gold and Palladium, furnished by Dr. Wollaston, but he does not consider that gold alone would be inferior.

Sect. IV.—Platinum.

(939.) A. Platinum is first known to have been seen by Mr. Wood, assay-master in Jamaica, in 1741. From him, Dr. Brownrigg received a specimen which was presented to the Royal Society in 1750. In 1749 it was seen by Ulloa, a Spanish Mathematician, who accompanied the French Academicians, in 1735, to Peru, for the purpose of measuring a degree of the meridian. Experiments on it were published by Wood, in 1750, (a.) and by Lewis, in 1754. (b.) Other dissertations on it may be found from the references to this section. (c.) The first Platinum known was from Choco and Santa Fé, in South America. Vauquelin detected it among some silver-ores from Estramadura; it has subsequently been brought from St. Domingo, and from the gold-mines of Brazil. Still more recently it has been found in the Province of Antioquia, in North America; and abundantly in the Ural mountains. (d.) Its name is derived from the Spanish as c diminutive from plata, silver; hence platina, and its Latin Platinum.

This substance is found in the metallic state either nearly pure, or alloyed with iron, copper, lead, gold, silver, palladium, rhodium, iridium, and osmium.

(940.) B. The grains of crude Platinum are to be dissolved in concentrated nitro-muriatic Acid, with as little heat as possible. Decant off the solution from a black precipitate which remains. A solution of sal ammoniac dropped into the solution, throws down a yellow precipitate; which is to be washed, dried, and gradually raised to a red heat in a porcelain-crucible. Pure Platinum remains in a pulverulent state, and may, by heat and mechanical compression, be reduced to an ingot. (d.)

(941.) C. Pure Platinum is less white than silver; and has inferior lustre. It is the heaviest Metal known, having a Specific Gravity = 21, or 22. It is soft, malleable, ductile, and of very difficult fusibility; and a comparatively slow conductor of heat. Has the property of welding.

(942.) D. Platinum is not oxidized by exposure to heat and air. Its oxides are obtained by precipitation from saline solutions. Three oxides are described by Chemists, but the first is not quite well ascertained. (943.) E. Nitro-muriatic Acid is the best solvent of Platinum; but it is also acted upon by pure Chlorine. The point is not fully ascertained, but it seems probable that there are three chlorides of Platinum:

(944.) F. Unknown.

(945.) G. Unexamined.

(946.) H. Sulphuret of Platinum has been formed, but it seems to be a compound not possessed of great stability. (e.) The phosphuret is a bluish-grey powder not fusible. The seleniuret is described by Berzelius. 

(947.) I. On the whole, Platinum may be considered as well disposed to form alloys with the other Metals; and, in some instances, the combination is effected with great violence.

(948.) K. Platinum is not acted upon by any Acid except the nitro-muriatic; but its oxides form numerous Salts with other Acids by indirect processes. The alkalis, also, aided by heat, have some action upon it; hence a caution arises with regard to the use of Platinum-crucibles in analysis.

(949.) L. Solutions of the Salts of Platinum have a yellowish or reddish-brown colour. They are not precipitated by infusion of galls, or by prussiate of potassa. Pure ammonia, or potassa, throw down small orange-coloured crystals. Hydrosulphuric Acid throws down a black, pulverulent precipitate.

(950.) M. The very difficult fusibility of Platinum renders it a valuable Metal, in forming apparatus for many purposes of Chemical research. Being harder and less fusible than gold, it is now used for the touchholes of guns; perhaps, also, it unites better with the iron of the barrel.

References to § 4.

Sect. V.—Gold.

(951.) A. This beautiful and valuable Metal has been known from the earliest times; a circumstance easily explained when we remember that it usually occurs in the native metallic state. From one other ore only is it obtained in any considerable quantity, in which it is combined with tellurium. Native Gold is found principally in filaments traversing primitive rocks, in the beds of rivers, in grains washed out from similar mountains, or in alluvial soils.

(952.) B. When the grains of Metal are sufficiently large to be visible, they are picked out and purified by fusion and cupellation. But when the grains are very minute, and mingled with sand, or it is necessary to pulverize the rocky matrix containing the Metal, it is usual to complete the process by amalgamation. The sand, or powder, is first washed with water in such a way as to allow the heavier particles of Gold to remain in the vessel; this auriferous sand is then agitated with mercury, by which the Gold is taken up and the silicious matter remains. The mercury is then distilled off from the Gold, and subsequent cupellation is employed to remove any impurity arising from the baser Metals. Should silver also be present, the assayer's operation of parting is resorted to to obtain absolute purity.

(953.) C. Various shades of yellow describe the colour of Gold; and it is singular that, without affecting any of its other properties, if a small quantity of borax be added to Gold in fusion, the colour becomes very pale, whilst nitre has the contrary property of rendering
CHEMISTRY.

Its specific gravity is about 19.3, being higher than any other metal, platinum excepted. It is the most ductile and malleable of metals. "It may be beaten out into leaves so thin, that one grain of gold will cover 56½ square inches. These leaves are only 1-252000 of an inch thick. But the gold leaf, with which silver wire is covered, has only 1-12 of that thickness. An ounce of gold upon silver wire is capable of being extended more than 1300 miles in length." (Thomson.)

Great as is the density of gold, if one of these leaves be carefully spread between two plates of glass, it will be found to transmit the green rays of light; and it is singular that the same colour is developed on the surface of a mass of gold in a state of fusion.

In tenacity, gold is inferior to iron, copper, platinum, and silver. Its fusing point may roughly be stated at 1300 °Fahrenheit. In all furnace heats it may be considered as absolutely fixed; but by the heat of Tschirnhaus's lens, the discharge of an electrical battery, or the gas blowpipe, it may be volatilized. The fumes raised by these processes were seen by Macquér to gild a plate of silver placed five or six inches above it.

(954.) C. Exposed to atmospheric air, to oxygen, or to water, gold undergoes no alteration, but aided by the heat of a powerful lens, or by an electric discharge, its oxide may be formed though in very minute quantities. By the heat of the Voltaic pile, or the gas blowpipe, leaves or small wires of gold undergo rapid combustion, and an oxide is produced. It is the general opinion of chemists that there are at least two oxides of gold. If a solution of gold in nitro-muriatic acid is evaporated just to dryness, and redissolved in water, and to this neutral solution caustic potash be added, and the whole exposed to heat, an abundant precipitate is produced. This is to be carefully washed with water, and dried, but without artificial heat. Thus is formed a reddish-brown powder, the tritoxide of gold; which by a very moderate heat again parts with its oxygen, and returns to the metallic state.

If instead of evaporating only to dryness the tritoxide formed in the above experiment, the heat is continued as long as any acid gas is evolved, a straw-coloured mass remains insoluble in cold water, which is a proto-hydrochlorate of gold; and from this a green-coloured protochlorate is produced by digestion in caustic potassa. This combination does not, however, possess great permanency, for one-third of it passes to the state of tritoxide at the expense of the other two-thirds, which return to the metallic state. Clearly, then, the tritoxide contains three as much oxygen as the protoxide, and Berzelius has strong grounds for his suspicion that an intermediate oxide exists.

(955.) E. When gold in a state of minute division is heated in chlorine, a yellow chloride is formed, which by the addition of water passes into a hydrochlorate, as is usual in such cases.

(956.) F. Unknown.

(957.) G. Hydriodate of potash produces in a solution of muriate of gold, a brownish-yellow precipitate, insoluble in cold water, and decomposable by heat.

(958.) H. Gold does not unite with azote, hydrogen, carbon, boron, or silicon. Pelletier formed the phosphuretted hydrogen gas. Its affinity for sulphur is very slight, but when an alkaline hydrosulphuret is dropped into a solution of gold, the black metallic sulphuret is precipitated.

(959.) J. As far as hitherto known, gold appears to unite with every metal, undergoing such change of properties, as to present a wide field of research. Most ably and laboriously has this inquiry been prosecuted by Mr. Hatchett. (A.) All metals, except silver, copper, and platinum, seem materially to injure its ductility and colour. Lead, bismuth, and antimony, in very small proportions, render it brittle.

(960.) K. Solution of chlorine and the nitro-muriatic acid are the only decided solvents of gold; two parts of muriatic to one of nitric acid form the usual proportions, but three of the former to one of the latter is considered still more effective.

Concentrated nitric acid dissolves the oxide, and thus a pernitrate is obtained; but the combination is so slight, that either heat or dilution again throws down the metallic oxide.

In a similar manner the tritosulphate is obtained. The hydrochlorate has been before described. Further researches on the salts of gold are wanted.

Pelletier states that oxide of gold is soluble in hydrate of potassa; and in this combination he considers that it acts the part of an acid. It would also appear that in the process given above for obtaining the tritoxide of gold, a portion of the metal remains in solution in the state of a double hydrochlorate of potassa and gold of high solubility.

(961.) If to a solution of hydrochlorate of gold diluted with twice its weight of water, ammonia be added so long as there is any precipitate, but without adding excess, the reddish-yellow precipitate, when washed in water and dried by exposure to air, is fuming gold, a preparation long known to chemists. By the slightest heat, by percussion, or by friction, it explodes with violence. The temperature necessary to produce this effect has been estimated by Bergman between 120° and 300°. The powder appears to be a true ammoniuret of gold; and on its detonation, according to Bergman, the following changes take place. The oxygen of the oxide attracts the hydrogen of the ammonia, and watery vapour is produced; the nitrogen as is liberated; and to the elasticity of these two gaseous bodies, increased by the temperature, the violent effects are attributable. See fuming powders in our Miscellaneous Division.

(962.) L. In the solutions of the salts of gold, prussiate of potassa produces a yellowish-white precipitate. Infusion of galls gives to the solution a greenish hue, and precipitates the gold in the metallic state. Hydrochlorate of tin, or a plate of metallic tin, produces a purple precipitate. Proto-sulphuret of iron throws down metallic gold, and from the powder thus produced, the most pure metallic gold may be obtained. The rationale of this precipitation is simple and beautiful; the protoxide of iron has a strong affinity for more oxygen, and the gold having only a very weak one, the former is oxidized at the expense of the latter, which being no longer soluble, falls down in the metallic state. Copper, iron, and zinc also precipitate gold in the metallic state, and several other metals in the state of a purple oxide.

(963.) M. Perhaps the most important among the uses of gold is that of coinage: its great ductility fits it
Chemistry, for receiving a sharp and beautiful impression from the die, while its scarcity gives to it a convenient value with reference to the other Metals of coinage. Pure Gold is not so well adapted to this purpose as those alloys which possess sufficient hardness to resist the wear to which all coin is subject. The standard or sterling Gold of England consists of twenty-two parts (carats) of pure Gold to two parts of alloy. The alloy consists of silver or copper, or both, according to the colour which is required; the latter Metal having a great tendency to heighten the colour of Gold. It would appear from Mr. Hatchet's experiments that the alloy used in our Gold coinage is the best possible for the purpose, as it resisted ordinary friction better than any other tried. The stamped Gold for watch-cases, &c. is of eighteen carats, for it contains one-fourth alloy; but compounds exist under the name of Jeweler's Gold, of every possible degree of deterioration.

One species of gilding upon Metal is performed by uniting Gold to the Metal at a gentle heat, and by the friction and pressure of the burnisher, but aetheral gilding, as it is called, is performed upon steel, by mixing a saturated solution of muriate of Gold with three times its weight of sulphuric aether; aether dissolves the oxide of Gold, and the Acid, or a great part of it, sub-sides. If polished steel be then dipped in the aetheral solution, and immediately immersed in water, it is found to have received a delicate coating of metallic Gold on its surface. (Stodart.) For colouring glass and porcelain, the beautiful, purple precipitate produced by adding gilding, as it is called, is performed upon steel, by mixing a saturated solution of Gold, has long been known under the name of the Purple powder of Cassius, the real nature of which still remains rather uncertain among Chemists.

Greatly as the Alchemists boasted of its virtues, Gold had fallen entirely into disuse as a medicine, until very lately; but it now seems to be likely again to have a place in the Materia Medica.

Sect. VI.—Iridium.

(964.) A. Iridium received its name from its discoverer, Professor Tennant, on account of the varying colours of its solutions. Together with osmium, it forms the black powder, remaining after the digestion and solution of crude platinum in nitro-muriatic Acid. Des-cottis made the same discovery, and Fourcroy and Vauquelin published a series of experiments on these two bodies. Dr. Wollaston perceived that the flat, foliated, white grains in crude platinum were in fact the native alloy of the two Metals.

(965.) B. The black powder above mentioned is to be mixed with an equal weight of potash in a silver-cru-cible, and continued in a red heat for some time. From this, water procures an orange-coloured solution. The remaining, undissolved powder is to be digested in hydrochloric Acid, and then again subjected to the action of potash as before; these alternate actions being repeated till all is dissolved. Thus an orange-coloured, alkaline solution is obtained, holding the oxide of osmium, combined with potash, and a deep-red acid solution of oxide of Iridium. By evaporating this latter solution to dryness, and again dissolving in water and evaporating, octahedral crystals of hydrochlorate of Iridium are obtained. From a solution of these, a plate of any Metal, except gold and platinum, will throw down Iridium as a black, metallic powder.

(966.) C. This powder, after the purification of a strong heat, is rather whiter than platinum, but can scarcely be said to have been fused, although Mr. Children's powerful Galvanic battery produced an imperfect agglutination of the particles, and the same has since been effected by Dr. Clarke with the Gas-blowpipe. The experiments of Vauquelin render it probable that, after a perfect fusion, this Metal may be slightly ductile; its Specific Gravity is certainly above 18.6.

(967.) D. The affinity of Iridium for oxygen is extremely slight, but it is probable that it forms more than one oxide. By the addition of an alkali to any acid solution of this Metal, one portion of the oxide is precipitated, and another retained in solution. Descotis procured also a blue, volatilized oxide by exposing the Metal to a strong heat.

(968.) E. F. G. Unknown.

(969.) H. Iridium may be indirectly combined with sulphur. Its action with phosphorus and selenium is not known, and with the other substances of this class its combination is not very probable.

(970.) I. Tennant alloyed it with lead, copper, silver, and gold, but could form no alloy with arsenic. Vauquelin combined it with tin; and like rhodium, it appears to increase the hardness of the Metals with which it is combined.

(971.) K. No single Acid is capable of dissolving Iridium; even the nitro-muriatic is with difficulty made to take up one-three-hundredth of its weight of the Metal.

The sulphate and hydrochlorate of this Metal give green or blue solutions according to their state of dilution; the nitrate, when concentrated, has a red colour. Double Salts of the hydrochloric Acid with the alkalis and oxide of Iridium exist, and are of a deep-purple colour.

(972.) L. From solutions of this Metal almost all Metals produce a precipitate of reduced Iridium, owing to its weak affinity for oxygen. Tincture of galls produces after some time a red precipitate; but according to Tennant the solution of the crystalized hydrochlorate is only rendered colourless by infusion of galls. Prussiate of potassa, hydrochlorate of tin, and carbonate of potassa, without any precipitation being produced. Hydrosulphurets destroy the colour of the solution, but by aid of heat produce a black precipitate.

(973.) M. None.

Tennant, Phil. Trans. 1804; Descotis, An. de Ch. vol. xlvii.; Fourcroy and Vauquelin, An. de Ch. vol. xlix. and vol. l.; Vauquelin, An. de Ch. vol. lxxxix.
We have now arrived at a difficult but most interesting and important branch of Chemical Science. There are but two methods for producing a really useful review of the state of knowledge on the subjects to which this Part refers. The one to give a detailed and systematic account of all the researches which have been made on the various Organic substances; and the other merely to recapitulate, giving little more than a complete series of references to the original Memoirs for the benefit of those who may wish to enter these fertile fields of discovery. A middle course would offer little real utility. From the former we are prohibited by the space which such a Treatise would occupy.

By Organic Chemistry we are to understand the examination of the properties, the proximate and ultimate analyses of all substances, immediately seen in, or ultimately to be traced to, the vegetable or animal kingdom; products obtained from, or substances existing in, organized bodies. Numerous as are the substances referable to this class they are formed from a very few ultimate elements; and can, therefore, differ only in the proportions of these elements, or in the mode of their combination. Oxygen, hydrogen, carbon, and nitrogen are the principal ultimate elements so employed by Nature. With these are united, but in far smaller quantities, some earths and metals, with phosphorus and sulphur. Organic substances, therefore, may generally be resolved into the same ultimate elements; though for the most part in dissimilar proportions, they readily undergo decomposition, a red-heat is at all times sufficient for this purpose, and in numerous cases the decomposition is rapid and spontaneous even at ordinary temperatures. By slight causes the affinities and constitutions of these substances are overturned, and new products result; but in most cases it is impossible to reproduce the original substance by a direct union of its constituent ultimate elements.

The proximate analysis of an Organic substance separates it into its proximate elements; that is, into various substances, acid, alkaline, or otherwise, each of which, though itself a compound body, possesses distinct properties, and a definite constitution of two or more ultimate elements. By the ultimate analysis each of these proximate elements is resolved into its ultimate elementary constituents. If, for instance, a few leaves of wood-sorrel were at once submitted to ultimate analysis, we should obtain carbon, oxygen, hydrogen, potash, and one or two other substances of minor importance, and should learn but little of the constitution of the plant or its juices: but if we proceed more systematically, we shall obtain in the proximate elements an Acid called the oxalic; an alkali, potassa, and a small quantity of residiary matter, producing the colour and substance of a plant; and we learn, that a true Chemical Salt, formed by the Acid and the alkali, constitute the peculiarities of the juices of the plant. We then may proceed to the ultimate analysis of both the potassa and the oxalic Acid, resolving the former into oxygen and a metal; the latter into oxygen, hydrogen, and carbon.

The proximate analysis of an Organic substance consists simply of destructive distillation, by which the substance might, indeed, be resolved into its Gaseous elements. Those, however, form new combinations among themselves, and this method is therefore very properly abandoned, except for special purposes.

M. Gay Lussac and Thenard proposed the application of some substance which should readily afford oxygen when heated with the substance to be analyzed. For this purpose they first employed chlorate of potassa, and subsequently the black oxide of copper. This oxide will, if alone, bear a white-heat without parting with its oxygen; though it readily does so at a much lower temperature if any combustible be present. Hence, if three or four grains of any Organic substance containing hydrogen and carbon be mixed with the oxide of copper in a green glass or metal tube, and then exposed to heat, so disposed as to collect the gaseous products over mercury, carbohonic Acid Gas and water will be obtained. The former indicates the quantity of carbon, the latter the quantity of hydrogen. The loss of weight sustained by the oxide should in this case agree with the oxygen employed in producing the water and the carbohonic Acid. But if oxygen also had been present in the substance analyzed, this would be indicated by a proportion of oxygenized products greater than that due to the mere loss on the oxide of copper. If nitrogen forms a constituent of the substance analyzed, it will pass over in the Gaseous state, and may be separated from the carbonic Acid by removing the latter by potassa. Such is the outline of this process, but for the numerous minutiae to be observed, consult the references. (a.) Very recently, Dr. Prout has devised a most elegant apparatus and method, which may be seen in the Philosophical Transactions. (b.) The presence of water in the substance to be examined is to be most carefully avoided; and this is best effected by drying it in an exhausted receiver, at some moderate elevation of temperature, and in presence of some highly absorbent substance, such as sulphuric Acid. A convenient apparatus for this purpose has been devised by Dr. Prout. (c.) We owe also to Mr. Cooper (d.) and to Dr. Ure some useful suggestions and apparatus in this branch of analysis.

It has been found that some proximate elements, having very distinctive Chemical properties, present on ultimate analysis the very same elements, and in the same proportions. Hence it is inferred that such differences as constitute distinct substances, may arise solely from different modes of combination existing among the ultimate elementary atoms. Of this opinion is Gay Lussac, who considers alcohol, for instance, as consisting of a compound of olefiant Gas with water, whilst Berzelius, on the other hand, considers it only a universal compound of atoms of hydrogen, carbon, and oxygen.
CHAPTER I.

CHEMISTRY OF VEGETABLE BODIES.

(975.) We shall now, for the most part, follow M. Thenard in giving a very brief abstract of Vegetable Chemistry. The following laws he considers to be general, as far as researches at present extend.

1. That when a Vegetable substance does not contain nitrogen, and that when the quantity of its oxygen is to the quantity of its hydrogen in a greater ratio than is due to the constitution of water, the substance is acid, whatever be the quantity of carbon entering into its composition.

2. That when these properties are reversed, the substance may still be acid, but that in general it is oily, resinous, alcoholic, or ethereal.

3. That when the oxygen and hydrogen are in just ratio for the formation of water, the substance is analogous to sugar, gum, woody fibre, &c.

4. That when any Vegetable substance contains much hydrogen, it contains at the same time much carbon, and the converse.

5. That many Vegetable substances may be represented, as to their composition, by a certain number of volumes of vapour of carbon, of hydrogen Gas, and of oxygen Gas; or by a certain number of volumes of some of those binary compounds which may be produced between hydrogen, oxygen, and carbon.

6. That no Vegetable substance contains at the same time oxygen enough to transform both its hydrogen and carbon into water and carbonic Acid.

According to these views, M. Thenard treats of Vegetable substances under seven different heads, a division which we can only in part adopt.

CLASS I. Vegetable proximate elements in which the oxygen is in excess with regard to the hydrogen as to the formation of water.

Division 1. Acids.
Division 2. Alkalis.

CLASS II. Vegetable proximate elements in which the oxygen is in defect with regard to hydrogen as to the formation of water. Oils, bitumens, alcohol, ethers, &c.

CLASS III. Vegetable proximate elements in which the oxygen and hydrogen are in just proportion for the formation of water. Sugar, honey, gums, &c.

CLASS IV. Vegetable colouring principles.

CLASS V. Vegetable proximate elements not noticed in any of the preceding Classes.

(976.) As a general outline of the properties of these substances, it may be well to bear in mind, that all are either solid or liquid at all ordinary temperatures. Most are volatile per se, as for example, alcohol, ether, essential oils; others are readily vaporized in different Gases, such as camphor, benzoic, and oxalic Acid. Others are fixed at all temperatures which do not produce their decomposition.

When submitted to distillation, the former undergo constitutional change, the second sort are partially volatilized and partly decomposed, and the last are entirely decomposed. From the decomposition of those which do not contain nitrogen, there result water, carbonic Acid, acetic Acid, gaseous oxide of carbon, oil, carbon, and carburetted hydrogen. But those which contain nitrogen, afford in addition ammonia, hydrocyanic Acid, and nitrogen Gas.

By the aid of air and moisture many of these substances undergo spontaneous decomposition. For more complete details of the action of the other simple and compound elements we must refer to the Work of M. Thenard.

CLASS I. DIVISION I.

Vegetable Acids.

(977.) With the greater part of these substances the salifiable bases unite to form Salts. All redden Vegetable blues, and all consist of oxygen, hydrogen, and carbon. M. Thenard enumerates thirty-four which have been mentioned by Chemists, but some are now proved to be identical substances.

Acids that are both natural and artificial.

(978.) Acetic. This Acid has been long known; it is most abundantly obtained by the acceous fermentation, or by the destructive distillation of Vegetable bodies, and it is found among the juices of some plants. The impure acceous Acid, now obtained from the distillation of wood, is called pyrolignous Acid, and by subsequent purification becomes a limpid vinegar, or a much stronger Acid according to circumstances. The strongest acetic Acid is obtained by distillation from the acetates, those especially of potassa or copper. Thomson has shown that the only correct estimate of acetic Acid is to be found in its neutralizing power, and that the Specific Gravity cannot be depended upon. This Acid forms numerous and important Salts.

(979.) Malic Acid was discovered by Scheele in 1785. It exists in the juice of the apple, and hence its name. Also in the juices of gooseberries, currants, and oranges. In the houseleek, where it is combined with lime. Mr. Donovan discovered in the juice of the fruit of the Sorbus aucuparia, an Acid which, not agreeing with the described characters of the malic, he called the sorbic. It seems now proved that the Acids are the same, but that Mr. Donovan's description was inaccurate, and those previous to his not so, from impurities present in the malic Acids heretofore examined. This Acid forms Salts which are soluble in water and some highly so.

See Donovan, Phil. Trans. 1815; Braconnot, An. de Ch. et Ph. vol. vi. viii.

(980.) Oxalic Acid. This Acid was first recognised by Bergman. It is found in the Oxalis acetosella, (wood-sorrel,) in the Rumex acetosa, (common sorrel,) and in several lichens. It may be formed abundantly by the action of nitric Acid on sugar. Oxalite
Acid seems to have this peculiarity that it contains no hydrogen. It is a most rapid and fatal poison. See Berzelius, *An. de Ch.* vol. xcv.; Döbereiner, *An. de Ch. et Ph.* vol. xix.; Gay Lussac and Thenard, *Rec. ; Thomson, First Principles*, vol. ii.; Wollaston, *Phil. Trans.* 1818.

**Acids produced by Nature only.**

(981.) **Benzoic Acid.** A substance found in some balsams; in vanilla, castor, in some plants, and in the urine of some herbivorous animals. It is obtained in white, crystalline filaments by sublimation. A few Salts formed by this Acid have been described.

(982.) **Citric Acid.** Scheele first submitted the juice of the lemon to Chemical examination and proved it to contain a distinct Acid. It exists also in small proportion in some other fruits. This Acid crystallizes readily. Consult Fourcroy, *Système*; Gay Lussac and Thenard, *Recherches*; Berzelius, *An. de Ch.* vol. xciv.

(983.) **Fungic Acid.** M. Braconnot has thus named an Acid found by him in the juice of some of the Fungi. See *An. de Ch.* vol. lxxxvii. p. 237, 253.

(984.) **Gallic Acid.** This Acid was examined and described by Scheele in 1786. It is found in some astringent barks and in the gall-nut.

(985.) **Ellagic Acid.** Such is the name formed by reversing the word Galle, and applied by M. Braconnot, in 1818, to an Acid first noticed by M. Chevreul in 1815; and supposed to exist in the gall-nut together with the gallic. This Acid is little known.

See *An. de Ch.* et *Ph. vol. ix.* p. 157.

(986.) **Igauric Acid.** This substance, so termed by MM. Pelletier and Caventou, was discovered by them in examining the active principles of the bean of St. Ignatius. (*Nux vomica.*) M. Thenard has doubts of this Acid being a true Natural Acid. See *Dict. de Chimie* de Klaproth and Wolff, *Thomson, Nich.* *Jour.* vol. vii. p. 129.

(987.) **Quinic Acid.** This Acid is found in the Quinque, or Cinchona bark, united with other Vegetable elements. It has a strong, acid flavour, free from all bitterness; does not easily crystallize; forms a class of Salts which have been little studied. See Vaquez, *An. de Ch.* vol. lix. By English writers this Acid is sometimes spelt Kinic.

See *An. de Ch.* vol. xxxiv. p. 301.

(988.) **Lactic Acid.** Such is the name given by M. John to an Acid which he obtained from Stick Lac. It is at present very little known. See Schweiggers, *Journ.* vol. xv.; or *An. de Ch.* et *Ph.* vol. i. p. 445; Pearson, *Phil. Trans.* 1794.

(989.) **Meconic Acid.** This Acid was discovered by M. Sertürner, in his valuable researches into the constituent principles of opium. It derives its name from *pisces*, a poppy. See Sertürner, *An. de Ch.* et *Ph.* vol. v. p. 21; Robiquet, *An. de Ch.* et *Ph.* vol. v. p. 280.

(990.) **Mallic Acid.** Klaproth discovered this Acid combined with alumina in a rare mineral then called Honey-stone from its colour. Consult *An. de Ch.* vol. xxxvi. p. 203, and vol. xlv. p. 232.

(991.) **Moric or Moroxylic Acid.** From the juice of the mulberry (*Morus alba*) M. Klaproth, in 1803, obtained this Acid. See *Dict. de Chimie* de Klaproth and Wolff. Thomson, *Nich. Jour.* vol. vii. p. 129.

(992.) **Pectic Acid.** This substance, admitted by M. Thenard into his *System,* was discovered by M. Payen first in the bark of the root of the plant producing Japan varnish. M. Braconnot has continued the inquiry, and found the same substance to exist in all Vegetables. The name is derived from *pectic*, a coagulum, from the gelatinous appearance which it always presents. See Payen, *Jour. de Pharmacie,* vol. x. p. 385; and *Jour. de Chim. Médicale,* vol. i. p. 589; Braconnot, *An. de Ch.* et *Ph.* vol. xxviii. p. 178, and vol. xxx. p. 96.

(993.) **Acid of the strychnos-pseudo-kina.** A substance very little known, but mentioned by Vaquel. *Bull. de la Société Philomatique,* Mars, 1823.

(994.) **Succinic Acid.** This Acid is obtained from amber by gentle distillation. It exists also in some sorts of turpentine, and a few of its Salts have been noticed. See Robiquet and Colin, *An. de Ch.* et *Ph.* vol. iv. p. 326; *An. Phil.* vol. xv. p. 388; Berzelius, *An. de Ch.* vol. xciv. p. 199.

(995.) **Sulpho-sinapic Acid.** MM. Henry and Garot separated this substance from the fixed oil of mustard. See *Jour. de Chimie Médicale,* No. X. and XI.

(996.) **Tartaric Acid.** After so many Acids, which are yet are scarcely known by name, we arrive at one that has been long noticed. Its presence was recognised in cream of tartar by Du Hamel, Margraaff, and Rouelle the younger; but Scheele first examined it in an uncombined form. Tartaric Acid seems to exist in the juices of several acidulous fruits, and is deposited in combination with lime and potassa in considerable quantity from new wines. The tartrates have excited considerable attention, as some are serviceable in Medicine: such are the tartrate of potassa and soda; (Rochelle Salts;) the bitartrate of potassa; (cream of tartar; tartrate of antimony and potassa, (tartar emetic.) See Retzius, *Stock. Trans.* 1770; *An. de Ch.* vol. xi.; Thenard, *Syst. vol. iii.* p. 677.

**Acids produced solely by artificial Processes.**

(997.) **Camphoric Acid.** This substance is obtained from camphor by treating it with a large excess of nitric Acid. It was discovered in 1755 by M. Kosegarten. See *An. de Ch.* vol. xxiii. p. 159; vol. xxvii. p. 19; and *An. de Ch.* vol. lxxiv. p. 301.

(998.) **Mucic Acid.** This Acid was at one time called the succalacte, because obtained by Scheele from sugar of milk in 1750. It is now formed by treating sugar of milk, gum, and some other substances with nitric Acid. See Scheele, *Memoirs*; Langier, *An. de Ch.* vol. lxxii. p. 81; Tromsdorff, *An. de Ch.* vol. lxxi. p. 79; Labillardière, *An. de Ch.* et *Ph.* vol. ix.; Berzelius, *An. de Ch.* vol. xciv.

(999.) **Nanceic Acid.** So named by its discoverer, M. Braconnot, from Nancy, the place of his residence. It appears to form spontaneously upon the change to accecence in certain Vegetable juices. *An. de Ch.* vol. lxxxvi. p. 84. The experiments of M. Vogel led M. Thenard to suspect this Acid to be identical with the lactic. *Jour. Pharmacie,* vol. iii. p. 491.

(1000.) **Suberic Acid.** This Acid was discovered by M. Brugnatelli in 1787; it is formed by the action of nitric Acid on Cork. See Brugnatelli, *Crefil's Annals,* 1787; Bouillon Lagrange, *An. de Ch.* vol. xxiii.; Chevreul, *An. de Ch.* vol. lxxi.; Bussy, *Jour. de Pharm.* vol. viii. p. 107.

**Pyr-Acids.** There is a class of Acids pro-
DIVISION II.

Vegetable Alkalis.

The Vegetable Alkalis best known are morphia, strychnia, brucia, cinchonia, quinina, veratria, delphina, and emetina. Daphnia, hyoscymia, daturia, aconitina, and cicuitina have been announced, but are still less known.

All these Vegetable saltifiable bases are solid, white, bitter or acrid, scentless, heavier than water, and change syrup of violet to green. Veratria, delphina, and emetina can only be obtained in powder, but the rest are capable of crystallization. When decomposed by heat, they all give ammoniacal products among other gases, in consequence of the nitrogen they contain. All are almost insoluble in water; alcohol being their true solvent. Sulphur does not combine with them. Chlorine and iodine, by aid of water, dissolve them. Their saturating power is feeble. Generally speaking, their sulphates, nitrates, and hydrochlorates are soluble. On the other hand, many neutral tartrates, oxalates, and gallates are insoluble. Excess of acid always induces solubility. All alkalis, and even magnesia, disengage the acids from these vegetable bases; but in their turn these are capable of removing the acids from most other oxides. In a neutral solution of one of these vegetable salts, infusion of galls forms, from the insolubility of the gallate, precipitates, which the acids or alcohol redissolve.

These Vegetable Alkalis do not exist free in the vegetables which produce them, but are there united with acids; and as far as present known, it is to the presence of these salts that the active properties of the plants are due.

The general outline of the process by which they are separated is this: The vegetable juices are boiled with magnesia and water. The precipitate obtained is dried and boiled in pure alcohol; thus a solution of the alkalies is obtained, and from this the alcohol may be removed by careful evaporation.

All these alkalis contain oxygen, carbon, hydrogen, and nitrogen. The action of all on the animal economy is very active, and is greatly increased when they are in the state of salts, from their more ready solubility.
Vegetable Proximate Elements, in which the Oxygen is in defect with regard to the Hydrogen, as to the formation of water.

These substances are in general oily, resinous, alcoholic, or ethereal; some among them possess acid properties. All are very rich in carbon, this substance sometimes amounting to four-fifths of their weight. They are in general fusible, and very combustible. Many may be volatilized by heat, unchanged; others are decomposed. Almost all are very soluble in spirits of wine, and insoluble, or very slightly so, in water.

(1014.) Stearine and Elaine. It appears from the researches of M. Chevreul that all fats and fixed oils contain two distinct principles to which he has applied these names. The former gives consistency, the latter, of a more liquid nature, produces fluidity. In the formation of soaps these principles are completely changed into three others, Margaric Acid, Oleic Acid, and Glycerine. See Chevreul sur les Corps Gras.

(1015.) Fixed Oils. These are for the most part liquid at our ordinary warmer temperatures. Yellow is the prevailing colour, and all are lighter than water. Of this class, olive oil, castor oil, nut oil, linseed oil, &c. will readily occur to the reader. For analyses of oils, see Gay Lussac and Thenard, Recherches; Sausure, An. de Ch. vol. xxiii. p. 351; Bracconnot, An. de Ch. vol. xcvii. p. 225. On the nature and formation of soaps, see Thenard, Syst. vol. iv. p. 70; D'Arcet, &c. An. de Ch. vol. xix. p. 253; Colin, An. de Ch. et Ph. vol. iii. p. 5; Marcel de Serres, An. de Ch. vol. xxvii. p. 54; Chevreul on les Corps Gras.

(1016.) Essential Oils. These oils, sometimes termed essences, contain the odoriferous properties of various plants, and hence they form, either alone, or as spirituous solutions, the basis of most perfumes. In many properties they differ from the fixed oils. They are acid, caustic, very fluid, highly volatile, and readily combustible on the approach of burning bodies. Partially soluble in water, not capable of forming very intimate combinations with alcali. Those most generally known are obtained from the lemon, bergamot orange, lavender, rosemary, aniseed, rose, jasmine, caraway seed, ambergris, and turpentine from the resin of the pine.

(1017.) Resins. These substances are generally solid, brittle, but little heavier than water, scentless and tasteless when pure, generally of a yellow or brown colour; non-conductors of electricity, but themselves readily electric by friction. Combustible in the open air with much flame and black smoke, which, when collected, condenses into the well-known substance lamp-black. The substances in this class are common resin, colophony, pitch, balsam of copiaha, copal, elemi, mastic, sandarac, dragon's blood, some viscid turpentes, Burgundy pitch, and a few others. For analyses of these bodies, see Gay Lussac and Thenard, Recherches, and some curious experiments by Mr. Hatchett, Phil. Trans. vol. xxiv., xxv., xxvi.

(1018.) Gum Resins. These substances are exudations from the bark and branches of trees; they are much used in Medicine and in the Arts. In this class are assafotida, gum ammoniac, galbanum, olibanum, myrrh, opompanox, scammony, aloes, lac, and a few others. For the Natural History of these bodies, consult any good Pharmacopoeia.
Specific Gravity is about 0.7, and it is highly volatile. Consult Thenard, *Système*, vol. iv. p. 146; *Mém. d'Arceil*, vol. i. ii.

(1025.) **Bitumens, Coal, Amber, &c.** It would require volumes to do justice to the Natural History of this important class of substances, which we must dismiss after a few lines of description. All are generally believed to be the results of the spontaneous decomposition of Vegetable matters, though the period at which they must have flourished is, in many cases, very remote. Bitumens proper, and naphtha, a more limpid and volatile bitumen, (containing no oxygen,) are generally found as exudations from the earth in parts subject to the operation of volcanic fires. Coal is found in extensive deposits in several parts of the earth, and forms by far the richest mineral treasure of England. Amber is found in masses, chiefly on the Northern European shores; and on the coast of Sicily, near the mouth of the Giaretta. Retinashphalt, first described by Mr. Hatchett in the *Phil. Trans.* for 1804, is found in small quantity with brown coal at Bovey, in Devonshire.

**CLASS III.**

**Vegetable Proximate Elements in which the Oxygen and Hydrogen are in just proportion for the formation of water.**

All substances in this class are solid, heavier than water, scentless, and have no action on Vegetable colours. They are not volatile, but are altogether decomposed by heat. When placed in contact with 100 or 150 times their volume of chlorine, they become carbonized in a few days, and the chlorine passes to the state of hydrochloric Acid Gas.

(1026.) **Sugar.** Of this substance four kinds at least are recognised by Chemists: that of the cane, beet-root, and other such Vegetables; of the grape, and other fruits; of some of the Fungi; and that which is found in the urine of persons labouring under one variety of Diabetes.

(1027.) **Honey** is a substance greatly analogous to sugar in its nature, secreted by some plants, and collected by bees. It has been questioned how far the process performed by this interesting animal is secretive or merely a process of mechanical separation. On this point see Huber, *Jour. de Phys.* 1804.

(1028.) **Mannite.** This name is given by M. Thenard to the saccharine principle of manna, an exudation from some species of ash.

(1029.) **Asparagine.** The vegetable principle peculiar to asparagus; discovered by M.M. Vauquelin and Robiquet. See *An. de Ch.* vol. iv. p. 88.

(1030.) **Starch.** This name is applied generally to a substance found in a great number of roots and grains; and forming a very considerable share of their nutritive substance. Consult Saussure, *An. Phil.* vol. vi. and *An. de Ch. et Ph.* vol. xi.; Caventou, *An. de Ch. et Ph.* vol. xxxi.

(1031.) **Gum.** This useful proximate element is obtained as an exudation from several plants. The most plentiful variety is from the *Mimosa* genus, growing in hot Countries, and well known as Gum Arabic. The gum of the plum and cherry tree, and even the mucilage obtained by macerating linden, are believed to be varieties of the same substance. See Bostock, *Nich. Jour.* vol. xvii.

(1032.) **Lignin, or Woody Fibre.** The main solid constituent of all trees and plants. See Braconnot, *An. de Ch. et Ph.* vol. xii.

**CLASS IV.**

**Vegetable Colouring Principles.**

The substances in this class are found in various parts of Vegetables; and as they are of great importance in the Arts, they have formed the subject of numerous experiments by the most expert Chemists.

(1033.) **Hematine.** The colouring principle of logwood, described by M. Chevreul, *An. de Ch.* vol. lxxiii. p. 128.

(1034.) **Carthamine.** Such might serve for the name of a deep-red colouring matter obtained from the *Carthamus tinctorius*, but which has as yet been little examined.

(1035.) **Indigo.** This most valuable and curious Vegetable product is obtained chiefly from a genus of plants produced in Asia and America, and also of inferior quality from the *Isatis tinctoria*, which has long been cultivated in Europe. See Chevreul, *An. de Ch.* vol. lxvi. p. 29; also *ib.* vol. lxxii. and lxxviii.

(1036.) **Polychroite.** Such is the name given by MM. Bouillon Lagrange and Vauquelain to the colouring principle of saffron, in consequence of the great variety of tints which it is capable of assuming. (*πολύχρωμος*, many, colour.) See their Memoir, *An. de Ch.* vol. lxxx. and that of M. Henri, *Jour. de Phar.* vol. vii.

(1037.) **Carmine.** This beautiful pigment is formed from the colouring principle of cochineal with alumina or oxide of tin for a base. Cochineal is obtained from an insect which feeds on the leaves of several species of *Cactus*. See Pelletier and Caventou, *Jour. de Phar.* vol. iv.

Other red dyes are obtained from madder, Brazil wood, &c. The principal yellow dyes, are *Reseda luteola*; quercitron bark; fustic; turmeric; fernambuc, &c.

**CLASS V.**

**Vegetable Proximate Elements not noticed in any of the preceding Classes.**

Many substances which will be, or might be, here mentioned, will, most probably, upon further investigation, require to be placed in some one of the preceding classes; but this is an intricate department of the Science, and in it there have been but few zealous labourers.

(1038.) **Gluten.** This substance is sometimes termed vegeto-animal, from partaking of the nature and properties of animal matter. It is a tough, elastic substance, most readily obtained by washing away the facula, mucilage, &c. from paste made of any kind of corn. M. Taddei has recently stated gluten to consist of two distinct principles, *gliadin*, soluble in alcohol, and *zymonie*, which has not that property. *An. Phil.* vol. xv.

(1039.) **Yeast.** The peculiar principle of this substance is called by some writers *Ferment*. Its distinctive property is that of exciting fermentation in Vegetable matter under certain conditions.

(1040.) **Tannin.** This curious and important body
CHEMISTRY.

Chemistry. exists in the bark of trees, in the gall-nut, and in the juices of some plants, as the Catechu and Kino; and chiefly in such leaves as possess astringent properties. Tannin is soluble in water, and is remarkable for the combinations which it forms both with Acids and alkalis. It has a strong affinity for oxide of iron; and upon the durable, insoluble compound which it forms with gelatine depends the valuable Art of the Tanner.

Mr. Hatchett discovered a mode of forming tannin artificially by the action of nitric Acid on charcoal and some bituminous substances. See Hatchett, Phil. Trans. or An. de Ch. vol. viii.; Chevreul, An. de Ch. vol. lxxii. p. 113; and vol. lxxiii. p. 36.

(1041.) Amidine rests on the authority of M. Saussure, who obtained it from starch. An. de Ch. et Ph. vol. xi.

(1044.) Cathartin. The active principle of senna. An. de Ch. et Ph. vol. xvi. p. 20.

(1046.) Cytisine. A substance like gum arabic, obtained by MM. Chevallier and Lassaigne from the seeds of the Cytisus laburnum.

(1047.) Extractive. This name is perhaps rather vague: it has been said that saffron, by maceration in hot water, affords the type of true extractive matter; but the term has been frequently applied to whatever could be extracted from a plant by a similar process, provided no peculiar principle were recognised.

(1048.) Fungin. The name applied by M. Braconnot to the solid matter of the Fungus tribe.

(1049.) Jelly. This term is given to the gelatinous matter which is found in many fruits: the currant and gooseberry afford good examples.

(1051.) Hordein. A principle found by M. Proust in barley. An. de Ch. vol. xvi. p. 294.

(1052.) Inuline. This name was proposed by Dr. Thomson for a principle discovered by M. Rose in the Inula Henrietana, and subsequently in some other roots.

(1053.) Lupuline. First recognised by Dr. Ives of New York in the hop; and subsequently examined by MM. Planche, Payen, and Chevallier. Jour. de Pharr. vol. viii. p. 209.

(1054.) Piperine. A principle discovered by M. Ersted in common pepper, and by him supposed an alkali. M. Pelletier, however, did not find it possessed of alkaline properties.

(1055.) Oleine. This substance was discovered by M. Pelletier in the gum of the olive tree. Jour. de Pharr. vol. ii. p. 337.

(1056.) Sarcocolla. A substance which exudes from the Pennea sarcocolla, a tree of Northern Africa.

(1057.) Suberine. The name proposed by M. Chevreul for the cellular tissue of cork.

(1058.) Ulmin. Discovered, in 1797, by M. Vauquelin in a substance often seen to issue from the bark of the elm. See An. de Ch. vol. xxi. p. 44; also An. de Ch. et Ph. vol. xii.

(1059.) Caffrin. Recognised by M. Robiquet in coffee; and independently by MM. Pelletier and Caventou. See Jour. de Pharr. May, 1826.

(1060.) Colocynthin. The name given by Vauquelin to what he considered the peculiar principle of the colocynth apple. See Brandes, Jour. vol. xviii. p. 400.

FERMENTATION.

Certain Vegetable Proximate Elements, such as alcohol, some pure Acids, and alkalis, may be left to themselves and undergo no changes. Others, such as sugar, gum, starch, &c., can be left but a very short time before spontaneous changes commence among their ultimate elements, and new combinations result. To these spontaneous changes the name of Fermentation is generally applied. It is to be remembered that so long as healthy, organic life is found in Vegetable matter, Fermentation does not commence. Four sorts of products give names to the four recognised kinds of Fermentation.

(1061.) Saccharine Fermentation. The only real instance of this process is seen in starch, which being kept in a moist state for a considerable time is gradually converted into sugar. Saussure, An. de Ch. et Ph. vol. xi. p. 379.

(1062.) Vinous Fermentation. It is generally supposed that the Vinous Fermentation depends entirely upon the conversion of sugar into alcohol; and that in order that the process should take place, water and yeast must be present with a certain elevation of temperature. The conversion of the elements of the sugar into alcohol has been elegantly illustrated by M. Gay Lussac, An. de Ch. vol. xcv. p. 317. In the process as it takes place in the juices of fruits, yeast is not added, as there seems to be present some principle capable of commencing the operation spontaneously. The well-known operations of making beer, wine, and spirits, depend upon the formation of alcohol from Vegetable decoctions, or from the juices of fruits and trees. See Colin, An. de Ch. et Ph. vol. xxviii. xxx. ; on wine, An. de Ch. et Ph. vol. xviii. p. 380; Duportal, An. de Ch. vol. lxvii. p. 178.

(1063.) Acetous Fermentation. Paste and numerous Vegetable substances, especially of a mucilaginous nature, become sour by keeping; and this whether they be exposed to the air or not. This, though it arises from the conversion of their elements into acetic Acid, is not to be considered the true Acetous Fermentation. The process to which the name is strictly applied, takes place upon some Liquid in which alcohol is existent from having previously undergone the vinous fermentation; or, which amounts to the same thing, alcohol may be mixed with water. For the Acetous Fermentation to take place, some elevation of temperature is requisite, and the presence of yeast, or some such substance, in order to determine the commencement of the process. A temperature of from 60° to 80° Fahrenheit succeeds best. The operation depends on the conversion of alcohol into acetic Acid.
CHAPTER II.

CHEMISTRY OF ANIMAL BODIES.

The substances which we shall enumerate in this Chapter consist of oxygen, hydrogen, carbon, and nitrogen, as their chief elements; but small portions of other substances are united with these, so as to produce important modifications in their general properties. The first three of our classes will consist of simple proximate elements; while the last class will contain those complex fluids or solids, which are distinctly recognised as ministering to the functions of animal life.

CLASS I.

Substances neither acid nor oelaginous.

These bodies are altogether decomposed by destructive distillation, and produce water, carbonic Acid Gas; ammonia, or nitrogen, as their chief elements; but small portions of other substances are united with these, so as to produce important modifications in their general properties. The first three of our classes will consist of simple proximate elements; while the last class will contain those complex fluids or solids, which are distinctly recognised as ministering to the functions of animal life.

(1065.) Fibrin. This is the main substance of muscular fibre, and it exists abundantly in blood and in the chyle. It is a white, solid, tasteless substance. See Chevreul, An. de Ch. et Ph. vol. xix.; Gay Lussac, An. de Ch. et Ph. vol. i.; Berzelius, An. de Ch. vol. lxxxviii.; Braconnot, An. de Ch. et Ph. vol. xiii.

(1066.) Albumen. This body is found in most animal fluids and solids; and almost pure in the white of the egg. Its most marked property is the power of coagulation by heat. See Chevreul, An. de Ch. et Ph. vol. xix.; Brande, Phil. Trans. 1809; Lassaigne, An. de Ch. et Ph. vol. xx.; Bostock, Medico-Chir. Trans. vol. xii.

(1067.) Gelatine. A substance readily soluble in water, and which forms a portion of most of the harder parts of animals. Glue is gelatine obtained by boiling the skins and hoofs of animals. Isinglass, a more pure or delicate sort, is obtained from the stomachs of certain fishes. Tannin has a strong affinity for it, and thus precipitates a solid compound of the two elements. See Gay Lussac and Thenard, Medico-Chir. Trans. vol. ii.

(1068.) Casous Matter. A substance existing in milk, and separated for the making of cheese. See Proust, An. de Ch. et Ph. vol. x. p. 29.

(1071.) Sugar of Milk. This seems to be of the same nature as the sugar already mentioned (1026) as occurring in the urine of diabetic patients. See Vaquercin, Bulletin de Pharmacie, vol. iii. p. 49; Vogel, An. de Ch. vol. lxxii. p. 156; Gay Lussac and Thenard, Rech.

CLASS II.

Animal Acids.

Among animal matters Thenard names twenty-six Acids; nine differing altogether from fatty bodies; ten very considerably allied to them in nature; three totally differing in origin and constitution; whilst some others are common to the animal and vegetable, or to the animal and mineral kingdoms.

Acids more or less oxygenated, and differing considerably from fatty Bodies.

(1072.) Uric, or Lithic Acid. This peculiar Acid was discovered by Scheele, in 1776; it exists with numerous other substances in the urine of many of the higher animals. See Henry, Manch. Mem. N. S. vol. ii.; Prout, Medico-Chir. Trans. vol. ix.

(1073.) Pyro-uric Acid. If uric acid be exposed to heat in a retort, this Acid is formed and volatilized. See Chevallier and Lassaigne, An. de Ch. et Ph. vol. xiii. p. 155.

(1074.) Purpuric Acid. This Acid was first recognised by Dr. Prout, and has exercised the ingenuity of some of the best Chemists, but at present it is not well understood. It is obtained by digesting pure uric acid in diluted nitric acid. See Prout, Phil. Trans. 1818; Vaquerin, Mém. du Mus. d'Hist. Nat. vol. vii. p. 253, and vol. ix. p. 159; Brugnatelli, An. de Ch. et Ph. vol. viii. p. 251; Lassaigne, An. de Ch. et Ph. vol. xii. p. 334.

(1075.) Rosacetic Acid. This substance has only been occasionally found in urine. See Proust, An. de Ch. vol. xxxvi. p. 258; Vaquerin, An. de Mus. d'Hist. Nat. vol. xvii. p. 133; Vogel, Jour. de Pharm. vol. ii. p. 27.

(1076.) Amniotic Acid. This Acid was found by MM. Vaquerin and Buniva in analyzing the amniotic liquor of a cow. See An. de Ch. vol. xxxii. p. 229.

(1077.) Lactic Acid. Scheele discovered this Acid in sour whey, in 1760. Berzelius considers it only the acetic disguised by the presence of animal matter, and the same opinion is maintained by Tiedemann and Gmelin in their important Work on digestion, Die Verdauung nach Versuche Heidelberg, 1826.

(1079.) Caseic Acid. M. Proust, who discovered this acid substance, first called it Caseous Oxide, a name which more recent authors have changed to Caseic Acid. Proust, An. de Ch. et Ph. vol. x. p. 29.

(1080.) Cyanic Acid. We have already mentioned this Acid in another part of this Treatise. (472.)

The following Acids contain little Oxygen, and approach to fatty Substances in their Constitution and Properties.

(1081.) Sebacic Acid. This Acid results from the distillation of fatty matters. M. Thenard first recognised it. See An. de Ch. vol. xxxix. p. 193.

(1082.) Cholesteric Acid. The sebaceous matter contained in the biliary calculi of man was termed Cholesterine by M. Chevreul. By treating this substance with nitric acid, MM. Pelletier and Caventou
obtained a peculiar Acid, and gave it the name of Cholesteric Acid. See Jour. de Phar. vol. iii. p. 292.

(1083.) Stearic Acid. M. Chevreul, the discoverer, so named this Acid from στεά, fat. He considers the formation of this Acid, and its union with an alkali, the essential process in the formation of soap. See Chevreul, op. cit.

(1084.) Margaric Acid. Discovered also by M. Chevreul, and named, from its pearly appearance, from παρξωφωτος, a pearl. This Acid exists in the fat of animals. See Chevreul, op. cit.

(1085.) Oleic Acid. Another of M. Chevreul's Acids, forming part of the same fatty matters, and capable, like the others, of saturating alkaline bases.

(1086.) Phocenic Acid. An Acid obtained by M. Chevreul, by acting on a peculiar oil with alkalis. This oil, called Phocenic, he obtained from the oil of the porpoise. (Delphinus phocaena.)

The Butyric, Caproic, Capric, and Hircic Acids have similar animal origin, and may be found in the Work of Chevreul. An Acid, called the Cevadic, is described by Pelletier and Caventou, An. de Ch. et Ph. vol. xiv. p. 71.

CLASS III.

Oleaginous Animal Substances.

The substances referable to this class have the following general properties. They become liquid at very slight elevations of temperature; are insipid; very inflammable; insoluble in water; produce by distillation a small carbonaceous residuum, with much fecid oil; but by being passed in a state of vapour through a heated, porcelain tube, they deposit much carbon and evolve carburetted hydrogen Gas: they do not contain azote, and but little oxygen. M. Berard obtained a substance very similar in general properties, by transmitting a mixture of one volume of carbonic Acid, ten volumes of carburetted hydrogen, and twenty volumes of hydrogen through a red-hot tube. Döbereiner produced a similar effect from a mixture of coal Gas and aqueous vapour.

(1087.) M. Thenard says, that before the researches of M. Chevreul the notions formed relative to the fatty bodies were altogether inaccurate. "The fats were considered similar to the fixed oils, in being all as different from each other as they could be; that is to say, as much so as the various species of sugar. M. Chevreul has demonstrated that they are composed of a certain number of ultimate elements, and that the greater part differ from each other only by the relative proportions in which these exist. Of these he distinguishes eight species, to which he gives the following names: Stearine, Oleine, Cetine, Colesterine, Ethal, Phocenic, Butyric, and Hircine.

These are divisible into four well-marked groups.

"The first containing fatty substances which are not altered by alkalis, and are not capable of uniting together, viz. cholesterol and ethal.

"The second are convertible by alkalis into glycerine and oleic, margaric, or stearic Acid. Stearine of the sheep, stearine of man, and oleine.

"The third contains those which are transformed by alkalis into ethanol, and into margaric and oleic Acids. Cetine.

"The fourth comprehends those bodies which the alkalies change into glycerine, into volatile Acids when distilled with water, and into oleic Acid, or oleic and margaric Acids; phocenic, butyric, hircine."

It is not in our power to enter into the detail of these substances, so that we must refer our readers to the excellent Work of M. Chevreul sur les Corps Gras.

CLASS IV.

Complex Animal Substances.

Besides the substances which have fallen under the preceding three Classes, there are certain other proximate elements, which enter more or less into the composition of Animal matters. Such are certain earthy or alkaline phosphates, carbonates, and sulphates; some Vegetable Salts with alkaline or earthy bases; some oxides; and some Salts formed by Animal Acids.

These, however, are inconsiderable in quantity, and are not exactly the bodies to which we turn our attention at this moment. We place in this class those Solids and Fluids which enter into the constitution of living animals. These substances are in general formed of numerous ultimate elements, which may be supposed to exist in groups, forming again proximate elements, by which the constitution of each substance, as blood, bile, &c., may be described.

Secretions subservient to the function of Digestion.

(1088.) Saliva. A limpid Fluid, secreted by glands surrounding the mouth, and poured forth in considerable quantities, to be mixed with the aliment during mastication, and conveyed with the food into the stomach. See Berzelius, An. de Ch. vol. Ixxviii. p. 123; Lassaigne, An. de Ch. et Ph. vol. xix. p. 176.

(1090.) Gastric Juice. A Liquid, supposed to be secreted by the stomach, and unquestionably of great importance to the process of digestion. The solvent power of this Fluid is most remarkable. See Johnson, Animal Chemistry, vol. i. p. 180.

(1091.) Bile. A bitter, yellow, or greenish Liquid, secreted by the liver, and conveyed by ducts into the duodenum, to be mingled with the aliment which has passed thither from the stomach. See Johnson, op. cit.; Thenard, Mém. d'Arcueil, vol. i.; and the Work of Tiedemann and Gmelin.

Substances immediately resulting from digested Aliments.

(1092.) Chyme. The aliment is conveyed into the stomach, and there converted into a sort of pulpy matter, which is termed Chyme. For greater clearness, this substance is mentioned, though, as must be obvious, it is not a Chemical element of any sort; nor at all definite in its composition. See Marck, An. de Ch. et Ph. vol. ii. p. 50; Prevost and Le Royer, An. des Sciences Naturelles, vol. iv. p. 481.

(1093.) Chyle. This name is applied to the Liquid absorbed by the lacteal vessels dispersed throughout the small intestines, and from these conveyed into the thoracic duct. Chyle is a white, opake, milky-looking fluid. See Vaquelin, An. de Ch. vol. lxxxv. p. 22; Brande, Phil. Trans. 1812; Prout, An. Philos. vol. xiii.; Prevost and Le Royer, vol. sup.

(1094.) Blood. The general appearance of this Fluid must be familiar to all: very numerous have been the researches made upon it by Chemists, especially...
Chemistry.

with reference to its colouring principle. Blood contains water, albumen, fibrin, a coloured Animal substance, a small quantity of fatty matter, and some Salts. When recent healthy blood is left at rest, it shortly separates into two portions, the one a transparent, yellowish Liquid called the serum; the other an opaque, reddish or brownish coagulum. The latest researches on this much agitated subject have proved that iron is the colouring principle of the Blood.

(1095.) Urine. This excrementitious fluid is separated by certain glands, the kidneys, in order to be rejected from the system. This liquid has been the subject of very numerous researches, in consequence of its important pathological relations. Consult Cruickshank in Rollio, on Diabetes, 2d Ed.; Berzelius, Animal Chemistry; Henry, An. Phil. vol. i.; Scheele, Essays; Vogel, An. de Ch. vol. xxiii.; Prout, An. Phil. vol. xiv.; Berzelius, An. Phil. vol. ii.; Nicolas, An. de Ch. vol. xiv.; Dupuytren and Thenard, Ibid. vol. lix.; Fourcroy and Vauquelin, An. de Ch. vol. xxxi. xxiii.; Wolleston, Phil. Trans. 1797; Berzelius, An. de Ch. vol. lxxxvii., and lxxxviii.; Proust, An. de Ch. et Ph. vol. xiv.; Prout, On the Nature and Treatment of Calculous Disorders.

(1096.) Intestinal Gases. A mixture of varied constitution, examined by Chevreul and Magendie, An. de Ch. et Ph. vol. ii.; Lameyran and Fremy, Bulletin de Pharmacie, vol. i.

Solid Parts of Animals.

(1098.) Cerebral Matter. This constitutes the brain, spinal marrow, and nerves of animals. See Vauquelin, An. Phil. vol. i.

(1099.) Skin. This consists of three distinct layers. The exterior is the epidermis, or cuticle; the central is the rete mucosum; and the interior, which covers the muscles, is the true skin. See Johnson, An. Ch. vol. i.

(1100.) Tendons, Membranes, and Ligaments. These seem to consist almost entirely of gelatine.

(1101.) Wool, Feathers, and Hair appear, from the experiments of Vauquelin, to contain a peculiar Animal substance, with oil, sulphur, silica, iron, phosphate, and sulphate of lime.

(1102.) Horn. The hoofs and nails of animals consist chiefly of gelatine, with a matter analogous to coagulated albumen.

(1103.) Muscle. This is the flesh of chiefly fibrin; but besides small portions of other ingredients, it contains a peculiar substance called osmazome; this produces the odour and nutritive portion of soups.

(1104.) Bone, Teeth, and Shell. Bone consists of a cartilaginous mass, rendered solid by interposition of earthy matter and gelatine. The earthy matter is chiefly phosphate and carbonate of lime. Teeth and ivory seem, by the analysis of Allen and Pepsy, to contain a much larger proportion of earthy substance, and less soluble matter. The shell of eggs, crabs, lobsters, and star-fish consists chiefly of carbonate of lime, with a little phosphate and Animal matter. In the shells of oysters and ordinary Mollusca, the phosphate of lime is absent.

Glandular and Membranous Secretions.

(1105.) Lymph. A colourless and transparent Liquid which circulates through a certain order of vessels, which seem to commence near the extreme ramifications of the arteries, and, uniting to form larger channels, return the lymph into the thoracic duct. See Brande, Phil. Trans. 1612; Leuret and Lassaigne, Jour. de Ch. Méd. vol. i. p. 155.

(1106.) Synovia. A Liquid secreted by a system of glands for the purpose of lubricating the joints, and the ligaments uniting them. See Margueron, An. de Ch. vol. xiv.; Vauquelin, Jour. de Phar. vol. iii.

(1107.) Fetal Liquids. These fluids are contained within the respective membranes surrounding the fetus. The exterior being the chorion, the intermediate one the allantois, and the interior the amnios. See Dulong and Labillardiere, Procès-Verbal de la Stance Publique de l'Ecole d'Alfort, 1817; Lassaigne, An. de Ch. et Ph. vol. xvii. p. 295.

(1108.) Humours of the Eye. Of these there are three: 1st, the aqueous, in the anterior chamber between the transparent cornea and the iris, and also in the posterior chamber between the iris and the crystalline lens; 2dly, the crystalline lens itself; and 3dly, the vitreous humour, occupying a considerable space at the back of the crystalline lens. See the experiments of Chenevix, Nicolas, and Berzelius, Bibl. Brit. vol. iv.; An. de Ch. vol. lii. p. 307, vol. lxxxvii., and lxxxviii. p. 138.

(1109.) Tears. A limpid Fluid, analyzed by MM. Fourcroy and Vauquelin, An. de Ch. vol. x. p. 113.

(1110.) Animal Mucus. This Liquid is not confined to any particular part of the body, nor is it secreted by any perceptible glandular tissue, but the secretion takes place at the surface of all mucous membranes. It is most abundant in the nose, mouth, esophagus, stomach, intestines, urinary passages, &c. See Fourcroy and Vauquelin, An. de Ch. vol. lxi. p. 26; Berzelius, Ibid. vol. lxxxviii. p. 113.

(1111.) Perspiration. The fluid issuing from the system under this name is at all times passing off, but sometimes as a vapour, when it is called the insensible perspiration; at other times in such quantities as to collect in moisture on the surface, when it is called sweat. See Berzelius, An. de Ch. vol. lxxix. p. 20; Seguin, Ibid. vol. xc. p. 14.

(1112.) Milk. A Fluid secreted by appropriate glands in animals of the class Mammalia, and designed for the sustenance of their young, contains three distinct proximate principles, the cream, curd, and whey. See Scheele, Mémo. vol. ii.; Fourcroy and Vauquelin, Mémo. de l'Institut, vol. vi. p. 22.

Concretions found in the Animal System, and all resulting more or less from diseased Action.

(1114.) Bilary. Gall stones, as they are called, are
Chemistry.
concretions formed in the gall bladder, and found there
or in the biliary ducts, where they, at times, produce
serious effects. See Thenard, Mém. d'Arcueil, vol. i.;
Orfila, An. de Ch. vol. lxxxiv. p. 84; Caventou, Jour.
de Pharr. vol. iii. p. 369; Chevreul, Jour. of Science,

(1115.) Urinary. From the constituent principles of
the urine these calculi are separated either in the kid-
neys primarily, or in the bladder by deposition upon
some nucleus. They exist also in the prostate gland,
which in such cases is probably the seat of their origin.
On this important subject consult Scheele's Essays ;
Wollaston, Phil. Trans. 1797 and 1810; Fourcroy and
Vaquerin, Mém. de l'Inst. vol. ii. p. 112; An. de Mus.

Gravel, Calculus, 

CHAPTER III.

FUNCTIONS OF ANIMAL AND VEGETABLE LIFE.

Animal Life.

(1122.) The changes produced upon the various
substances employed for the support of life are mainly
connected with physiological researches, but to such
researches Chemistry lends an important and even
necessary assistance. Food and air are essential to the
continuation of vitality. The former undergoes mas-
tication, is mixed with saliva, and then descends into
the stomach. It is there acted upon by the gastric
juice, and the mass is termed chyme. The changes
produced upon the food during the process of digestion
have exercised the ingenuity of many physiologists.
Among the most recent and most remarkable dis-
coveries, is that made by Dr. Prout, and published in
the Philosophical Transactions for 1824, of the
production of hydrochloric Acid during this process.
Passing thence into the intestines the bile and pancreatic
juice are added to it. Here it is separated into excre-
mentitious matter to be rejected from the system, and
chyle to be absorbed by a peculiar set of vessels and
applied to nutritive purposes.

From this period the chyle forms a part of the circu-
lating system. From the lacteal vessels it is poured
into the thoracic duct, but whether in the process it un-
dergoes any further change is not certain. By the
thoracic duct the chyle is conveyed to the larger veins
proceeding to the heart; the blood is thence trans-
mited to the lungs where the essential process of aera-
tion takes place. It is then returned to another cavity
of the heart, from whence it is propelled through the
arterial system to the utmost extremities of the frame,
and having there supported and excited all the func-
tions of vitality in every organ, it is returned again by
the veins to be mixed with fresh supplies of energetic
matter, and again diffused throughout the body.

The changes produced upon the blood by its passage
through the lungs have formed the subject of numerous
experiments. It seems well established that among
these the absorption of oxygen is most important and
extensive. Hence the necessity of the presence of oxy-
gen Gas in air to fit it for respiration; and the diminu-
tion of that element which is found to take place in air
that has undergone the process. Besides that portion
of oxygen which goes to aerate the blood, and to pre-
pare it for the arterial circulation, another portion is
converted into carbonic Acid Gas, and emitted with the
aerial mass that is returned into the atmosphere by
expiration.

Vegetable Life.

(1123.) The germination of a seed is the first step
towards Vegetable life. The seed itself consists of a
cuticle enveloping the germ, and the cotyledons, or
seed-lobes. The germ consists of the radicle and the
plumula. Moisture, air, and a certain degree of heat are
requisite for vegetation. The heat must exceed 32°
Fahrenheit, and must not reach that of boiling water.
Light, which is of first-rate importance to the growing
plant, is injurious to germination. This process con-
ists in the development of the parts already named.
The radicle descends into the earth in search of nutri-

ement; the plumula expands into the stem and first
elements of the future tree; the cotyledons afford nutri-
tment in the early stages of vitality.

The process of Vegetable assimilation is this. The
root absorbs moisture and soluble Vegetable matter, the
food of the plant. The juices so imbibed are carried
up through certain vessels, and spread by ramifications
throughout the leaves, which, acting as aeraating sur-
faces, or lungs, prepare the juices for strict assimilation.
The juices are then transmitted to the proper vessels,
returned through the inner bark, and thence employed
in the increase of the plant. In these juices the pecu-

liar properties of each plant chiefly reside.
(1124.) The object of Chemical analysis is the separation of all compound bodies into their proximate or ultimate elements. For this purpose the first step is the application of tests for the purpose of ascertaining what the substance before the analyst may be, and what elements enter into its composition. When the presence of certain elements are ascertained, it becomes necessary to devise processes by which each of these may be separated from the rest and its quantity ascertained. The meeting with a substance no longer capable of qualitative division, and differing in properties from all substances previously known, is the discovery of a new element, and forms one of the highest rewards to the industry of the analytical Chemist. To enter upon these branches of the subject, even in abstract, would extend far beyond the limits to which we are confined. On the subject of tests the reader will find Payen and Chevallier, *Traité des Réactifs*, valuable guides. On the subject of analysis he will do well to consult the last Volume of M. Thenard’s *Traité de Chimie*, or a translation of it by Mr. Children. Most important information will always be obtained by consulting the numerous analyses in the periodical *Transactions and Journals*.

It has not been unusual in Treatises on Chemistry to insert descriptive catalogues of mineral substances. With such a plan we should not concur even if our limits permitted; for it would seem that by so doing the respective boundaries of Mineralogical and Chemical Science are confounded. It is the province of the Mineralogist to describe the substances with which he may meet according to all those external and physical characteristics by which minerals are distinguished from each other. In some, but in very few cases, Chemistry has made a further separation; but in all cases the history of a mineral is incomplete unless also its Chemical analysis be given. This it is the province of the Chemist to furnish. Thus the full description of the mineral results from the application of two distinct branches of Science, generally more or less united among the attainments of the same individual but not essentially coexistent. It would not be difficult to name Chemists of first-rate excellence who are not Mineralogists; nor, on the contrary, to point out able Mineralogists who are utterly incompetent to the analysis of the mineral they describe. Unquestionably the wants of the Mineralogist frequently demand the employment of the skill of the Chemist, but the Chemical examination of any substance artificially prepared and placed before him, is as justly the task of the latter, that of the native produce of the rock and the mine.

</table>

Note by Dr. Henry. "In this Table, the real Acid in nitric Acid of Specific Gravity 1.5, is rated at 4.8 per cent. more than is contained in it according to Dr. Wollaston and Mr. Phillips, the mean of whose numbers is 25.1 water + 74.9 Acid in 100 parts of Acid of that density. The numbers in the Table will, I believe, however, be very near the truth, if reduced at the rate of 6 per cent. Thus 6 per cent. on 79.7 is 4.782; and 79.7 – 4.782 = 74.918, which is very near the true number."

This Table is by Lowitz, Crell's An. 1796, vol. i. p. 202: the column for temperature 60° is a convenient addition by Dr. Thomson. For more extensive Tables, see Blagden, Ph. Tr. 1790, and Gilpin, Ph. Tr. 1794. Gilpin considered his strongest alcohol of 825, temperature 60°, to consist of 100 parts of alcohol, Specific Gravity 0.944, + 0.5 of water. See also Tralles, Mém. Acad. Berol. 1811, or Gilbert's Annates, vol. xxxviii. p. 389.

</table>
TABLE XII. THE ATOMIC WEIGHTS, CONSTITUTIONS, &c. OF BODIES.

The following Table serves partly as a reference by which to find any substance mentioned in this Treatise. In thus employing it, the reader will be immediately struck with the very general and limited nature of the description of each individual substance, which it is possible to convey in a Treatise of this extent; but with this unavoidable disadvantage, the unity of method is preserved, and the outline of a plan for what may be enlarged by any one into a more ample Treatise is developed. The Table is also designed to show the state of our knowledge with regard to the combining proportions, or our belief respecting the atomic constitution of substances. The nomenclature made use of has been already explained in Art. (110), (111), and (112). It possesses the following advantages. In Oxydes, Iodides, Chlorides, Sulphures, Salts, &c. it invariably employs such a name as will point out at once the degree of oxidation, &c. In all Salts it points out with precision the atomic proportion between the Acid and the base; and also the degree of oxygenation of the base. The Greek prefixes Prot-, Deut-, Trib-, Tetart-, &c. are solely confined to the degree of oxygenation; while in the Iodides, Sulphures, &c. h., tetr., quater, &c. are employed as in the case of Salts stated in the Paradigm (111). The practical consequences for this will be found by any one who shall try to interchange these two terms; and it is from such compulsion that we depart from our original design mentioned in (111), of applying these Greek terms to the Chlorides, Sulphures, &c. Our nomenclature does not, however, extend to a description of the water in each Salt.

It may be objected that these descriptive names are inconveniently long; let us, therefore, fairly examine one or two of the longest names in the following Table, and inquire whether the advantage of a true atomic description is sufficient to justify the change. The following, for example, is the simplest case of all that could be proposed against us. Persesquisulphate of Iron is called Hemi-deuto-semi-bisulphate of Iron. The word Persesquisulphate implies that the Salt contains the Peroxide of Iron, but then we know not the proportion between the atoms of Iron and Oxygen. By Sesqui we learn conventionally that there is base one atom + Acid 1 atom, or, perhaps, only that there is half as much more Acid in this Salt as in the Sulphate. The name we employ tells us more. As an invariable rule we take the Greek commencement of the name Hemi-deuto, from this we learn that the oxide contains Oxygen $\frac{1}{2}$ atom + metal 1 atom. From the next portion semi-bi-we learn that the Salt contains Acid $\frac{1}{2}$ atom + base 1 atom, and from the remainder of the word the nature of the Acid and of the base are obvious.

Deuto-semi-bisulphate of Uranium may be similarly analyzed, and will be found equally explanatory; while Sulphate of Uranium, the common name, neither expresses the degree of oxidation of the Metal, nor the atomic constitution of the Salt.

The less important classes of Salts are not given at length for want of space. A valuable Table of Double Salts given in Thomson's First Principles is omitted for the same reason.

The main authority admitted for the following Table is The First Principles of Dr. Thomson: this Work has been employed wherever it was available. It was at first designed to cite the exact authority for every number here inserted, but here also our unavoidable limits of space have checked us. Hydrogen is the unit to which all other atomic weights are referred; but should any one prefer the oxygen scale, it is easy to divide all the numbers by 8. In the column headed State, S means solid. L, Liquid. G, a Gas. V, vapour. C, crystallized. H, hydrous. A, anhydrous.

**Note.** From the use of descriptive names in this Table, it must not be inferred that these are designed in all cases to supersede those already in use; thus, for instance, among the Oxides, Pemptoxide of Nitrogen is placed in the first column to preserve the harmony of the system of nomenclature, and to inculcate a descriptive appellation; but the synonyme, Nitric Acid, is well established, and will doubtless continue in use.

In Art. (878), an inaccuracy exists, the origin of which we cannot comprehend. The union of Selenium with Mercury should have been noticed under Art. (577); whilst under (573), it should have been stated that Mercury has generally a strong tendency to unite with other Metals; and that it refuses to do so in very few, and even these uncertain, cases.

In Art. (111) the reader is requested to erase a paragraph of four lines, beginning "The definite," &c. at the ninth line from the end, as it has been found necessary to abandon that plan, and to confine the prefixes Prot-, Deut-, &c. to the oxides only.
SOUND.

PART I.

OF THE PROPAGATION OF SOUND IN GENERAL.

§ I. Of the Propagation and Velocity of Sound in Air.

Sound. To explain the nature and production of Sounds, the laws of its propagation through the various media which convey it to our ears, and the manner of its action on those organs; the modifications of which it is susceptible in speech, in music, or in inarticulate and unmeaning noises; and the means, natural or artificial, of producing, regulating, or estimating them, are the proper objects of Acoustics.

Every body knows that Sounds are conveyed to our ears from a distance through the air, but it is not equally apparent that they would not reach us as well through a space perfectly void; or, in other words, that the air itself is the vehicle, or active agent, by whose operation they are conveyed to us. Such, however, is the case. Shortly after the invention of the air-pump, it was found that the collision of hard bodies in an exhausted receiver produced no appreciable Sound. Hanksbee (Philosophical Transactions, 1705) having suspended a bell in the receiver of an air-pump, found the Sound die away by degrees, as the air was exhausted, and again increase on its readmission; and when made to sound in a vessel full of air, the Sound was not transmitted through the interval between that and an exterior vessel from which the air had been extracted, though it passed freely when readmitted. On the other hand, when the air was condensed in a receiver, the Sound of a suspended bell was stronger than in natural air, and its intensity increased with the degree of condensation. Roebuck, (Transactions of the Royal Society, Edinburgh, vol. v. p. 24) when shut up in a cavity excavated in a rock, which served as a reservoir of air for an iron foundry in Devonshire to equalize the blast of the bellows, observed the intensity of Sound to be considerably augmented in the air thus compressed by their action. The same effect has been experienced in diving-bells. More recently M. Biot has repeated the experiment of the exhausted receiver, with a much more perfect vacuum than could be procured in Hanksbee's time; and found the Sound to be quite imperceptible, even when the ear was held close to the receiver, and all attention paid. (Mém. d'Arcueil, vol. ii. p. 97.)

The diminution of the intensity of Sound in a rarefied atmosphere is a familiar phenomenon to those who are accustomed to ascend very high mountains. The deep silence of those elevated regions has a physical cause, independent of their habitual solitude. Saussure relates, that a pistol fired on the summit of Mont Blanc, produced no greater report than a little Indian cracker (petit petard de Chine) would have done in a room. (Voyage dans les Alpes, vol. vii. p. 337, § 2020.) We have ourselves had occasion to notice the comparatively small extent to which the voice can be heard, at an altitude of upwards of 13,000 feet on Monte Rosa. Observations on this point in the elevated passes of the Himalaya Mountains would be interesting. They should be made by the explosions of a small detonating pistol, loaded with a constant charge, and the distances should be measured, for the voice loses much of its force from the diminution of muscular energy in rarefied air, and distances are extravagantly underrated by estimation in such situations. The height, however, to which an atmosphere, or medium capable of conveying Sound extends, far exceeds any attainable on mountains, by balloons, or even by the lightest clouds. The great meteor of 1783 produced a distinct rumbling Sound, although its height above the earth's surface was full 50 miles at the time of its explosion. (See Sir Charles Blagden's interesting Paper, Philosophical Transactions, 1784.) The Sound produced by the explosion of the meteor of 1719, at an elevation of at least 69 miles, was heard as "the report of a very great cannon, or broadside;" shook the doors and windows of houses, and threw a looking-glass out of its frame and broke it. (Halley, Philosophical Transactions, vol. xxx. p. 978.) These heights are deduced by calculation from observations too unequivocal, and agreeing too well with each other, to allow of doubt. Scarcely less violent was the Sound caused by the bursting of the meteor of July 17, 1771, near Paris; the height of which, at the moment of the explosion, is assigned by Le Roy at 20,598 toises, or about 25 miles. (Mém. Acad. Par. 1771, p. 668.) The report of a meteor, in 1756, threw down several chimneys at Aix in Provence, and was taken for an earthquake. These instances, and others which might be adduced, are sufficient to show that Sound can be excited in, and conveyed by, air of an almost inconceivable tenuity (for such it must be at the heights here spoken of) provided the exciting cause be sufficiently powerful and extensive, neither of which qualities can be regarded as deficient in the case of fire-balls, such as those of 1719 and 1783, the latter of which was half a mile in diameter, and moved at the rate of 20 miles in a second. It may, however, be contended, and not without some probability, that at these enormous heights Sound may owe its propagation to some other medium more rare and elastic than air, and extending beyond the limits of the atmosphere of air and vapour.

Sound is not instantaneously conveyed from the sounding body to the ear. It requires time for its propagation. This is a matter of the most ordinary observation. We hear the blows of a hammer at a distance, a very sensible interval of time after we see them struck. The report of a gun is always heard later than the flash is seen, and vol. iv.
the interval is longer the more distant the gun. We estimate the distance of a thunder-storm by the length of
the interval between the lightning and the thunder-clap, which often arrives when we have ceased to expect it.
The report of the meteor of 1753 was heard at Windsor castle, ten minutes after its disappearance. This is,
probably, the longest interval yet observed.
A great multitude of experiments have been made to determine the precise velocity of Sound. The earlier
results differ more than might have been expected, from the influence of several causes not immediately obvious,
but chiefly from want of due attention to the influence of the wind. It is evident from the mechanical concus-
sion attending loud noises, that Sound consists in a motion of the air itself communicated along it by virtue of
its elasticity, as a tremor runs along a stretched rope. If, then, the whole body of the air were moving in a
contrary direction, with the velocity of Sound, it would never make its way against the stream at all; and, on
the other hand, when the wind blows from the sounding body direct towards the ear, it is equally clear that
the velocity of the wind itself will be added to that of Sound in still air. If a stone be thrown into a still lake, the
waves spread with equal rapidity in all directions, in circles whose centre is the stone. If into a running river,
they still form circles, but their centre is carried down the stream; and, in point of fact, the wave arrives oppo-
site to a point of the bank above the place where the stone fell, later than a point at the same distance below
it in proportion to the rapidity of the stream. Hence all experiments on the velocity of Sound ought to be made,
if possible, either in calm weather, or in a direction at right angles to that of the wind.

The assumption of 1900 feet per second for the velocity of Sound by Roberts, (Phil. Trans. 1694,) and the
inaccurate determinations of Mersenne, Bayle, and Walker, (Phil. Trans. 1698,) which give respectively 1474,
1200, and 1305 feet, (the latter by a mean of 12 experiments disagreeing no less than 370 feet inter se,) scarcely
deserve more mention than the rude guesses of Roberval and Gassendi, which differ by an amount nearly equal
to the whole quantity to be measured; the former fixing it at 560, the latter at 1478. The first experiments
which appear to have been made with any degree of care, were those instituted by the Florentine Academy Del
Cimento. It was observed in these that at a distance equal to 5739 English feet, the Sound of a harquebus
arrived five seconds after the flash; and repeating the experiment at half the distance, they found exactly half the
time to be required. This gives, for the velocity of Sound, 1146 feet per second.

Cassini the Elder, Picard, and Roëmer, from experiments made at a distance of 1280 toises, as related by
Duhamel in the Hist. de l'Acad. Par. assign 1172; while Flamsteed and Halley, from a series of observations
at the Royal Observatory, the origin of the Sound being three miles distant, concluded the velocity to be 1142 feet
per second.

In a Paper communicated to the Royal Society in 1708, by Dr. Derham, the subject of the velocity of Sound
is investigated more fully and distinctly than had before been done, and with some degree of attention to a
variety of circumstances which appear likely to influence its propagation. These are chiefly

1. The direction and velocity of the wind.
2. The amount of barometrical pressure.
3. The temperature of the air through which the sound is conveyed.
4. Its hygrometrical state of moisture and dryness.
5. The actual weather, whether fog, rain, snow, sunshine, &c.
6. The nature of the Sound itself, whether produced by a blow, a gunshot, the voice, a musical instru-
   ment; its pitch, quality, and intensity.
7. The original direction impressed on the Sound—by turning, for instance, the muzzle of a gun one way
   or the other.
8. The nature and position of the surface over which the Sound is conveyed; whether smooth or rough,
   horizontal or sloping; moist or dry, &c.

To all these circumstances, except the wind, Derham attributes no effect; and, in fact, none of them, except
the temperature of the air, have been ascertained to exercise any material influence on the velocity; though
many, indeed all, have a very powerful one on its intensity, or the loudness of the Sound as it reaches the ear
from a given distance. The quantity of aqueous vapour indeed ought (as we shall see) to affect the velocity,
but in a degree only appreciable in the most delicate experiments. Derham concludes, from the whole of his
observations, that Sound is propagated at the rate of 1142 feet per second, agreeing with the result of Flamsteed
and Halley, and with that of the Florentine Academicians; and as the distances of the stations employed were
considerable, in one case amounting to upwards of 12 miles, this determination appears deserving of some
reliance. The temperature, unfortunately, was not registered; so that the experiment loses much of its value
from the impossibility of applying with certainty the requisite correction.

In 1737-1738, the Academy of Paris directed a reinvestigation of the subject, and Messrs. Cassini de Thury,
Maraldi, and La Caille, who were at that time engaged in the triangulation of France, were charged with the
conduct of the experiments; an account of which, by Cassini, is to be found in the volumes of the Histoire de
l'Acad. for the latter year and for 1739. Their observations were carefully made, and the distance of the stations
was considerable, (from 2931 to 16,079 toises.) In these experiments we find the first example of observations
so disposed as to eliminate in some measure the disturbing effect of the wind. To apprehend how this may be
done, let us suppose a current of wind to blow uniformly with any velocity from one station A to another B at
any distance, and at these two stations let shots be fired. The Sound of the shot fired at A will then be acceler-
ated, and that of the signal at B will be retarded, in traversing the interval, by equal quantities; and conse-
quently (since the velocity of Sound is very much greater than that of the most violent wind) the time in which
the Sound runs over the line A B will be diminished, and that in which it traverses B A increased, by equal
quantities; so that the mean will be unaffected

In fact, supposing V to be the velocity of Sound, v that of the wind, and S the space described, the velocities of the Sound in the two oppo-

---

---
Sound.

will be \( V + v \) and \( V - v \); and the times of description of the space \( AB \) will be \( \frac{S}{V + v} \) and \( \frac{S}{V - v} \), whose mean is equal to \( \frac{SV}{V^2 - v^2} \), or to \( \frac{S}{V} \left( 1 + \left( \frac{v}{V} \right)^2 + \left( \frac{v}{V} \right)^4 + \cdots \right) \), which when \( v \) is small with respect to \( V \), reduces itself simply to \( \frac{S}{V} \). The most violent hurricane moves at a rate less than one-tenth that of Sound; so that in the worst case the neglect of the terms depending on the velocity of the wind will entail an error less than \( \frac{v^2}{V} \) of the whole result, or about 11 feet; and under ordinary circumstances such as are likely to be selected for experiment, their influence is quite inappreciable.

It is evident, however, that any want of uniformity in the rate of the wind will destroy, so far as it goes, the precision of the result so obtained; and that, in consequence, if the corresponding signals are not strictly simultaneous so as to make the Sound traverse the same identical portion of the aerial current, a great part of the advantage of this mode of experimenting is lost. M. Arago indeed remarked, that even in that case, if the wind be very irregular, and in sudden gusts, it will still affect the result; to conceive which, we will suppose a gust of wind to arise suddenly at the station A at the moment of firing the signals both at A and B. The Sound which proceeds in the direction A B, as it runs quicker than the wind, will leave it behind, and be propagated at every point of A B in still air, before the agitation of the wind has had time to reach it. On the other hand, the Sound from B will meet the wind; and, during the latter part of its course, at least, will be propagated in a moving atmosphere. Still, it will be observed, that it can be only the latter part of its course which can be thus affected, less, at all events, than one-tenth of the whole space; and the effect during that tenth being to retard the Sound by one-tenth at most of that interval, will produce a total effect, not exceeding a hundredth of the whole time of traversing A B; and, consequently, will affect the mean of the two deduced velocities by a quantity not exceeding a two-hundredth part of its value, or about five feet per second. We have already seen that the neglect of the square and higher powers of the velocity of the wind may in the same extreme case produce double this amount of error. This, however, is the error produced by a sudden gust equal to the most violent tornado. In ordinary winds, then, it must be quite inappreciable; and the method of simultaneous observations at opposite stations, provided they be strictly such, may be regarded as completely eliminating the wind’s influence.

In the experiments of Cassini and his colleagues, however, none of these niceties were attended to; a long interval elapsed between the corresponding observations when obtained; and, indeed, the greater part of their series was made without any regard to correspondence at all. They conclude the velocity of Sound to be 179 toises, or 1106 British feet per second, at the temperature between 4° and 6° Reaum. at which the experiments were made. The extreme difference of velocities due to a favourable and a contrary wind they found to be about one-eleventh of the whole, giving \( \frac{1}{12} \) for the ratio of the velocity of the wind to that of Sound as their maximum, or 50 feet per second. When the correction for the temperature of the air is applied, it will be seen presently that their result justifies the reliance placed on it by its authors; being, in fact, within about a yard of the truth.

Nearly about the same time Bianconi in Italy, and La Condamine at Quito and at Cayenne, instituted a series of experiments for the same purpose, of which accounts will be found in the Comment. Bonon. ii. p. 365; in La Condamine’s Introduction Historique, &c. 1751, p. 98; and in the Mém. Acad. Par. 1745, p. 448. But the theory of Sound being at that time but imperfectly understood, and the necessary corrections in consequence being not sufficiently, or not at all attended to, the subject has been regarded as still open to further discussion; and accordingly a great number of researches by later experimenters have been instituted, of which the principal are those by Müller in 1791, (Götting. Gelehrte Anzeigen, 1791, No. 159;) by Espinosa and Bauza, in Chili, in 1794, (Ann. de Chim. vii. 93;) by Benzenberg in 1809, (Gilbert’s, Annalen, new series, v. 839;) by Arago, Bouvard, Matthieu, Prony and Humboldt, and Gay Lussac, in 1822, (Connaiss. des Temps, 1825, p. 361;) by Moll, Vanbeek, and Kuytenbrouwer in Holland, in 1822, (Phil. Trans. 1824, p. 424;) by Mr. Goldingham, in 1820, at Madras, (Phil. Trans. 1823, p. 96;) by Dr. Gregory, at Woolwich, in 1823, (Trans. of Cambridge Phil. Soc. 1824;) and by General Myrbach and Professor Stapfer, at Salzburg, (Jahrh. der Polyt. Inst. zu Wien, vol. vii.)

Of these by far the most considerable and circumstantial, as well as in all probability, from the instrumental means employed and precautions used, the most exact, are those of the Dutch and the Parisian Philosophers. Every attention was paid in them (at least in the case of the Dutch experimenters) to obtain signals strictly coincidental, by guns fired at the same instant of time at the two ends of the line of observation; all those corrections depending on Meteorological circumstances which theory points out, and which it will be the object of subsequent parts of this Essay to explain, being carefully applied; and the distances of the stations being at once considerable, and determined with sufficient exactness by Trigonometrical operations.

One very material difficulty in the way of former observers (Benzenberg excepted) lay in the want of adequate means of measuring with precision intervals of time to a minute fraction of a second. This difficulty was obviated in the experiments of the Dutch Commissioners, by the use of the stop-watch of Breguet, and the chronograph of Rieussec, a species of watch, one of whose hands performs a revolution per second, and can be made to touch with its extremity the dial-plate, at any instant, and leave there a dot, without interrupting its motion of rotation, by the sudden pressure of a small lever; to effect which it carries with it a drop of printer’s ink in a peculiar and ingenious species of dotting pen. In the Dutch experiments, a clock with a conical pendulum was used, capable of determining intervals to the hundredth of a second, by suddenly suspending the motion of the index, without stopping the clock. By the use of these instruments it was found practicable to ascertain the
interval between the sight of the flash, and the arrival of the report, of a gun, with such precision as to destroy all
material error in the result which might arise from this cause; an improvement of great importance, when we
consider that an error of a single tenth of a second in the measure of time is equivalent to 110 feet in that of
distance.

The close agreement of the results of these experiments is a convincing proof of their accuracy. The
French Philosophers state 331.05 met. = 1086.1 feet, as the velocity of propagation of Sound in air of the tem-
perature of freezing water, while the Dutch experimenters make it 332.05 met. = 1089.42 feet in perfectly dry
air of the same temperature. The latter seems to deserve the preference, if only from the circumstance of the
signals from which it is deduced having been strictly simultaneous, the guns at the two extremities of the line
(nine miles in length) having been fired at the same second of time, while in the former series this exact
coincidence was not obtained.

We subjoin a list of the results arrived at in the various determinations above enumerated, with their dates,
the distances of the stations employed, &c. to bring the whole subject under one view.

</table>

The agreement between such of the above results as are reduced to the standard or freezing temperature, i.e.
of the last six, and the first determination of Cassini at Paris, is very close; their extreme discrepancy being less
than seven feet, or a 160th of the whole amount, and their mean (1089.7) agreeing almost precisely with the result
of Moll, Vanbeek, &c.; we may, therefore, adopt 1090 feet without hesitation (as a whole number) as no doubt
SOUND.

with a yard of the truth, and probably within a foot. The reduction to the zero of temperature has been made
(when not performed by the authors themselves) on the supposition that every additional degree of atmospheric
temperature, on Fahrenheit's scale, adds 1.4 feet to the velocity, a correction of which the 21
groundswill be hereafter explained. (See Art. 68.)

It may, therefore, be stated in round numbers, that Sound, in dry air and at the freezing temperature, travels
at the rate of 1090 feet, or 363 yards per second, and that at 62°Fahrenheit (which is the standard temperature
of the British metric system) it runs over 9000 feet in eight seconds, 12 British standard miles in a minute,
or 765 miles in an hour, which is about three-fourths of the diurnal velocity of the Earth's equator.

Hence, in latitude 42°N, 42°N 40°N) if a gun be fired at the moment a star passes the meridian of any
station, the Sound will reach any other station exactly west of it at the precise instant of the same star's arriving
on its meridian.

In the experiments of Dr. Gregory, the velocity of the wind was measured by an anemometer, and allowed
as Derham states from memory, but according to the map at least 120.

Dr. Hearn, a Swedish physician, relates that he heard guns fired at Stockholm, on the occasion of the death
of one of the Royal family in 1685, at the distance of 30 Swedish, or 180 British miles.

The cannonade of a sea-fight between the English and Dutch, in 1672, was heard across England as far as
Shrewsbury, and even in Wales, a distance of upwards of 200 miles from the scene of action.

That Sounds of all pitches, and of every quality, travel with equal speed, we have a convincing proof in the
performance of a rapid piece of music by a band at a distance. Were there the slightest difference of velocity in
the Sounds of different notes, they could not reach our ears in the same precise order, and at the exact intervals
of time in which they are played, nor would the component notes of a harmony, in which several Sounds of different
pitch concur, arrive at once. M. Biot caused several airs to be played on a flute at the end of a pipe 951 metres,
or 3120 feet, long, which were distinctly heard by him at the other end, without the slightest derangement in
their measurement of the distances, or in the calculation founded on them, must have been committed. Our
authority is the Annales de Chimie, vol. vii. (N. S.) p. 93.

Guns fired at Carlscroon were heard across the southern extremity of Sweden as far as Denmark; 80 miles,
as Derham states from memory, but according to the map at least 120.

Dr. Hearn, a Swedish physician, relates that he heard guns fired at Stockholm, on the occasion of the death
of one of the Royal family in 1685, at the distance of 30 Swedish, or 180 British miles.

SOUND.

Conveyance of Sound along a wall.

When Sound in the course of its propagation meets with an obstacle of sufficient extent and regularity it is reflected, producing the phenomenon we call an Echo. A wall, the side of a house, or the surface of a rock, the ceiling, floor, and walls of an apartment, the vaulted roof of a church, all, under proper circumstances, give rise to Echos more or less audible. The reflected Sound meeting another such obstacle is again reflected, and thus the Echo may be repeated many times in succession, becoming, however, fainter at each repetition till it dies away altogether. We shall here set down a few localities in which Echos, remarkable either for distinctness, or frequency of repetition, may be heard.

1. An Echo in Woodstock Park, (Oxfordshire,) repeats 17 syllables by day, and 20 by night, (Plot, Nat. Hist. Oxford. ch. i. p. 7.) One on the banks of the Lago del Lupo, above the fall of Terni, repeats 15.

2. In the Abbey Church of St. Albans is a curious Echo. The tick of a watch may be heard from one end of the church to the other. In Gloucester Cathedral, a gallery of an octagonal form conveys a whisper 75 feet across the nave.

3. In the Whispering Gallery of St. Paul's, London, the faintest Sound is faithfully conveyed from one side to the other of the dome, but is not heard at any intermediate point.

4. In the Manfroni Palace at Venice is a square room about 23 feet high, with a concave roof, in which a person standing in the centre, and stamping gently with his foot on the floor, hears the Sound repeated a great many times, but as his position deviates from the centre the reflected Sounds grow fainter, and at a short distance wholly cease. The same phenomenon occurs in the large room of the Library of the Museum at Naples.

5. Beneath the Suspension Bridge across the Menai Strait, in Wales, close to one of the main piers, is a remarkable Echo. The Sound of a blow on the pier with a hammer, is returned in succession from each of the cross-beams which support the roadway, and from the opposite pier at a distance of 576 feet, and, in addition to this, the Sound is many times repeated between the water and the roadway. The effect is a series of Sounds which may be thus written &c.; the first return.

The Echo from the opposite pier is best heard when the auditor stands precisely opposite to the middle of the breadth of the pier and strikes just on that point. As he deviates to one or the other side the return is proportionably fainter, and is scarcely heard by him when his station is a little beyond the extreme edge of the roadway.
the pier, though another person stationed (on the same side of the water) at an equal distance from the central point, so as to have the pier between them, hears it well. Thus, in the reflexion of Sound, there is an evident approach to the law of equality between the angles of incidence and reflexion which obtains in that of Light; and a tendency in the reflected Sound to confine itself to the direction which a ray of Light regularly reflected at the echoing surface would follow, and not to spread into the surrounding air equally in all directions. This experiment (which we had an opportunity of making, with the assistance of Mr. Babbage, in 1827) might be carried much farther under more favourable circumstances; and, we doubt not, would lead to remarkable confirmations of the law of interference, and the general analogy between Sound and Light, to which all Optical and Acoustical phenomena point, and of which we shall have occasion to say more hereafter. (See also our Essay on Light.)

The span of the bridge between the piers is 576 feet, and the breadth of each pier about 30 feet.

The most favourable position for the production of a distinct Echo from plane surfaces is, when the auditor is placed between two such, exactly half way. In this situation the Sounds reverberated from both will reach him at the same instant, and reinforce each other. If nearer to one surface than the other, the one will reach him sooner than the other, and the Echo will be double and confused. If the Echoing surface be concave towards him, the sounds reflected from its several points will, after reflexion, converge towards him, exactly as reflected rays of Light do; and he will receive a Sound more intense than if the surface were plane, and the more so the nearer it approaches to a sphere concentric with himself: the contrary if convex. If the Echo of a Sound excited at one station be required to be heard most intensely at another, the two stations ought to be conjugate foci of the reflecting surface, i.e., such that if the reflecting surface were polished, rays of Light diverging from one would be made after reflexion to converge to the other. Hence if a vault be in the form of a hollow ellipsoid of revolution, and a speaker be placed in one focus, his words will be heard by an auditor in the other as if his ear were close to the other's lips. The same will hold good if the vault be composed of two segments of paraboloids, having a common axis, and their concavities turned towards each other; only in this case, Sounds excited in the focus of one segment will be collected in the focus of the other, after two reflexions.

An attention to the doctrine of Echos is of some, though we think a rather overrated, importance to the architect in the construction of buildings intended for public speaking, or music, especially if they be large. In small buildings, the velocity of Sound is such that the dimensions of the building are traversed by the reflected Sound in a time too small to admit of the Echo being distinguished from the principal Sound. In great ones, on the other hand, as in Churches, Theatres, and Concert rooms, the Echo is heard after the principal Sound has ceased; and if the building be so constructed as to return several Echos in very different times, the effect will be unpleasant. It is owing to this that in Cathedrals the service is usually read in a sustained uniform tone, rather than that of singing than speaking, the voice being thus blended in unison with its Echo. A good reader will time his syllables, if possible, so as to make one fall in with the Echo of the last, which will thus be merged in the louder Sound, and produce less confusion in his delivery. For music, in apartments of moderate size, all objects which can obstruct the free reflexion of Sound from the walls, floor, and ceiling are injurious. The Echo is not sensibly prolonged after the original Sound, and therefore only tends to reinforce it, and of course highly advantageous. In large ones, an Echo can only be advantageous in the performance of slow pieces, (as Church music.) The prolongation of a chord, after the harmony is changed, can be productive of nothing but dissonance. When ten notes succeed one another in a second, as is often the case in modern music, the longitudinal Echo of a room 55 feet long, will precisely throw the second reverberation of each note on the principal Sound of the following one whenever the auditor be placed; which, in most cases, will produce (in so far as it is heard) only discord. Much mistake seems to be prevalent on this subject. Thus it is said that the form of an orchestra should be parabolic, &c., that the rays of Sound should be reflected out in parallel lines to the audience. But even if they were so, the reflected Sound cannot possibly reach them in the same time with the direct; and in Acoustics it is of little moment in what direction sounds reach the ear, which is not, like the eye, capable of appreciating direction with any precision, or collecting the rays or waves of Sound to a focus within the ear. It is not possible to place a whole band in the focus of a parabolic or elliptic orchestra, or a whole audience in that of a corresponding opposite segment. We may add, too, that an apartment would be worse lighted, were its internal surface a polished semi-ellipsoid, with a candle in the focus, than if it were of the usual shape, and its walls and ceiling a dead white. The object to be aimed at in a Concert-room is, not to deafen a favoured few, but to fill the whole chamber equally with Sound, and yet allow the Echo as little power to disturb the principal Sound, by a lingering after-twang, as possible. But, whether for music or for oratory, open windows, deep recesses, hangings, or carpeting, and a numerous audience in woollen clothing, are all unfavourable to good hearing. They are to Sound, what black spaces in an apartment would be to light; they return back none, or next to none, of what falls on them. Their fault is not so much that they reflect it irregularly, as that they do not reflect it at all.

The rolling of thunder has been attributed to Echos among the clouds; and if it is considered that a cloud is a collection of particles of water, however minute, yet in a liquid state, and therefore each individually capable of reflecting Sound, there is no reason why very loud Sounds should not be reverberated confusedly (like bright lights) from a cloud. And that such is the case, has been ascertained by direct observation on the Sound of cannon. Messrs. Arago, Matthieu, and Prsy, in their experiments on the velocity of Sound, observed, that under a perfectly clear sky, the explosions of their guns were always heard single and sharp, whereas when the sky was overcast, or even when a cloud came in sight over any considerable part of the horizon, they were frequently accompanied with a long continued roll like thunder, and occasionally a double Sound would arrive from a single shot.

But there is, doubtless, also another cause for the rolling of thunder, as well as for all its sudden and capricious bursts and variations of intensity, of which our knowledge of the velocity of Sound furnishes a perfect explanation. To understand this, we must premise that, ceteris paribus, the estimated intensity of a Sound will
Sound.

be proportional to the quantity of it (if we may so express ourselves) which reaches the ear in a given time.

Two blows equally loud, at precisely the same distance from the ear, will Sound as one of double the intensity; a hundred, struck in an instant of time, will sound as one blow a hundred times more intense than if they followed in such slow succession that the ear could appreciate them singly. Now let us conceive two equal flashes of lightning, each four miles long, both beginning at points equidistant from the auditor, but the one running out in a straight line directly away from him; the other describing an arc of a circle having him in its centre. Since the velocity of Electricity is incomparably greater than that of Sound, the thunder may be regarded as originating at one and the same instant in every point of the course of either flash. But it will reach the ear under very different circumstances in the two cases. In that of the circular flash, the Sound from every point will arrive at the same instant, and affect the ear as a single explosion of stunning loudness. In that of the rectilinear flash, on the other hand, the Sound from the nearest point will arrive sooner than from those at a greater distance; and those from different points will arrive in succession, occupying altogether a time equal to that required by Sound to run over four miles, or about 20 seconds. Thus the same amount of Sound is in the latter case distributed uniformly over 20 seconds of time, which in the former arrives at a single burst; of course, it will have the effect of a long roar, diminishing in intensity as it comes from a greater and greater distance. If the flash be inclined in direction, the Sound will reach the ear more compactly, (i. e. in shorter time from its commencement,) and be proportionally more intense. If (as is almost always the case) the flash be zigzag, and composed of broken rectilinear and curvilinear portions, some concave, some convex to the ear; and if, especially, the principal trunk separates into many branches, each breaking its own way through the air, and each becoming a separate source of thunder, all the varieties of that awful Sound are easily accounted for.

We will only mention one other phenomenon which is accountable for on the same principle. In the eruption of a volcano it is often remarked, that every ejection of stones, &c. is accompanied with an explosion like artillery when heard at a distance; but when near, the Sound resembles rather that of a loud and deep sigh, unaccompanied with any sudden burst. In both cases the cause of Sound is the same, the upward rush and displacement of the air by the stone; but where the auditor is near the bottom of the column of Sound, it reaches his ear more in detail than when at a distance, and therefore nearly equidistant from all its parts. In fact, let \( t = \frac{\sqrt{a^2 + x^2}}{v} \) be the time taken by the stone to rise to a height \( x \), and let \( d \) be the distance of the observer from the bottom of the column, and \( v \) the velocity of Sound, then will \( t + \frac{\sqrt{a^2 + x^2}}{v} = \) time elapsed from the moment of ejection to that of the Sound of the column at the height \( x \) reaching the ear. Hence the whole Sound of the portion \( x \) of the column will arrive in an interval of time represented by \( t + \frac{\sqrt{a^2 + x^2}}{v} \). Now, as \( a \) increases, \( x \), and therefore \( t \) remaining constant, this function diminishes rapidly, and ultimately approaches \( t \) as its limit. Thus the Sound arrives continually more and more condensed. Should any discharge be made obliquely towards the observer’s station, a still greater concentration of the noise will happen, as may be easily seen by considering that if shot directly towards him, with the velocity of Sound, the report would reach him from every part of the line strictly at the same moment. Now, as these discharges have been known to rise to a height of 10,000 feet, in spite of the resistance of the air, their initial velocity must be, at least, equal to that of Sound. At great distances it is probable that only the Sounds produced by such oblique ejections have intensity or (as we may express it) body enough to affect the sense.

\[ \text{§ II. Mathematical Theory of the Propagation of Sound in Air, and other Elastic Fluid Media.} \]

A general notion of the mode in which an impulse communicated to one portion of the air, or other elastic fluid, is diffused through the surrounding portions, and successively propagated to portions at a greater and greater distance from the original source of the motion, may be obtained by considering the way in which a tremor runs along a stretched cord, or in which waves excited in the surface of still water dilate themselves circularly, and propagate a motion impressed on one point of the surface, in all directions to a distance. In the former case, conceive a blow given to a point in the middle of the cord, transversely to its length. The point to which the blow is given will be thrown out of the straight line, and a flexure, or angle, will be formed in that part. Owing, however, to the inertia of the cord, the displacement of the particles in the first instant will be confined to the immediate neighbourhood of the point of impulse; so that the cord will not at once assume the state represented in fig. 1, consisting of two straight portions \( AB, BC \), forming a very obtuse angle \( ABC \); but rather that in fig. 2, in which the greater part of the auditors in the middle of \( AB, DC \), retain their original position; and a small part \( D E \) is projected to the violence and suddenness of the blow, is, as it were, bulged out into an angular form \( D B E \). The particle at \( B \) then is solicited on both sides by the tension of the cord in directions \( BD, BE \); but these tensions, which in the quiescent state of the string exactly counteract each other, now only do so in respect of those parts of each which, when resolved, act in directions parallel to \( DA, CE \) respectively. The other resolved portions, perpendicular to these, conspire and urge the point \( B \) towards its point of departure \( b \). As there is no force to counteract this (the impulse being supposed momentary) \( B \) will obey their solicitation, and approach \( b \) with an accelerated velocity. But, action and reaction being equal and contrary, the same force by which the molecule \( E \) drags \( B \) down, will be exerted on \( E \) to drag it up, or out of the line; so that
by the time B has performed half its course towards C, E will have been raised above the line, and will have acquired a velocity capable of carrying it still further in that direction. At this instant the figure A D' D B E E' C. At the next moment the forces are reversed, B then tends to drag both D and E down to the line; but its own acquired momentum is expended in the effort, and by the time it has reached its original place in the line, its inertia is destroyed, and it rests there without a tendency to go beyond it on the other side. Meanwhile, however, D and E have attained their greatest elevation; and thus the protuberance D B E is resolved into two D' D B and B E E' (of less height, however) on either side. In like manner the particles D and E, in returning to their places, drag up the next adjoining D' and E', and then the next, and so on; and thus the summits of the protuberances advance along the line, and correspond in succession to all its points; and the visible effect is an undulation, or wave, which runs along the cord with a velocity greater the greater is the force with which the cord is strained, as it manifestly ought to be, since the rapidity with which each molecule returns from its displaced situation is greater as the force urging it is so; and this force is nothing more than the resolved part of the tension.

In like manner, when a wave is excited in the surface of water, as when by throwing in a stone one portion is violently driven down, and the surrounding part heaped up above its natural level; this subsides and fills up the vacancy; but as its pressure takes place alike on both sides of the ridge, the fluid on the outside of the ridge is also pressed on, from below upwards, by the reaction of the fluid stratum which sustains the ridge, and whose pressure is propagated equally in all directions. Thus the ridge, in subsiding, not only fills up the central vacancy, but forces up another ridge exterior to it; and this, in subsiding, another, and so on; and thus an advancing wave is formed; and the same action taking place on all sides of the centre, the wave can advance no otherwise than in the direction of radii on all sides diverging therefrom.

It is by no means intended, in what is here said, to give an accurate account of what passes in either of these cases, (in fact, it is very far from being so, as the reader by a little attention will soon perceive,) but only to give a first conception of the propagation of motion by undulations or waves.

In this general account of the above cases, one thing, however, cannot fail to strike the reader, that the same of a wave on the surface of water—the sinuosity which runs along the stretched cord—are neither of them things, but forms. They are not moving masses advancing in the direction in which they appear to run; but outlines, or figures, which at each instant of time include all the particles of the water or the cord which, it is true, are moving, but whose motion is in fact transverse to the direction in which the waves advance. But this is by no means an essential condition. We may generalize this idea of a wave, and conceive it as the form, space, or outline, whether linear or superficial, comprehending all the particles of an undulating body which are at once in motion, (supposing, for the present, that the motion of each consists of a simple displacement and return to quiescence, and not in a repetition of several such displacements and returns in succession.)

The waves in a field of standing corn, as a gust of wind passes over it, afford a familiar example of the relation between the motion of the wave, and that of the particles of the waving body comprised within its limits, and of the mutual independence which may in certain cases subsist between these two motions. The gust in its progress depresses each ear, in its own direction, which, so soon as the pressure is removed, not only returns, by its elasticity, to its original upright situation, but by the impetus it has thus acquired, surpasses it, and bends over as much, or nearly as much, on the other side; and so on alternately, oscillating backwards and forwards in equal times, but continually through less and less spaces, till it is reduced to rest by the resistance of the air. Such is the motion of each individual ear; and as the wind passes over all of them in succession, and bends each equally, all their motions are so far similar. But they differ in this, that they commence not at once, but successively. Suppose (to fix our ideas) the wind runs over 100 feet in a second, and that the ears stand one foot asunder, and each makes one complete vibration to and fro in a second. Suppose A (fig. 3) to be the furthest point which the wind at any given instant of time has reached, or the last ear which it has just bent, and let the action of the wind be regarded as lasting only for a single instant. Then will the next preceding ear B have already begun to rise from its bent position, the next C will have risen rather more, and the 25th ear G (since the distance A F is 25 feet, and consequently since ) will have gone through one-fourth of its complete vibration to and fro, and will have therefore just attained its upright position; so that the ears F, E immediately adjacent towards A will not yet have quite recovered their perpendicularity, but still lean somewhat forwards; while those on the other side H, I will have surpassed the perpendicular, and have begun to sway backwards; consequently at G the stalks will be convex towards G, and the ears at that place will be further asunder than in their state of rest, and will appear as they were rarefied when viewed by a spectator so distant as to take in a great extent at once. Still further in rear of the wind, as 50 feet, at L, the 50th ear will have swung backwards as far as possible, and will just have its motion destroyed. The preceding stalk, K, will still want somewhat of its extreme backward flexure; the subsequent one, M, will already have risen a little, and therefore the interval of the ears K, N will be just what it was in the state of rest. At L, then, the spectator will see the ears at their natural distances from each other. Again the 75th stalk, Q, in rear of the wind will have had time to rise again erect from its backward inclination, three-fourths of a second having elapsed since its first bending forward. The 74th, P, will not be quite erected; the 76th will have surpassed the erect state, and have again begun to lean forward. The stalks then on both sides of Q will curve towards Q, and their ears will therefore be closer together than in their natural state, and will appear condensed to the spectator above mentioned. Finally, the 99th, 100th, and 101st ears will be again in the same relative state as the 49th, 50th, and 51st; only leaning forwards instead of backwards, and therefore neither condensed nor rarefied. The field, then, will present to the spectator a series of alternate condensations and rarefactions of the corn ears, separated by intervals in their natural state of density; and this series will extend so far in rear of the wind, till the resistance of the air and want of perfect elasticity in the stalks shall...
756  SOUNO.

Sound.

46. Velocity of the wave distinguished from that of its component parts.

It matters not, for our present purpose, that the impulse is, in the case here taken, not propagated mechanically from ear to ear by mutual impulse, but that each moves independently of all the rest. All we want to illustrate is the distinction between the wave and the moving matter, and the independence of their motions. The waves here run along with the speed of the wind, whatever that may be; for it is always the point 25 feet in rear of the wind that is most rarefied, and that at 75 that is most condensed; and the interval between the first and 100th ear, comprehending ears in every state or phase of their vibrations, is what we term a wave. The velocity of the wave, then, is, in this case, that of the wind; and is totally distinct from, and independent of, that of each or any particular ear. The one is a constant, the other a variable quantity; the one a general resulting phenomenon, the other a particular, individual, mechanical process, going on according to its own laws.

47. And independent of their excursions from the state of rest.

Neither is it of the least consequence whether the excursions of the several stalks from their position of rest be great or little; whether the degree of bending, or force of the wind, be great or small, provided its velocity be constant. In the case of wind, indeed, the force depends on the velocity; but if we conceive the impulse given by a rigid rod made to sweep across the field, any greater or less degree of flexure might be given, with the same velocity, by a mere change of its level; but the velocity of the wave would still be that of the rod in every case.

But with respect to the breadth of the wave, or the magnitude of that interval which comprises particles in every phase or state of their motion, going and returning, it is otherwise. This is a result depending essentially on the motions of the particles themselves; for we see evidently in the above instance, that this breadth, which is equal to the space run over by the wind in a time equal to that of one complete vibration, going and returning, of each individual ear. Now this time depends only on the elasticity of the stalk, and the weight of the ear it carries. In general then we may state, that "The breadth of a wave is equal to the space run over by it in a time equal to that in which any molecule of the waving body performs one complete vibration, going and returning, through all the phases of its motion." In the case here taken, the motion of the individual molecules is not, as in the former instances, transverse to that of the wave, but parallel to it. It is then hardly to be termed a form, or an outline. To such a wave, the term pulse is often applied. Whatever be the nature of the internal motions, however, the general name wave or undulation will equally apply, and will be used in future indiscriminately for all sorts of propagated impulses. It is not even necessary that the motions of the constituent particles should be rectilinear, or even lie in one plane. We may suppose the impelling cause to be a whirlwind. In this case each ear will have a rotatory or twirling motion, or the stalk a conical one, simply, or in addition to its flexure in a vertical plane; but the wave is independent of these particularities.

In the case just described, each particle is supposed to be set in motion by an external cause, and to be uninfluenced in its motions by the rest. It is, therefore, not a case of the propagation of motion at all. It is quite otherwise with Sound, or other similar cases, where every particle of a medium receives its whole motion from those which were moving before, and transmits it to others previously at rest. The problem to investigate the various species of waves.

48. Breadth of the waves.

49. Sonorous waves propagated in air.

50. Propagation of Sound in air in one dimension.

Let us then consider, as the simplest case, the propagation of Sound in a straight canal of equal bore throughout, filled with air or any other elastic fluid of equable density and elasticity, unacted on by gravity, and of which the transverse section is so small, and the sides so perfectly polished, that we may regard the motions of all particles in the same section as exactly similar; so that each section shall merely advance and receive in the pipe, without any lateral change of place of its constituent molecules inter se. Let A B (fig. 4) be such a pipe, and let any section of it, as A, be agitated by an external cause, with any arbitrary motion, i.e. one whose duration and extent, and whose velocity at every instant, shall be entirely dependent on the will, or, if we please, the caprice of an external operator sufficiently powerful to command it, and let us inquire how any other section whatever, situated at any assigned distance, x, from A, will move in consequence of this arbitrary motion of A.

51. Analysis of this case.

Let us then conceive, that, in general, the section or stratum of molecules a a b b, whose distance from the initial place A of the section A is represented by x, shall, after the lapse of any time t, have been transported into the situation a a b b, at a distance A a = y from the same fixed point A. Let x' x", &c. be the distances of the next consecutive sections from the fixed point A, in their state of rest, and y', y", &c. their distances after the lapse of the same time t. Then we have x' = x = d x, x" = x = d x, &c. be the thicknesses (supposed infinitely small) of these strata, or the spaces occupied by them (taking the area of the section for unity) in their quiescent state, and y" = y, y' = y" = y", y" = y", &c. the same in their state of
motion. Now as these strata were in contact at the origin of the motion, and are held together by the pressure of the surrounding fluid, they will remain in contact, and advance and recede along the pipe as one mass, only the space they will occupy at different points of their motion will be variable, according to the degree of condensation or dilatation they may have undergone in virtue of their motion itself. If, for instance, at any moment the hinder of them dy be in the act of urging forward the next dy', it will be condensed; if retreating, rarefied in comparison with the state of the preceding one dy'.

Now any stratum of molecules dy' interjacent between two others dy and dy' can only undergo a change in its velocity when urged by some force, and the only force which can urge it is the difference of pressures it may experience on its two faces by the difference (if any) of the elasticities of the adjacent strata dy' and dy. If we can estimate this, the laws of Dynamics will enable us to express the consequent change of motion. To this end, then, let the elasticity of the air in its quiescent state be represented by E, which is a given quantity, and is measured by the weight of a column of mercury sustained by it, or by the length of a homogeneous column of air of the same density, whose weight shall suffice to keep it so compressed, or be equal to that of the column of mercury in the barometer. Then, since the elasticity of air is inversely as the space it occupies, (ceteris paribus,) the elasticity of the air when occupying the stratum dx: its elasticity when occupying dy: dx: dy, and therefore the elasticity when occupying the space dy = E. Hence the elasticities of the air occupying d y' and dy' will be represented by E. dx/dy and E. dx''. dx'''/dy. Therefore the plane separating the strata dy and dy' will be pressed forward by the elasticity E. dx/dy, and backward by E. dx'/dy'. So that it will, on the whole, be urged forward by E (dx'/dy - dx/dy) that is, by E d dx/dy, the differentials being all on the supposition of t, the time being constant, and x and y only variable. Now, if we denote by H the length of a homogeneous column of air necessary to counterbalance the elasticity of the quiescent air, and by D its density, we have H D = its weight = the elasticity E, and dx' D = the weight of the stratum dx', which, substituting for D its value E/H, becomes dx'. E/H. Thus, then, the moving force - Ed dx/dy is exerted in urging forward a weight = dx'. E/H, and is therefore equivalent to an accelerating force regarding dx as constant, or all the strata dx, dx', dx'', &c. as originally equal.

Now the distance of the mass thus urged from the fixed point A, at the expiration of the time t, is y'. Hence, if we regard only the motion of the particle dy'(or which comes to the same) of dy, which is in contact with it, we have by Dynamics

\[
\left(\frac{dy}{dx}\right)^2 \cdot \frac{dy''}{dx'} = 2 g H \cdot \frac{dy''}{dx'},
\]

where \(2 g = 9.8 m/s^2\) is the acceleration due to gravity, for the unit of accelerating force, and in which equation \(x\) is expressed in mean solar seconds; and all linear quantities, such as H, x, y, in metres or feet, according as we take the metre or foot as the unit of linear measure.

This is, in fact, an equation of partial differentials, \(y\) being at once a function both of \(x\) the original distance of the stratum dx from the origin of the motion, and of \(t\) the time elapsed. In its present form, simple as it appears, it is altogether intractable and incapable of integration. In fact, it embraces a class of dynamical problems of very great complexity; for it is evident that since no hypothesis has been made in any way limiting the extent of the excursions of the original or subsequent strata from their points of quiescence, this equation must contain the general expression of all possible motions of elastic fluids in narrow pipes, whether great, as when urged by pistons or driven by bellows, or small, as are the tremors which cause Sound. In the theory of Sound we suppose the agitations of each molecule so minute as not to move it sensibly from its point of rest. Experience confirms this. Sounds transmitted through a smoky or dusty atmosphere cause no visible motion in the smoke or floating dust, unless the source of Sound be so near as to produce a wind, which, however, is always insensible at a very moderate distance.

If we introduce this condition, the equation (a) admits of integration; for the whole amount of motion of each molecule being extremely minute, their differences for consecutive molecules, or the amount of the rarefactions and condensations undergone, must be much more so. Hence the value of \(\frac{dy}{dx}\), which expresses the ratio of the condensation of the stratum dy in motion and in rest, may be regarded as equal to unity, and the equation becomes simply,

\[
\frac{dy''}{dx'} = a \cdot \frac{dy'}{dx'},
\]  

where \(a = \sqrt{2 g H}\); (b)
which is the equation of Sound regarded as propagated in one dimension, that of length, only; or, as prevented from spreading laterally by a pipe.

The complete integral of this equation is well known to be

\[ y = F(x + at) + f(x - at), \] (c)

where \( F \) and \( f \) denote arbitrary functions of the quantities within the parenthesis, and which must be determined by a consideration of the initial state of the fluid, or by the nature of the motion originally communicated to its molecules.

Let us then suppose, that, at the commencement of the motion, we have impressed on each section of the fluid, along its whole extent, any arbitrary velocities and condensations, by any means whatever, so as to comprehend in our investigation all possible varieties of initial motion, whether expressible by regular analytical functions, or depending on no regular law whatever. It is manifest that these conditions will be expressed by assuming arbitrary functions of \( x \), such as \( \phi(x) \) and \( \psi(x) \) for the initial values of the two partial differentials

\[ \frac{dy}{dt} \] and \[ \frac{dy}{dx}, \]

whereof the former represents in all cases the velocity (v) of a particle which would be at the distance \( x \) from the origin of the coordinates in the state of equilibrium, and the latter the linear extent (e) of that particle compared with its original extent, to which its density and elasticity are reciprocally proportional.

Now, differentiating (c) we get for the general values of \( v \) and \( e \)

\[ v = \frac{dy}{dt} = a \left\{ F'(x + at) - f'(x - at) \right\}; \] (d)

\[ e = \frac{dy}{dx} = F'(x + at) + f'(x - at); \] (e)

consequently their initial values, making \( t = 0 \), will be

\[ \phi(x) = a \cdot \left\{ F'(x) - f'(x) \right\}; \]

\[ \psi(x) = F'(x) + f'(x), \]

whence we get immediately

\[ F'(x) = \frac{1}{2a} \left\{ a \psi(x) + \phi(x) \right\}; \]

\[ f'(x) = \frac{1}{2a} \left\{ a \psi(x) - \phi(x) \right\}; \] (f)

and multiplying by \( dx \) and integrating

\[ F(x) = \frac{1}{2a} \int \left\{ a \psi(x) + \phi(x) \right\} dx; \]

\[ f(x) = \frac{1}{2a} \int \left\{ a \psi(x) - \phi(x) \right\} dx; \]

and thus the forms of the functions \( F \) and \( f \) become known when those of \( \phi \) and \( \psi \) are given.

58. The question of the propagation of Sound, however, does not require us to concern ourselves with these functions, as a knowledge of the actual velocity and density of any molecule at any instant is sufficient for our purpose. Substituting then in (d) and (e) for \( F' \) and \( f' \), the forms corresponding in \( \phi \) and \( \psi \), we get

\[ v = \frac{dy}{dt} = \frac{a}{2} \left\{ \psi(x + at) - \psi(x - at) \right\} + \frac{1}{2} \left\{ \phi(x + at) + \phi(x - at) \right\}; \] (g)

\[ e = \frac{dy}{dx} = \frac{1}{2} \left\{ \psi(x + at) + \psi(x - at) \right\} + \frac{1}{2a} \left\{ \phi(x + at) - \phi(x - at) \right\}; \] (h)

or, as it may also be written,

\[ v = \frac{1}{2a} \left\{ \phi(x + at) + a \psi(x + at) \right\} + \frac{1}{2} \left\{ \phi(x - at) - a \psi(x - at) \right\}; \] (i)

\[ e = \frac{1}{2a} \left\{ \phi(x + at) + a \psi(x + at) \right\} - \frac{1}{2a} \left\{ \phi(x - at) - a \psi(x - at) \right\}; \] (j)

These are essentially the same expressions with those given by Euler in his Paper on the Propagation of Sound, in the Berlin Memoirs for 1759, and by Poisson in his elaborate Memoir on the Motion of Elastic Fluids in Pipes, and on the theory of Wind Instruments, and they comprisethewhole theory of the linear propagation of Sound. But before we proceed to the interpretation of their meaning in particular cases, we have a few remarks to make on their general form.

59. And, first, it is evident, that since the variable quantity \( x \) enters into all the terms both of \( v \) and \( e \) under the functional characteristics, these quantities, regarded as functions of \( t \), are modified essentially by the value of \( x \), which may be regarded as a parameter, or constant element in the composition of the functions expressing the nature of the motion of any assigned molecule. If only \( x + at \), or only \( x - at \), separately entered upon the characteristics, since \( x + at = a \left( t + \frac{x}{a} \right) \) and \( x - at = a \left( t - \frac{x}{a} \right) \) the variation of \( x \) would only vary the origin of \( t \); and the motions of all the successive molecules would be performed according to the same laws, only commencing at a different epoch for each molecule; but, as both these quantities are involved, that is not universally the case. Consequently, in general, it appears that the undulation, or pulse, as it is propagated onward, becomes modified essentially in its quality by the distance it has passed over, it is no longer
Sound. the same sound, i.e. not identical with what would be produced by shifting the initial stratum forward. Its
velocity, intensity, and pitch, it is true, will remain (as we shall see) unaltered; but its quality, its mode of
action on the ear, (which must be differently affected by changes in the nature of the impulse made on it,) will
undergo a change. This establishes an essential difference between a Sound wave and such a wave as we took
for an illustration in Art. 45, where every point was in succession agitated by the same identical motion.

Consequently every theory of Sound in which it is assumed that the several particles in a sounding column are
all in succession agitated alike, is defective. This is the case with Newton’s doctrine of the propagation of
Sound as delivered in the 47th proposition of the 2nd book of the Principia, and, were there no other objection
against it, would suffice to vitiate the whole. This, and other unsatisfactory points in the celebrated theory
alluded to, were first distinctly perceived and pointed out by Lagrange, in the first volume of the Turin Miscel-
lanies, and an exact and rigorous investigation substituted in its place, in which the sounding column is regarded,
as consisting of a series of finite, insulated particles, mutually repelling each other; a mode of conception
which leads, by a very complicated analysis, to the same results with that above stated, but which has the advan-
tage of setting in a distinct light the internal mechanism, if we may so term it, by which Sound is propagated,
and to which we therefore willingly refer the reader.

Moreover, since by differentiating the equation (d) we get
\[ \frac{d^2 y}{dt^2} = ax \left( F''(x + at) + f''(x - at) \right), \]
this will be proportional to the accelerating force acting on the molecule. It is therefore by no means universally
proportional to \( y - x \), the distance of the molecule from its point of rest; and therefore another assumption on
which the Newtonian doctrine of Sound rests, viz. that the motion of each molecule necessarily follows the law of a
vibrating pendulum, is equally destitute of foundation. In fact, Cramer had shown, before the examination of
Lagrange, that any other law of molecular motion might be substituted in Newton’s enunciation of his
general proposition, and the demonstration would be equally conclusive, and the resulting velocity of Sound the
same.

Let us now descend more into particulars; and, first, let us suppose the initial state of the fluid to consist in
a general repose of the whole of an infinitely extended column, except a very small portion at A the origin of
the coordinates, which we will suppose agitated with any arbitrary motion. This is, in fact, the simplest case of
the production of Sound; the initial disturbance of the air being always confined within extremely small limits
compared to the distances to which the Sound is propagated. Let us then conceive the initial disturbance to
take place over a minute length 2a of the column, whose middle we will suppose to be in the origin of the x.
This amounts to supposing \( \phi(x) = 0 \), and \( \psi(x) = 1 \), for every value of x not comprised within the limits
\( x = -a \) and \( x = +a \), admitting them to have any arbitrary values between these limits.

If we suppose now \( t \) to be less than \( \frac{x-a}{a} \), and regard at first what happens only on the positive side of
the origin of the x, since \( t < \frac{x-a}{a} \) we have \( a t < x - a \), and therefore \( x - at > +a \), and, \( \alpha \) for'tiori,
\( x + at > +a \), consequently for all values of \( t \) less than \( \frac{x-a}{a} \) we have \( \phi(x - at) = 0 \), \( \phi(x + at) = 0 \);
\( \psi(x - at) = \psi(x + at) = 1 \); and therefore for all values of \( t \) less than \( \frac{x-a}{a} \) we have \( v = 0 \), and \( e = 1 \).

Consequently the molecule at the distance \( x \) from the origin of the coordinates, will remain at rest and uncondensed,
or expanded, so long as \( t \) remains less than \( \frac{x-a}{a} \); that is, for a time proportional to the distance
from the nearest point of the initial disturbance. But the moment \( t \) has attained this limit, \( \phi(x \pm at) \) will have
finite values, and \( \psi(x \pm at) \) values differing from unity, and \( v \) and \( e \) will consequently have such. The particle
then will begin to move, and to undergo a change of density, and will continue to do so till \( t = \frac{x+a}{a} \). At
this limit we have \( x - at = -a \), \( x + at = 2a t - a = 2(x + a) - a = 2x + a \), and consequently \( x + at > +a \).
Hence at this limit we have again \( \phi(x - at) = \phi(x + at) = 0 \), and \( \psi(x - at) = \psi(x + at) = 1 \),
and the motion and condensation of the particle will cease; and will not be resumed afterwards, because the
supposition \( t > \frac{x+a}{a} \) gives \( x - at < -a \), and \( x + at > 2x + a \), and, \( \alpha \) for'tiori, \( > +a \), so that the
functions retain their values 0 and 1 from this moment for ever.

Thus we see that the molecule distant by \( x \) from the origin of the coordinates will remain at rest for a certain
time \( t = \frac{x-a}{a} \), will then begin to move, and continue moving, during a time equal to \( \frac{x+a}{a} - \frac{x-a}{a} \)
\( = \frac{2a}{a} \), or till \( t = \frac{x+a}{a} \), and will then return to a state of permanent rest. A similar reasoning will
apply for negative values of \( x \). Hence if we consider any two molecules at distances \( x \), \( x' \) from A, we see that
Sound.

Sound. the more distant will commence and terminate its motion later than the nearer, by an interval of time

\[ \frac{d^2x}{d^2t} - x = a \cdot \frac{d^2x}{d^2t} \cdot \frac{a - x}{t} \]

Hence it follows that the velocity of Sound is uniform, is independent of the nature, extent, and intensity of the primitive disturbance, (for the arbitrary functions do not enter it,) and is expressed by the quantity we have called \( a \), that is \( \sqrt{2gh} \).

Let us reduce this to numbers, in order to compare theory with observation. To this end, if we call \( \Delta \) the density of mercury, \( h \) the height of the mercury in a barometer exposed to the same pressure as the sounding column, and \( D \) the density of the air in it, we have for the height of a homogeneous column of such air capable of counterbalancing the elasticity of the sounding fluid, the following value

\[ H = h \cdot \frac{\Delta}{D} \]

and, calling \( V \) the velocity of Sound, we should have

\[ V = \sqrt{2gh} \cdot \frac{\Delta}{D} \]

Now, at the freezing temperature, and in a mean state of barometric pressure, we have, according to Biot,

\( h = 0.76; 2g = 9.8088; \) and \( \frac{\Delta}{D} = 10463; \) so that we obtain, by executing the numerical operations,

\[ V = 279.42 = 916.32. \]

The actual value of \( V \) obtained by experiment is, as we have seen, 1089.42. The difference, 173 feet, is nearly one-sixth of the whole amount; a discrepancy far too great to be attributed to any inaccuracy in the determination of the data, which are all of the utmost precision. It is evident, then, that there is something radically insufficient in the theory, as above delivered; and, accordingly, Geometers for a long while endeavoured to account for it on various suppositions. Newton, who, by a singularly happy coincidence, which certainly deserves to be called a divination, had, from a theory totally inapplicable in all its points, elicited the correct expression \( \sqrt{2gh} \) above demonstrated, for the velocity of Sound, and who immediately encountered this difficulty in deducing its numerical value, endeavours to account for the deficient 173 feet by supposing the molecules of the air to be actual spherical solids of a certain diameter, \( \frac{4}{3}\pi \) of the interval between them, and that the Sound is propagated through them \( \text{instantaneously} \). It is needless to comment on this explanation. Lagrange treats the whole matter lightly, and seems inclined to attribute the deviation of fact from theory to erroneous data; in other words, dissembling the difficulty, which Euler, on the contrary, broadly acknowledged; and considered that it might possibly arise from an incorrectness of analysis, in assuming the factor \( \left( \frac{dy}{dx} \right)^2 = 1 \) in the equation (a) Art. 53, previous to integration. The true explanation was reserved for the sagacity of Laplace. But before we state it, it will be necessary to consider what will be the effect of variations of temperature and pressure on the velocity, according to the principles already laid down, and the formula arrived at.

With regard to an increase of pressure, its effect is to increase the density of the air; but since at the same time it increases its elasticity, and in exactly the same ratio, the mass to be moved, and the moving force, are increased alike, and therefore the accelerating force remains unaltered. The velocity, therefore, ought to undergo no change by this alteration. On the other hand, an increase of temperature, under a constant pressure, tends to dilate the air, and either renders it more elastic in the same space, or more rare with the same elasticity. Hence, on a variation of temperature, the moving force remains unaltered, while the mass moved decreases, and therefore an acceleration in all the resulting motions must arise. The velocity of Sound then ought to be greater in warm than in cold air, \( \text{ceteris paribus} \). These two conclusions are both amply confirmed by experiment. They agree too with the formula above stated; for, if we denote by \( h \) the mean height of the mercury in the barometer (0.76), and by \( D \) the density of air under this pressure at the freezing temperature, since, by the experiments of Gay Lussac, air expands 0.00375 of its volume by every degree centigrade of increase of temperature, its density under the pressure \( h \) at any other temperature \( + \theta \) (centigr.) will be \( \frac{D}{1 + \theta \cdot 0.00375} \), and under the pressure \( h \) it will be \( \frac{h}{D} \times \frac{D}{1 + \theta \cdot 0.00375} = D \); consequently the expression (Art. 66.) for the velocity becomes

\[ V = \sqrt{2gh} \cdot \frac{\Delta}{(D)} \cdot \left( \frac{1}{1 + \theta \cdot 0.00375} \right) \]

Now, if we call \( V \) the velocity under the mean pressure \( h \), and at the freezing point, this gives

\[ V = \sqrt{2gh} \cdot \frac{\Delta}{(D)} \]
SOUND.

and therefore \[ V = (V) \cdot \sqrt{1 + \tau \cdot 0.00375} = (V) \{ 1 + \tau \cdot 0.001975 \}, \]

or if \( \tau \) be expressed in degrees of Fahrenheit's scale,

\[ V = (V) \{ 1 + \tau \cdot 0.001042 \}; \]

which shows, first, that the velocity is independent of the pressure, since \( k \) is not contained in its expression; and that, secondly, \( \tau \) increases by very nearly the 0.001975 part of its whole quantity for every degree centigrade, or \( \frac{\tau \times 0.001975}{0.001042} \) for every degree Fahrenheit above the freezing point, that is in feet 1.86, (see Art. 17.) and decreases by the same quantity for each degree below freezing.

The law of Mariotte, which makes the elastic force of the air proportional to its density, and which has been employed in estimating the elasticity with which each molecule of the aerial column resists condensation, and transmits it to its neighbour, assumes that the temperature of the whole mass of air is alike, and undergoes no change in the act of condensation, and is therefore only true of masses of air which, after compression, are of the same temperature as before. But it is an ascertained fact, that air and all elastic gaseous fluids give out heat in the act of compression, i.e. actually become hotter, a part of their latent heat being developed, and acting to raise their temperature. This is rendered evident in the violent and sudden condensation of air by a tight-fitting piston in a cylinder closed at the end. The cylinder, if of metal, becomes strongly heated; and if a piece of tinder be enclosed, on withdrawing the piston it is found to have taken fire; thus proving that a heat, not merely trifling, but actually that of ignition, has been excited, of at least 1000° of Fahrenheit's scale. Now when we consider how small the mass of air in such an experiment is, compared with that of the including vessel, which rapidly carries off the heat generated, it is evident that if air by any cause could be compressed to the same degree without contact of any other body, a very enormous heat would be generated in it. It would, therefore, resist the pressure much more than if cold; and, consequently, would require a much more powerful force to bring it into that state of condensation than, according to Mariotte's law, would be necessary.

Air, then, when suddenly condensed, and out of contact with conducting bodies, resists pressure more (i.e. requires a greater force to condense it equally) than when slowly condensed, and the heat developed carried off by the contact of massive bodies of its original temperature. In other words, it is under such circumstances more elastic, and our analytical expression for its elasticity must be modified accordingly. In fact, the condensation of the aerial molecules in the production of Sound is precisely performed under the circumstances most favourable to give this cause its full influence; the condensations being so momentary that there is no time for any heat to escape by radiation; and the condensed air being in contact with nothing but air, differing infinitesimally from its own temperature; so that conduction is out of the question. Let us see now how this will affect the matter in hand.

It was assumed in Art. 35, that the elasticity of the air occupying the space \( dx \), or (E) : its elasticity when occupying \( dy \) : \( dy : dx \). But, in fact, the varied temperature being taken into account, the latter ratio should have stood : \( dy (1 + a \tau) : dx (1 + a \tau') \), where \( a \) denotes the coefficient 0.00375, and \( \tau \) and \( \tau' \) the original and altered temperatures in centigrade degrees. Hence in place of \( E \frac{d x}{d y} \) we must have \( E \frac{d x}{d y} \{ 1 + a (\tau' - \tau) \} \), that is, \( E \frac{d x}{d y} \{ 1 + a (\tau' - \tau) \} \), for the elasticity of the molecule of air when occupying the space \( dy \),

because, the condensations being all along supposed exceedingly small, \( \tau' \) differs from \( \tau \) only by a quantity of the same order as the condensations; so that \( (\tau' - \tau)^4 \) and its higher powers may be neglected.

Now, whatever may be the law according to which the temperature of a mass of air is increased by a sudden diminution of its volume, it is obvious that for very small condensations, such as those considered in the theory of Sound, the rise of temperature will be proportional to the increase of density; because, the quantity of latent heat having sustained only a very minute diminution, by a given extremely small condensation, a repetition of the same condensation will develop a quantity of heat falling short of the first only by a quantity of the second order; so that, neglecting such quantities, double the condensation will develop double the heat, and so in proportion. Hence we must have \( \tau' - \tau = k \{ 1 - \frac{d y}{d x} \} \) where \( k \) is a constant coefficient, whose magnitude may become known either by direct experiment, or by the very phenomena under consideration. Substituting this for \( \tau' - \tau \), we get, for the elasticity of the condensed molecule,

\[ E \frac{d x}{d y} \{ 1 + k a (1 - \frac{d y}{d x}) \} = E (1 + k a) . \frac{d x}{d y} - k a E. \]

And the difference of elasticities on either side of the plane separating the molecules \( dy \) and \( dy' \), instead of being, as in (Art. 35.) \( -E \cdot \frac{d x}{d y} \), will be now represented by \( -d \{ E (1 + k a) \cdot \frac{d x}{d y} - k a E \} \), that is, by

\[ -E (1 + k a) \cdot \frac{d x}{d y}. \]

This differs from the expression originally obtained only by the constant factor \( 1 + k a \). Without, therefore, going again through all the foregoing analysis, we see at once that the general equations of Sound will be precisely as before, writing only \( 1 + k a \). If for 11 throughout; and, therefore, if instead of putting, as before,
Sound.

\[ a = \sqrt{2gH} \text{, we put } a = \sqrt{2gH (1 + ka)} = \sqrt{2gH} \times K \text{, when } K = 1 + ka \text{ the equation (a) will become} \]

\[ \left( \frac{dy}{dx} \right)^2 \frac{d^2y}{dx^2} = a^2 = \frac{d^2y}{dx^2} ; \]

and all the other equations will remain unaltered, and the velocity of Sound on this new hypothesis will be expressed by the new value ascribed to \( a \), that is, by

\[ V = \sqrt{2gH (1 + a \times k)} \]

\[ = \sqrt{2gH} \times \frac{\Delta}{\Delta} K (1 + a \times r) \]

where \( a = 0.00375 \).

74. Value of \( K \) how determinable.

The actual numerical value of the constant coefficient \( K \) may be determined, as we have before said, in two ways; either by direct experiment on the increase of temperature developed in a given volume of air by a given condensation, or by a comparison of the formula to which we have arrived with the known velocity of Sound. As we have already observed, however, the circumstances under which Sound is propagated are far more favourable to the free and full production of the whole effect of the cause in question than those of any experiments in close vessels. We must not, therefore, be surprised, if the value of \( K \) as derived from such experiments should differ materially from its value deduced from the velocity of Sound; nor vice versa, if the observed velocity of Sound should differ materially from that obtained by calculation, from an experimental value of \( K \). It is sufficient, in a philosophic point of view, to have pointed out a really existing cause, a vera causa, which must act to increase the velocity, and is fully adequate to do so to the extent observed.

We have seen that the numerical value of \( V \) neglecting \( K \) is equal to 916.322 feet. The observed value on the other hand, is 1089.42. Hence we have the following equation for determining \( K \) and \( k \),

\[ 1089.42 = 916.322 \times \sqrt{1 + k \times 0.00375} = 916.322 \times \sqrt{K} \]

whence we obtain

\[ K = \left( \frac{1089.42}{916.32} \right)^2 = 1.4132, \]

and

\[ k = \frac{1}{0.00375} \left\{ \left( \frac{1089.42}{916.32} \right)^2 - 1 \right\} = 110.26. \]

75. Determined from the velocity of Sound itself.

The actual amount of heat given out by a given amount of condensation is not an element very easily or exactly determinable by direct experiment with thermometers. If a common mercurial thermometer be enclosed in a receiver, and the air suddenly compressed, the thermometer, it is true, rises; but the amount of its rise is evidently far inferior to the actual increase of temperature; for, first, its mass is enormously greater than that of the air immediately in contact with it; secondly, it is brought into contact successively with an unknown, and, no doubt, a variable quantity in different experiments, by the effect of circulation; thirdly, the vessel used carries off by far the greater part of the heat, and one which we have no means of estimating. It is accordingly found that by increasing the sensibility of the thermometer, by extending its surface compared to its mass, higher and higher degrees of temperature are indicated for the same condensation; and highest of all when the delicate pyrometer of Breguet is used, which consists of two extremely thin strips of platinum and palladium soldered together over their whole surface, and coiled up in a spiral, which twists and untwists by the different expansions of the metals constituting its inner and outer face. Still, however, though almost all surface, the materials of which this instrument consists are so infinitely denser than air, that its indications must fall far short of the truth.

76. Experiment of Clement and Desormes.

Another very ingenious method has been practised by Messrs. Clement and Desormes. (Journal de Physique, November, 1819, p. 334.) Suppose we have any quantity of air enclosed in a receiver communicating, first, with an air-pump, by a valvular orifice, \( (A) \); second, with the upper part of a barometer tube containing mercury, whose height therefore measures the elasticity of the air in the receiver by its depression below the barometric level of the external atmosphere; thirdly, with the external air, by a stopcock, or valve, \( (B) \), so large that the pressure within may be instantaneously restored to an equilibrium with that without, on opening it. Let the whole apparatus be at the temperature of the atmosphere, \( (\tau) \) and suppose the valve \( (B) \) open, then will the internal elasticity, or pressure, \( (P) \) be equal to that without, and also the density \( (D) \). Close the valve \( B \), and open \( A \), and, by means of the air-pump, exhaust a small portion of the air; and, again closing the valve \( A \), let the apparatus remain at rest till the whole has attained the temperature \( \tau \) of the atmosphere. In this state let the internal pressure be observed by the barometer, which call \( P' \); and \( D' \), the density, will, of course, be equal to \( D \). \( \frac{P'}{P} \), and is therefore known. Now suddenly open the valve \( B \). The external air will rush in and restore the equilibrium. The moment this is done (which will be known by the cessation of the inward current) let the valve \( B \) be closed. It will then be found that the internal temperature is raised by the condensation thus effected, and has become \( \tau' \); and the increase of temperature \( \tau' - \tau \) may be measured by a delicate thermometer, and that with the more precision the greater the capacity of the receiver. But it will be much more exactly measured by the following process, which, in fact, amounts to making the receiver itself an air thermometer. At the moment of closing the valve the internal pressure is, of course, \( P \). But as the air cools, its elasticity diminishes, and, being cut off from a fresh supply from without, the mercury will rise in the barometer tube till the whole...
SOUND.

763

The heat evolved is dissipated. Let the internal pressure, then, be again observed when this state is attained, and call it \( P'' \), then will the corresponding density, or \( D'' \), be equal to \( D \). It is required from these data to deduce the value of \( \tau' - \tau \) and the coefficient \( k \).

Now, this is easy; for, first, since in the final state of the receiver the density is \( D'' \) at a temperature \( \tau' \); therefore, the same quantity of air in the same space, raised to the temperature \( \tau' \), would sustain a pressure \( P'' \times \{ 1 + a (\tau' - \tau) \} \) where \( a = 0.00375 \), \( \tau' \) being in centigrade degrees, its density remaining \( D'' \). But at the moment of closing the valve \( A \), the temperature was \( \tau' \), and the pressure simply \( P \); we have, therefore,

\[
P = P'' \{ 1 + a (\tau' - \tau) \},\]

whence \( \tau' - \tau = \frac{P - P''}{a P''} \).

Now, secondly, this is the elevation of temperature due to the sudden transition of the air from the density \( D' \) to the density \( D'' \), by the introduction of that portion of external air which rushed in on opening the valve. Calling \( I \) the capacity of the receiver, \( 1 \times D' = D' \) expresses the quantity of air in it before the valve was opened, and \( 1 \times D'' \) or \( D'' \) the quantity after, so that \( D'' - D' \) expresses the quantity of air admitted. Its density before admission being \( D \), and afterwards \( D'' \), it had undergone a dilatation equal to \( 1 - \frac{D''}{D} \), and therefore its temperature had diminished by an amount represented by \( k \left( 1 - \frac{D''}{D} \right) \). On the other hand, the quantity of air in the receiver before opening the valve was \( 1 \times D' = D' \), and this quantity having changed its density suddenly from \( D' \) to \( D'' \), must have undergone an elevation of temperature represented by \( k \left( 1 - \frac{D'}{D''} \right) \). These two masses of air, the one cooled by dilatation, the other heated by condensation, became suddenly mixed, and therefore must have undergone a mean rise of temperature

\[
\text{mean elevation of temperature} = \frac{\{ D'(1 - \frac{D'}{D}) - (D'' - D') (1 - \frac{D''}{D}) \} k}{D' + D'' - D' = D''},
\]

But we have

\[
\frac{D''}{D} = \frac{P''}{P}, \quad \text{and} \quad \frac{D'}{D} = \frac{P'}{P}, \quad \text{so that} \quad \frac{D' - D''}{D'} = \frac{P - P''}{P''},
\]

and therefore substituting, we find for the value of the above expression, or \( \tau' - \tau \),

\[
k \left( \frac{P''}{P} \left( 1 - \frac{P'}{P''} \right) - \left( 1 - \frac{P'}{P''} \right) \right) = \frac{P'' - P'}{P} \left( 1 - \frac{P}{P''} \right).
\]

If we suppose the changes of pressure sufficiently small to allow of their squares being neglected, the value of \( \tau' - \tau \) is reduced to \( k \cdot \frac{P''}{P} \left( 1 - \frac{P'}{P''} \right) = k \cdot \frac{P'' - P'}{P} \). Equating this to \( \frac{P - P''}{a P''} \), the previously determined value of \( \tau' - \tau \), we get

\[
k = \frac{1}{a} \cdot \frac{P - P''}{P'}; \quad k a = \frac{P (P - P'')}{D'' (P'' - P')}.
\]

In an experiment of Messrs. Clement and Desormes, on which M. Poisson has grounded his computation of the theoretical velocity of Sound, the values of \( P, P', P'' \) were

\[
P = 0.7665; \quad P - P' = 0.01381; \quad P - P'' = 0.00361;
\]

and, consequently,

\[
P'' - P' = 0.01020,
\]

which gives, by the approximate formula,

\[
k a = 0.3492, \quad \text{and} \quad 1 + k a = 1.3492;
\]

whence the velocity, at a mean pressure and freezing temperature, comes out

\[
916^{322} \cdot \sqrt{13492} = 1064.35,
\]

which falls short of the actually observed velocity only by about 25 feet. If the rigorous value of \( k a \) be employed, the deficiency is rather less, the velocity coming out 1066.2. In this experiment, the time occupied

Vol. IV.

50
by the introduction of the air was about half a second; the whole elevation of temperature, computed from the formula \( \frac{P - P'}{a P'} \), must have been 1\(^{\circ}\) - 3\(^{\circ}\) centig. (= 2\(^{\circ}\) - 378 Fahr.) M. Poisson has shown (Annales de Chim. xxiii. 1823, p. 11) that an absorption of \( \frac{1}{3} \) of a degree (cent.) by the receiver, which might very well happen, would completely reconcile the observed and theoretical velocities. Laplace, calculating on the experiments of Messrs. Welter and Gay Lussac, has, since, obtained a still nearer approximation to the theoretical velocity, the difference amounting only to about 3 metres. In inquiries of such delicacy, and where the effects of minute errors of experiment become so much magnified, it seems hardly candid to desire a more perfect coincidence.

Laplace, guided by peculiar theoretical considerations respecting the constitution of gaseous fluids, has been induced to put the foregoing expression for the velocity of Sound under a somewhat different form. Let \( K \) denote the ratio of the specific heat of air under a constant pressure to its specific heat if retained at a constant density; that is, a fraction whose numerator is the quantity of heat requisite to raise a given mass of air 1\(^{\circ}\) under a constant pressure, (its volume being permitted to increase,) and whose denominator is the quantity necessary to raise it 1\(^{\circ}\) in a constant volume, or when so confined as not to dilate. Then will the velocity of Sound be

\[
V = \sqrt{\frac{2g(h)}{(D)}(1 + a\tau)} K.
\]

To show this, let \( Q \) and \( q \) be the quantities of heat above mentioned. It is evident, first, that when forcibly prevented from expanding, and thereby absorbing heat and rendering it latent, a less quantity of heat will suffice to raise the temperature of a given mass of air any given quantity, as 1\(^{\circ}\), than if unconfined. In fact, suppose it heated 1\(^{\circ}\), and allowed meanwhile to dilate, so that the temperature of the dilated air shall be 1\(^{\circ}\) above its primitive state, then, if compressed back into its original volume, the whole quantity of heat developed by the condensation will be employed in raising the temperature still higher. If then the quantity \( Q \) of caloric raise the temperature 1\(^{\circ}\) under a given pressure, it will raise it more than 1\(^{\circ}\) when confined to a given volume, by the whole amount of temperature due to a compression equal to its dilatation in the former case. Suppose the initial temperature freezing, then if \( a = 0.00375 \), an increase of temperature of 1\(^{\circ}\) cent. will produce, under a constant pressure, a dilatation \( a \), and the volume from 1 will become \( 1 + a \). Let the air so dilated and raised in temperature be compressed back to its former volume, then will its temperature be further increased by \( k a \), \( k \) denoting as before; so that the quantity of caloric \( Q \) will have ultimately produced a rise of temperature

\[
1 + k a, \text{ under a constant volume; and therefore a quantity } \frac{Q}{1 + k a} \text{ only would be required to raise it } 1^{\circ}. \text{ Hence } q = \frac{Q}{1 + k a}, \text{ and } 1 + k a = \frac{Q}{q} = K. \text{ This demonstration assumes, as an axiom, that the temperature produced by the introduction of the same quantity of caloric is the same, whether it be introduced into air confined in a given space, or into air allowed to expand freely, and then forcibly compressed back; which it evidently is, since the heat given out by the compression must of necessity exactly equal that absorbed and rendered latent in the act of expansion.}

§ II. Of the Linear Propagation of Sound in Gases and Vapours.

The analysis by which we have in the foregoing articles determined the laws and velocity of the propagation of Sound in air, applies equally, mutatis mutandis, to its propagation in all permanently elastic fluids, and in vapours, in so far as their properties are the same as those of gases. The formula so often referred to then

\[
V = \sqrt{\frac{2g(h)}{(D)}(1 + a\tau)} K.
\]

expresses the velocity of Sound in all such media, provided for \( D \) we write instead of the density of atmospheric air that of the gas at the freezing temperature, and under the mean pressure \( (h) \). In the case of vapours, we must suppose in calculating the value of \( D \) that they follow the law of gases in their condensation, and that no portion of them undergoes a change of state to a liquid, by reduction to the standard temperature and pressure. Suppose, then, the specific gravity of atmospheric air to be denoted by \( s \), and that of any gas or vapour under the same temperature and pressure by \( s' \); then if \( V \) and \( V' \) be the velocities of Sound in air, and in the gas or vapour, we have

\[
V = \sqrt{\frac{2g(h)}{s} K(1 + a\tau)}, \quad V' = \sqrt{\frac{2g(h)}{s'} K'(1 + a\tau)},
\]

because (see Pneumatics, Heat) the law of dilatation, or the value of \( a \), is alike in all. Consequently, we have

\[
\frac{V'}{V} = \sqrt{\frac{s}{s'}} \frac{K'}{K}.
\]
whence the ratios of \( \frac{V'}{V} \) and of \( \frac{K'}{K} \) being known, the ratio of the velocities is also known, being, \textit{ceteris paribus}, in the inverse subduplicate ratio of the specific gravities.

To compare this with experiment directly is impracticable, as no column of any gas but atmospheric air can be obtained of sufficient length and purity to determine the velocity of Sound in it by direct measure. Indirectly, however, the comparison may be performed by comparing the Sounds of one and the same organ-pipe, filled with the gases to be compared, successively, or by other means of a similar kind, of which more hereafter. (See \textit{Index}, under the heads \textit{Gases, Vapours, Sounds of Pipes}.)

The following Table exhibits the Velocities of Sound, as deduced from theory, and compared with experiments instituted by M. Van Rees, in conjunction with Messrs. Frameyer and Moll.

When we give this Table, to the best of our comprehension, from a very imperfect and obscure abstract of an inaugural dissertation of M. Van Rees, (printed in 1819,) given in the \textit{Journal de Physique}, 1821, p. 40. We have not been able to procure the original. The differences of the columns probably arise from impurities in the gases, as difficulty in estimating the exact pitch of Sounds propagated by them.

These determinations are, of course, liable to considerable errors; but the differences between the results of theory and experiment in the case of hydrogen is so great as to warrant a conclusion, otherwise not improbable, that the value of the coefficient \( K \) in that gas (at least) is materially different from what it is in others. Experiments in hydrogen are hardly yet sufficiently multiplied to enable us to speak with certainty on this point; but if by any means we are enabled to determine precisely the velocity of Sound, in a gas, or indeed in any medium, the ratio of the values of this coefficient in it, and in air, may be obtained by the analogy

\[
\frac{K'}{K} = \left(\frac{V'}{V}\right)^2 = \left(\frac{V'}{V}\right) \left(\frac{1}{\sqrt{\text{specific gravity of the medium}}}\right)
\]

which expresses that the value of \( K \) is as the square of the velocity of Sound, and the specific gravity of the medium jointly. Thus the specific gravity of pure hydrogen being to that of air as \( 0.0894 : 1 \), (Thomson, \textit{Attempt to establish the first Principles of Chemistry}, i. 72.) and the velocity of Sound in it being to that in air as \( 2999.4 : 1089.4 \), we have

\[
K \text{ in hydrogen : } K \text{ in air : } \left(\frac{2999.4}{1089.4}\right)^2 \times 0.0894 : (1089.4)^2 \times 1 = 0.0366 : 1 : 1.901.
\]

But not only the velocity of Sound differs in media of different chemical and mechanical natures. Its intensity, i.e. the impression it is capable of producing on our organs of hearing, \textit{ceteris paribus}, also varies extremely with a variation in the density of the transmitting medium. This we have already remarked in the case of air, whether rarefied or condensed. Priestley (\textit{Observations and Experiments}, iii. 355.) enclosed a piece of clockwork, by which a hammer could be made to strike at intervals, in a receiver filled successively with different species of gas. The distances at which the Sound ceased to be heard were measured. He thus found that in hydrogen the Sound was scarcely louder than in a vacuum, (such a one as he could produce.) In carbontic acid it was louder than in air, and somewhat louder also in oxygen. Perolle (\textit{Mém. Acad. Turin}, 1781; \textit{Mém. Acad. Turin}, 1786-1787) has described some experiments not altogether in agreement with these. The distance at which a given Sound ceased to be heard in atmospheric air being 56 feet, he found that in carbontic acid it was 48 only; while in oxygen and nitrous gas the distance was 68, and in hydrogen only 11. Chladni found the Sound of oxygen gas in an organ-pipe remarkably feeble and difficult to distinguish, and that of oxygen stronger than that of atmospheric air, but remarked nothing particular in the case of carbontic acid. (\textit{Acoust.} 281.)

Leslie (\textit{Camb. Phil. Trans.} i. 267.) relates some very curious experiments, by which it should appear that...
Sound.

SOUND.

Hydrogen gas is peculiarly indisposed for the conveyance of sound. He rarefied the air of a receiver in which a piece of clockwork was enclosed, striking a bell every half minute, 100 times; and then introduced hydrogen gas, when no augmentation whatever of the sound took place. Yet more; when the air in the receiver was only half exhausted, and the deficiency filled up with hydrogen gas, not only the sound was not increased, but was actually diminished so as to become scarcely audible. If this last fact be correctly stated, (which from the high character of Mr. Leslie, as an experimenter, we must not doubt,) some peculiar modification of the usual process by which sound is propagated must have taken place. It must be regretted that the circumstances are not more fully stated; the pitch of the bell in air, in the mixed gases, and in hydrogen alone; the dimensions of the receiver; the distances at which the sounds ceased to be heard; and whether the same effect took place when bells of different pitch were struck, and when the bell was muffled so as to produce no musical sound, are all particulars of essential consequence to enable us to form a judgment of what really took place in this interesting experiment, which we venture to express a hope will be repeated and varied by its author on a scale proportioned to its importance. We shall have occasion again to refer to this subject. (See Index, Interference of Sonorous Vibrations and Propagation of Sound in Mixed Media.)

When hydrogen is breathed (which may be done for a short time, but not altogether without inconvenience and even danger) the voice is singularly affected, being rendered extremely feeble, and at the same time raised in pitch. (Odius, Journal de Physique, vol. xlvi.) This is just what ought to arise from the lungs, larynx, and fauces being filled with an exceedingly rare medium; but if, as some experimenters relate, the effect subsists long after the hydrogen is expired, and the lungs completely cleared of it, this can only be ascribed to some physiological cause depending on its peculiar action on the organs of the voice. The singular sounds produced by breathing this gas in pipes of proper construction have nothing to do with the propagation of sound in the gas itself.

The propagation of sound in vapours offers two distinct cases in which it would at first appear that very different effects should take place. In the first, in which the vapour is subjected to a less compression than what is sufficient to reduce a portion of it to the liquid state, experiments have sufficiently proved the identity of the laws which regulate the compression and dilatation of this species of elastic fluids with those which prevail in the case of ordinary gases; and, indeed, recent researches have proved that a great number, and rendered it probable that all the latter, are in fact only vapours of certain liquids capable of sustaining a very much greater than the ordinary atmospheric pressure; or, which is the same thing, habitually maintained at a temperature far above their boiling point. In this state, then, the propagation of sound in vapours differs in no respect from that in gases. But when the pressure sustained by the vapour is sufficient to condense a portion of it, as, for instance, in the upper part of a vessel in which water is kept boiling, and which is therefore full of steam at 212° Fahr., it would seem, at first sight, that no sound could be propagated through such a medium; for, since the slightest additional pressure is sufficient to reduce a portion of the vapour to the liquid state, it would appear that the whole effect of an impulse suddenly communicated to any portion of the vapour, urging it towards the adjacent stratum, would be, not the compression of the whole of such portion into less dimensions, accompanied with increased elastic force, but the absolute condensation of a small portion into inelastic water, the remainder retaining precisely the same elasticity as before. Thus the necessary conditions for the propagation of the impulse are nullified, and it should seem, therefore, that no sound could be excited in such a case.

But if in vapours, as in gases, the act of compression develops a certain portion of heat, it is evident that this may be such as to prevent altogether the mechanical condensation of the compressed vapour, and maintain it in its elastic state even under the increased pressure; and therefore sound ought on this supposition to be propagated freely. Thus it appears that we are furnished with an experimentum crucis for deciding on the validity of the explanation above stated of the excess of the observed above the theoretical velocity of sound. If the momentary condensations and dilatations of an elastic fluid do, as supposed in that explanation, give out and absorb heat, sound should be freely propagated in a saturated vapour, (i.e. a vapour in contact with liquid, or under a pressure which it can just sustain.) If not, no sound can be transmitted by it. The experiment has been made with care by M. Biot, assisted by Messrs. Berthollet and Laplace, (Mémo. d'Arcueil, ii. 99.) by means of a bell suspended in a large glass balloon. When completely exhausted, no sound was heard on striking the bell; but on the admission of a little water it was feebly heard, and as the water and balloon were warmed, became stronger and stronger. When allowed to cool, the vapour condensed, and the sound became enfeebled by the same degrees. When alcohol was used instead of water the sound was more powerful, and still more so when ether was introduced, the vapours of these liquids at a given temperature being more dense than that of water. As in these experiments care was taken to keep the inside of the balloon constantly wet with the liquid, it is evident that the only condition requisite to be observed, that of maintaining the vapour in the interior, at its maximum of pressure, was completely fulfilled. The reader is referred to the original Memoir for an account of the details of this elegant experiment. The reasoning above stated is M. Biot's. We would remark, however, on it, that the development of the latent heat of a vapour on its condensation into a liquid, though, no doubt, analogous to, is still in a material point different from, the development of heat in a gas by mere compression, unaccompanied with a change of state. If the latent heat of steam at 212° (amounting to about 945°) be not conducted away, the steam cannot be condensed into water of 212°. A portion will be condensed, but the latent heat will be employed in raising the temperature of the water produced and of the remaining steam, and thus increasing its elasticity and resistance to the pressure. Thus, the propagation of sound in saturated vapour is not incompatible with the reduction of a portion of the vapour to a liquid state at every condensation caused by the sonorous pulse, and its reconversion into vapour when the condensation goes off: nor is it to be assumed as proving any thing with respect to gases or vapours under less than their maximum pressure. The heat developed (for any thing this experiment proves) come entirely from the liquefied
§ IV. Of the Propagation of Sound through Liquids.

The experiments of Canton, and the more recent ones of Perkins, Oersted, Colladon, and Sturm, have shown that water, alcohol, ether, and, no doubt, all other liquids, are compressible and elastic, though requiring a very much greater force to produce a given diminution of bulk than air. Water, according to the experiments of Perkins, (Phil. Trans. 1820, p. 234.) as computed by Dr. Roget, suffers a condensation of \( \frac{3}{4} \) by a pressure of 100 atmospheres. This result agrees sufficiently well with that of Canton, which gave a condensation of 0.900046 for every atmosphere of pressure, (Phil. Trans. 1764,) and has been since confirmed by Oersted’s researches.

Since water, then, and other liquids have the essential property of elastic media, on which the propagation of Sound depends, it may be presumed, a priori, that Sounds are capable of being conveyed by them as well as by the air; and, indeed, better, by reason of their greater density, pursuant to the same law which obtains in gases. This conclusion is abundantly confirmed by experiment. Hauksbee (Phil. Trans. 1726, 371.) ascertained that water would transmit a Sound excited in air. Anderon (Phil. Trans. 1748, p. 151.) describes a number of experiments on the hearing of fishes, from which, indeed, he concludes, that they are altogether devoid of this sense. But a very different conclusion really follows from them. fishes enclosed in a glass jar appeared (says Anderon) utterly insensible to any Sound excited in the air without them, (if unaccompanied with motion,) but the slightest tap with the nail on the edge of the jar, although made in such a situation that the motion could not be seen by them, immediately disturbed them. This is easily explicable; and is, in fact, just what ought to happen. The intensity of Sound excited in any medium must evidently be proportioned to the energy of the original impulse, and must therefore be much greater when arising from the direct impact of a solid body on the water, or its containing vessel, than from that of the particles of the air in a sonorous wave, whose momentum is necessarily very small.

As fishes have no external organs of hearing, Sounds must be conveyed to their sensorium by direct propagation, through the bones of their heads; and they are probably insensible to, or habitually careless of, those feeble impulses which are communicated from the air. But that the latter impulses do exist, and are audible by our ears, Anderon’s Paper furnishes proof enough. He made three people, stripped quite naked, dive at once, and remain about two feet below the surface of the water. In this situation he spoke to them as loud as he was able. At their coming up he repeated his words, but said he spoke very low. He caused the same persons to dive about 12 feet below the surface, and discharged a gun over them, which they said they heard, but that the noise was scarce perceptible. He further caused a diver to hallow under water, which he did; and the Sound was heard, though faintly. A grenade, exploded about nine feet below the surface, gave a prodigious hollow Sound, with a most violent concussion of the earth around. Lastly, he caused a diver to descend with a bell in his hand, whose ringing he (the diver) assured him he could hear distinctly at all depths; adding, also, that he could hear the rushing of the water through a flood-gate at 20 feet distance from the place he was in.

The Abbé Nolleth having descended to various depths, from 4 to 24 inches, could hear all Sounds made in the air (as a clock striking, a hunter’s horn, the human voice, &c.) distinctly, but faint and attenuated. (Brocklesby, Phil. Trans, 1748, p. 237.) Franklin, having plunged his head below water, caused a person to strike two stones together beneath the surface; and at more than half a mile distance heard the blows distinctly. These instances are sufficient to show that Sound is audibly conveyed through water as well as through air; and, indeed, if properly excited, much better.

A series of experiments on the velocity of Sound in sea-water was instituted by M. Beudant, at Marseilles. Two observers, with regulated watches, were stationed in boats at a known distance. Each was accompanied by a diver. A bell was struck at stated intervals at one station; and at the instant of its being heard by the diver at the other he made a signal, and the time was noted by the observer in the boat. Of course, time was lost. The mean result of these observations gives 1500 metres = 4921 feet per second for the velocity.

A more careful and no doubt more exact determination was undertaken and executed in 1826, by M. Colladon, in the Lake of Geneva. After trying various means for the production of the Sound, as the explosion of gunpowder, blows on anvils, and bells; the latter were preferred, as giving the most instantaneous, and, at the same time, most intense Sound, the blow being struck about a yard below the surface by means of a metallic lever. The experiments were all made at night, to avoid the interference of extraneous sounds, and for the better observing of the signals made at each blow by the flash of gunpowder.

To render audible to an observer out of water (in which situation only can any observations worthy of confidence be made) sounds excited at a great distance, a very ingenious method was practised by M. Colladon. He found, that although the Sound of the blow was well heard directly above the bell, yet the intensity of the Sound so propagated into the air diminished with great rapidity as the observer removed from its immediate neighbourhood, and at two or three hundred yards it could no longer be heard at all. This fact renders it probable, that the waves of Sound, like those of light, in passing from a denser into a rarer medium, undergo a certain acuteness of incidence, a total reflection; (see Litter, Art. (184); see also Index to this Article—
Sound.

Reflection of Sound—Echo.) and cease to penetrate the surface, so that the Sound heard beyond that limit is merely that which diverges, in the air, from the point immediately above the bell. Acting on this idea, M. Colladon plunged vertically into the water a thin tin cylinder, about three yards long and eight inches in diameter, closed at the lower end, and open to the air above; thus forming an artificial surface on which the sonorous waves, impinging perpendicularly, might enter the air, and be thence propagated freely as from a new origin; just as we may look into water at any obliquity by using a hollow tube with a glass plate at the end perpendicular to the axis. This contrivance succeeded completely, and he was enabled by its aid to hear the strokes of a bell under water at a distance of 2000, 6000, and even 14,000 metres, (about 9 miles,) viz. across the whole breadth of the lake of Geneva, from Rolle to Thonon. A better spot could not have been found, the water being exceedingly deep, without a trace of any current, and of the most transparent purity. The signals were made by the inflammation of gunpowder, which being performed by the same blow of the hammer by which the bell was struck, all loss of time was effectually avoided. The time was reckoned by a quarter second stop-watch, from the appearance of the flash to the arrival of the Sound.

By the mean of 44 observations on three different days, it appeared that a distance of 13.487 metres was traversed in 9.295 seconds, the greatest deviation being less than three-tenths of a second. M. Colladon assumes 9.4 as the true interval, regarding it as probable that a minute portion of time is necessarily lost in the estimation of the interval. The mean temperature of the water, from trials made at both stations, and half way between, was found to be 8°1 cent. (= 46°6 Fahr.) At this temperature, then, the velocity of Sound in the water of the lake of Geneva was 1435 metres = 4708 feet per second.

97. Comparison with theory.

To compare this result with theory, we will take the data afforded by the experiments of Messrs. Colladon and Sturm on this very water; whose foreign contents, as appears by the analysis of M. Tingry, amount only with theory to 9.0 of its weight, and which may, therefore, be regarded as pure water, (though, of course, saturated with air.) They state the compressibility, both at this and at the freezing temperature, at 0.00495 for every atmosphere; i.e. that an increase of pressure of one atmosphere produces a diminution of bulk equal to \[
\frac{1}{1000} \times \frac{0.00495}{\text{specific gravity of mercury at } 0^\circ \text{ cent.}}
\]

of the whole, or very nearly one two-hundred-thousandth. But as the atmospheric pressures used in their experiments were not standard ones, but each equal to a column of mercury 0.76 metres long, at a temperature of 10° cent., instead of 0° the compressibility by one standard atmosphere must be equal to \[
0.000495 \times \frac{\text{specific gravity of mercury at } 10^\circ \text{ cent.}}{\text{specific gravity of mercury at } 0^\circ \text{ cent.}} = 0.000495 \times \frac{1.0018}{1.0000} = 0.000495589.
\]

To apply the general analysis by which the velocity of Sound in an elastic medium was deduced (Art. 52.) to this case, we must express the elasticity in a form somewhat different from that before employed in the case of aeronautical fluids. Let us then put \( e \) for the compressibility of any elastic medium, or, the diminution of bulk it will sustain by an additional pressure of a single atmosphere; or by immersion to the depth of 0.76 metres (= 29.927 inches) in mercury of the freezing temperature, (so that in water \( e = 0.00495589 \)). Then, if we neglect the heat disengaged by compression, an infinitesimal column \( dx \) of the medium, when compressed into a space \( dy \), will exert a resistance on the compressing column equal to one atmosphere \( \times \frac{d y}{e} \). Let \( A \) be the area of the section of the sounding column, then will the weight of the particle \( dx \) be represented by \( A \times dx \times D \), where \( D \) is the density of the medium; and its elastic pressure on the section \( A \), which separates it from the preceding particle, will be \( A \times \frac{d y}{e} \times (h) \Delta \), where \( (h) \) = the standard height of mercury in the barometer and \( \Delta \) = the density of mercury at the freezing temperature. This, then, is the force mutually exerted between \( dx \) and the particle immediately preceding it. Similarly the force exerted between \( dx \) and the particle \( dx' \) immediately preceding it is represented by \( A \times \frac{d y'}{e} \times (h) \Delta \); and the difference of these, or the whole force by which \( dx \) is urged forwards, is therefore

\[
- d \left\{ \frac{A \Delta}{e} \left( 1 - \frac{d y}{d x} \right) \right\} = A \Delta \frac{d y}{e} \cdot \frac{d^2 y}{d x^2};
\]

so that the accelerating force acting on \( dx \) is

\[
\frac{(h) \Delta}{e} \cdot \frac{d^2 y}{d x^2};
\]

98. Different mode of expressing the coefficient of elasticity.

If we take into consideration the heat developed by compression, we have only to multiply this by the coefficient \( K \). Finally, therefore, if, as before, we represent by \( a \) the velocity of Sound, we shall have

\[
a = \sqrt{\frac{2 g (h) \Delta}{e D}} K = \sqrt{\frac{9.8088 \times 0.76 \times 13.568}{0.000495589 \times D}} K.
\]
SOUND.

Part I.

769

Sound. The specific gravity of the water of the lake at the temperature of the experiment was found to be exactly that of distilled water at its maximum density, the trilling expansion due to the excess of temperature being exactly counterbalanced by the superior density due to the saline contents, so that \( D = 1 \). Reducing, then, the value of \( a \) to numbers, we find

\[
a = 1428.2 \text{ met.} (\approx 4685.6 \text{ feet}) \times \sqrt{K}.
\]

As we have seen, the velocity actually observed was 1435 metres. The agreement of this with the coefficient of \( \sqrt{K} \) within 7 metres (a space run over by the aqueous pulse in one 200th of a second) is so near, as to authorize the conclusion that in water, at least, the heat developed by compression, and consequent increased resistance to sudden condensation, is insensible.

In the course of these experiments, M. Colladon was led to remark some very curious particulars respecting the nature, intensity, and duration of Sounds propagated by water. He observed, first, that the Sound of a bell struck under water, when heard at a distance, has no resemblance to its Sound in air. Instead of a continued tone, a short sharp sound is heard, like two knife-blades (messerklagen) struck together. The effect produced by hearing such a short dry sound, at a distance of many miles from its origin, he compares to that of seeing, for the first time, very distant objects sharply defined in a telescope. When tried at different distances, it preserved this character, varying only in intensity, so as to render it impossible to distinguish whether the sound heard arose from a violent blow at a great distance, or a gentle one near at hand. It was only when within 200 metres (about a furlong) that the musical tone of the bell was distinguishable after the blow. In air the contrary takes place, as every one knows; the shock of the first impulse of the hammer being heard only in the immediate neighbourhood of the bell, while the continued musical Sound is the only one that affects the hearing at a distance. The reason of this curious difference will be apparent when we come to speak of Musical Sounds. (See Index. Musical Sounds. Vibrations of Bodies in different media.)

Another very curious and important observation of M. Colladon, is that of the effect of interposed obstacles. Sounds in air spread round obstacles with great facility, so that by a hearer situated behind a projecting wall, or the corner of a building, sounds excited beyond it are heard with little diminution of intensity. But in water this was far from being the case. When the tin cylinder, or hearing-pipe, already mentioned, was plunged into the water, at a place screened from rectilinear communication with the bell by a projecting wall running out from the shore, whose top rose above the water, M. Colladon assures us, that a very remarkable diminution of intensity in the Sound was perceived, when compared with that heard at a point very near the former, but within reach of direct communication with the bell; or, so to speak, out of the acoustic shadow of the wall. Thus the phenomena of Sound in water approximate in this respect to the rectilinear propagation of light, and may lead us to presume, that in a medium incomparably more elastic than water, the shadow would be still more perfect and more sharply defined. A material support is thus afforded to the undulatory doctrine of Light, against one of its earliest and strongest objections—the existence of shadows.

It appears, from these experiments, that the velocity of Sound in water may be correctly computed when its compressibility is known, without the necessity of having regard to the heat developed during compression. From all direct experiments hitherto made, it appears that in water, and all other liquids, the quantity of heat thus developed is either altogether insensible, or at least very minute; so that, most probably, the same thing will hold in other liquids. The Memoir of Messrs. Colladon and Sturm, then, which contains a very elaborate determination of the compressibility of a variety of liquids, will afford the means of computing the velocity of Sound in them. We, therefore, subjoin a Table of their results, and of such others as we have been able to collect.

**Of the Propagation of Sound in Solids and in Mixed Media.**

104. Elasticity in solids, what is it? Solids, if elastic, are equally well, or better, adapted for the conveyance of sound with fluids. By elasticity in a solid is not meant a power of undergoing great Extensions and compressions, after the manner of air, or Indian rubber, and returning readily to its former dimensions; but rather what is commonly called hardness, in contradistinction to toughness, a violent resistance to the displacement of its molecules in all directions. Thus the hardest solids are, generally speaking, the most Elastic, as glass, steel, and the hard brittle alloys of copper and tin, of which mirrors are made; and in proportion as they are so, they are adapted to the free propagation of sound through their substance.

105. Effect of interrupted structure in solids on the propagation of sound. But an important condition in their constitution is homogeneity of substance; and in a substance perfectly homogeneous, we may add, too, uniformity of structure. The effect of want of homogeneity in a medium, on its power of propagating sound, is precisely analogous to that of the same cause in obstructing the free passage of light, and (as the undulatory doctrine of light teaches) for the very same reason. The sonorous pulses, in their passage through it, are at every instant changing their medium. Now, at every change of medium, two things happen; first, a portion of the wave is reflected, (see Reflection of Sound, — Echo, in the Index.) and the intensity of the transmitted part is thereby diminished; secondly, the direction of propagation of the transmitted part is changed, and the sonorous rays, like those of light, are turned aside from their direct course. (See Refraction of Sound, in the Index.) Thus the general wave is broken up into a multitude of non-coincident waves, emanating from different origins, and crossing and interfering with each other in all directions. Now, whenever this takes place, a mutual destruction of the waves, to a greater or less extent, arises, and the sound is stifled and obstructed. Further yet:—as the parts of a non-homogeneous medium differ in Elasticity, the velocities with which they are traversed by the sonorous pulses also differ; and thus, among the waves which do ultimately arrive at the same destination in the same direction, some will arrive sooner, some later. These, by the law of interference, tend mutually to destroy or neutralize each other.

106. Effect of imperfect junction of parts. But of all causes which obstruct the propagation of sound, one of the most effective is a want of perfect adhesion at the junctures of the parts of which such a medium consists. The effect of this may be conceived, by regarding the superficial strata of molecules of each medium when in contact, as forming together a thin film of less Elasticity than either; at which, therefore, a proportionally greater reflection of the wave will take place than if the cohesion were perfect,—just as light is much more obstructed by a tissue of cracks pervading a piece of glass, than it would be by any inequality in the composition of the glass itself.
A pleasing example of the stifling and obstruction of the pulses propagated through a medium, from the effect of its non-homogeneity, may be seen by filling a tall glass (a Champagne glass, for instance) half full of that sparkling liquid. As long as its effervescence lasts, and the wine is full of air-bubbles, the glass cannot be made to ring by a stroke on its edge, but gives a dead, puffy, disagreeable sound. As the effervescence subsides, the tone becomes clearer, and when the liquid is perfectly tranquil the glass rings as usual; but on reexciting the bubbles by agitation, the musical tone again disappears. To understand the reason of this, we must consider what passes in the communication of vibrations through the liquid from one side of the glass to the other. The glass and contained liquid, to give a musical tone, must vibrate regularly in unison as a system; (see Vibrations of a System of bodies) and it is clear, that if any considerable part of a system be unsusceptible of regular vibration, the whole must be so. This neat experiment seems to have been originally made by Chladni, (Acoustique, § 214,) and has been employed by Humboldt, to illustrate by it a natural phenomenon equally familiar and striking; we mean, the greater audibility of distant sounds by night than by day. This he attributes to the uniformity of temperature in the atmosphere by night, when upward currents of air, heated by their contact with the earth under the influence of the sun's rays, are no longer continually mixing the lower with the upper strata, and disturbing the equilibrium of temperature. It is obvious that sound, as well as light, must be obstructed, stifled, and dissipated from its one original direction, by the mixture of air of different temperatures, (and consequently elasticities;) and thus the same cause which produces that extreme transparency of the air at night, which astronomers only fully appreciate, renders it also more permeable to sound. There is no doubt, however, that the universal and dead silence generally prevalent at night renders our auditory nerves sensible to impressions, which would otherwise escape them. The analogy between sound and light is perfect in this as in so many other respects. In the general light of day the stars disappear. In the continual hum of noises which is always going on by day, and which reach us from all quarters, and never leave the ear time to attain complete tranquillity, those feeble sounds which catch our attention at night make no impression. The ear, like the eye, requires long and perfect repose to attain its utmost sensibility.

To a cause of the same kind, particularly modified, possibly might be attributable the singular effect of hydrogen gas when mixed with air, already described, Art. 85, in unfitting it for the free propagation of sound. Chemists maintain that when gases are mixed, the molecules of each form separate and independent systems, being mutually inelastic, and each sustaining a part of the pressure proportional to its own density. They admit, however, that the molecules of one gas (A) act as obstacles, to obstruct the free motion of those of another (H;) and on this principle they explain the slow mixture of two gases in separate vessels communicating by a narrow aperture. Granting these postulates, let us conceive a pulse excited in a mixture of equal volumes of two gases. If the velocity of sound in both be alike, the pulse will run on in each, although independently, yet with the same speed, and at any instant, and at any point of the medium, the contiguous molecules of both gases will be moving in the same direction and with the same velocity. They will, therefore, offer no mechanical obstruction to each other's motion, and sound will be freely propagated. But if they differ in their specific elasticity, the case will be altered. Each being non-elastic to the other, two distinct pulses will be propagated, and will run on with different velocities; the molecules of either gas, at different points beginning, and ceasing to be agitated with the pulsation at different instants. Thus an internal motion, a change of relative position among the molecules of the gas (H) and those of the gas (A) will take place, the one set being obliged to force themselves a passage between the other; in which, of course, a portion of their motion will be diverted in all sorts of lateral directions, and will be mutually destroyed. It is evident that the greater the difference of specific elasticities, the greater will be the effect of this cause. In hydrogen the velocity of the pulse is nearly three times its velocity in atmospheric air; and, of course, it may be expected in this case to act with great efficacy. In azote and oxygen the velocities are so nearly alike, that very little obstruction can arise from its influence; so that, in so far as the phenomena of sound are concerned, atmospheric air may be looked upon as a homogeneous medium.

If saturated with aqueous vapour, at high temperatures, however, it is possible that the effect may become sensible, and, perhaps, to this cause may be attributed a phenomenon, mentioned by one experimenter on this branch of Physics, of the occasional duplication of the sound of a gunshot heard from a great distance, a part of the sound being transmitted quicker than the rest by aqueous vapour, or even by water in the liquid state suspended in the air. If this be the case, sounds might be expected to heard double in thick fogs, or in a snow-storm. But the remarkable obstruction to sound caused by fog, and especially by snow, (see Art. 21,) would, probably, prevent any sound from being heard far enough to permit the interval of the two pulses to be distinguishable. This latter phenomenon, we may here observe, affords another and very satisfactory illustration of the general principle explained in Art. 107. To it we may add the well-known effect of carpeting, or woollen cloth of any kind, in deadening the sound of music in an apartment. The intermittent mixture of air and solid fibres in the carpets through which the sound has to pass, deadens the echo between the ceiling and floor by which the original sound is swelled.

A phenomenon noticed by every traveller who visits the Solfaterra near Naples, but whose true nature has been much misconceived, is easily explicable on this principle. The Solfaterra is an amphitheatre, or extinct crater, surrounded by hills of lava, in a rapid state of decomposition by the action of acid vapours issuing from one principal and many subordinate vents and cracks. The whole soil of the level at its bottom consists of this decomposed lava, whose disintegration, however, is not so complete as to reduce it to powder; but leaves it in coherent white masses of various particular form, a large fragment of which, against the soil, is observed to produce a peculiar hollow sound, as if some great vault were below. Accordingly it is usually cited as a proof of the existence of some vast cavity below, communicating with the ancient vent of the volcano, and perhaps with subterraneous fires; while others ascribe it to a reverberation from the surrounding hills, with which it is nearly concentric; and others to a variety of causes more or less fanciful. It seems most

SOUND.

111. **Essential difference in the constitution of fluids and solids.**

Through fluids and solids, the same formula may be used to express its velocity when the specific elasticity is known. There are, however, two very important particulars in which they differ: first, the molecules of fluids are capable of displacement inter se. Those of solids, on the other hand, are subjected to the condition of never changing their order of arrangement. Secondly, each molecule of a fluid is similarly related to those around it in all directions; in solids each molecule has distinct sides, and different relations to space and to the surrounding particles. Hence arise a multitude of modifying causes, which must necessarily affect the propagation of sonorous pulses through solids, which have no place in fluids, and modes of vibration become possible in the former, which it is difficult to conceive in the latter, whose parts have no lateral adhesion. Thus we may conceive pulses propagated in solids, like those of a cord vibrating transversely, in which the motion of each molecule is transverse, or oblique, to the direction in which the general pulse is advancing. Again, the cohesion of the molecules of crystalized bodies is different on their different sides, as their greater facility of cleavage in some directions than in others indisputably proves. They must, in consequence, have unequal elasticities in different directions; and thus the velocity of the pulse propagated through a crystalized solid will depend on its direction with respect to the axes of crystallization. Among uncrystalized solids, too, there are many, such as wood, whale-bone, &c. which have a fibrous structure, in virtue of which, it is evident, they are very differently adapted to convey an impulse longitudinally and transversely.

112. **Interruptions of crystalline structure, then, ought to produce an effect on the conveyance of Sound analogous to that of the mixture of extraneous matter in a medium.** The conducting power of wood along the grain is certainly very surprising. A simple experiment will show it. Let any one apply his ear close to one end of the longest stick of sound timber, and let an assistant at the other end scratch with the point of a pin, or tap so lightly with its head as to be inaudible to himself. Every scratch or tap will be distinctly, nay loudly, heard at the other end, as if close to the head. In general, however, all solids tolerably compact conduct Sound well, and transmit it rapidly.

Chladni relates an experiment made by Messrs. Herhold and Rafn, in Denmark, where a metallic wire 600 feet long was stretched horizontally. At one end a plate of sonorous metal was suspended, and slightly struck; an auditor placed at the other, and holding the wire in his teeth, heard at every blow two distinct sounds; the first transmitted almost instantaneously by the metal, the other arriving later through the air. Messrs. Hassenfratz and Guy Lusanc made a similar experiment in the quarries at Paris; a blow of a hammer against the rock produced two Sounds, which separated in their progress; that propagated through the stone arriving almost instantly, while the Sound conveyed by the air lagged behind. The same thing has been observed in the blasting of rocks in the deep mines of Cornwall. These experiments were, however, made at intervals too short to give any numerical estimate of the velocity of transmission of Sound in the iron or stone. The only direct experiments we have on this subject are those of M. Biot himself, who, assisted by Messrs. Bouvard, Malus, and Martin, ascertained the interval required for the Sound of a blow on the cast-iron conduit pipe already spoken of, Art. 24, to traverse measured lengths of it. The pipe consisted of joints of cast iron, each 2 m. 515 = 8'251 feet long, and connected by flanches with collars of lead covered with tarr'd cloth interposed, and strongly screwed home; each collar measured 0 r. 14256 = 0'46776. A blow being struck at one end, and heard at the other, the interval between the arrival of the Sound through the air and through the iron was noted. The length being known, the time required for the transmission of the aerial Sound became known with great precision, and thence the time of transmission through the iron became known also. The following is a statement of the results:

The last result was obtained as follows. Each observer holding in one hand a chronometer and in the other a hammer, (the chronometers being carefully compared,) the one (M) at the precise beats of 0° and 30° struck on the pipe, and the other noted the moment of arrival of that Sound only which was propagated through the solid, (i.e. the first.) At every 15° and 45°, and also precisely on the best of his chronometer, the observer (B) struck the pipe, and (M) noted in the same manner the moment of arrival of the metallic Sound by his watch. From
such reciprocal observations, a very little consideration will show that the exact time required for the Sound’s propagation through the solid may be obtained, independent of any observation of the aerial Sound, as well as of the rates of the watches. The agreement of the results obtained by the two methods sufficiently proves that the result of Mears, Bouvard and Malus, in the above Table, is too large; rejecting this for that reason, and the first on account of the shortness of the pipe, we have, as a mean result, $9275$ for the time required to traverse $951$ feet, which gives a velocity of $3450$ feet per second for the velocity of Sound in cast iron at the temperature of the experiment, $11^6$ cent. $= 51^6$ Fehr.; and neglecting the very small retardation due to the collars, whose united thickness was $561 = 15^2$ only. This is about $10^4$ times its velocity in air. Chladni assigns $397$ metres for the velocity of Sound in brass. Laplace, calculating on an experiment of Borda, on the compressibility of brass, makes it $3360^4$. According to Chladni, the following are the velocities of Sound in different solids, that in air being taken for unity: $\tan = 7, \text{ silver } = 9, \text{ copper } = 12, \text{ iron } = 17, \text{ glass } = 17, \text{ baked clay } (\text{ porcelain }) = 10 \ldots 12$, woods of various species $= 11 \ldots 17$. The error in the case of iron throws a doubt on all the rest; unless, perhaps, steel be meant. (Adams, § 219.) From this determination we may estimate the time it requires to transmit force, whether by pulling, pushing, or by a blow, to any distance, by means of iron bars or chains. For every $11090$ feet of distance the pull, push, or blow, will reach its point of section one second after the moment of its first emanation from the first mover. In all moderate distances, then, the interval is utterly insensible. But were the sun and the earth connected by an iron bar, no less than $10^4$ days, or nearly three years, must elapse before a force applied at the sun could reach the earth. The force actually exerted by mutual gravity may be proved to require no appreciable time for its transmission. How wonderful is this connection!

§ VI. Of the Divergence and Decay of Sound.

Hitherto we have taken no account of the lateral divergence of Sound, which we have supposed confined by a pipe; but it is evident that condensation taking place in any section of such a channel will urge the contained air laterally against the side of the pipe, as well as forward along its axis; and, consequently, if the pipe were cut off at any point, the Sound would diverge from that point into the surrounding air. Accordingly, when any one speaks through a long straight tube the voice is heard laterally, as if proceeding from the mouth of a speaker at the orifice.

In general, a Sound excited in, or impulse communicated to, any portion of the air or other elastic medium, spreads, more or less perfectly, in all directions in space. We say more or less perfectly; for though there are Sounds, as the blow of a hammer, the explosion of gunpowder, &c. which spread equally in all directions, yet there are others which are far from being in that predicament. For instance, a common tuning-fork (a piece of steel in the shape represented in fig. 6) being struck sharply, when held by the handle (A) against a substance, is set in vibration, the two branches of the fork alternately approaching to and receding from each other. Each of them, consequently, sets the air in vibration, and a musical tone is produced. But this Sound is very unequally audible in different directions. If the axis of the fork, or the line to which it is symmetrical, be held upright about a foot from the ear, and it be turned round this axis while vibrating, at every quarter revolution the Sound will become so faint as scarcely to be heard, while in the intermediate axes of rotation it is heard clear and strong. The audible situations lie in lines perpendicular and parallel to the flat faces of the fork, the inaudible at $45^6$ inclined to them. This elegant experiment, due originally to Dr. Young, has recently been called into notice by Weber. (Wellenlehre, § 271.)

The non-uniformity of the divergent pulses which constitute certain Sounds is easily demonstrated by considering what happens when a small disc is moved to and fro in a line perpendicular to its surface. The aerial molecules in front of the disc are necessarily in an opposite state of motion from those similarly situated behind it. Hence, if we conceive a wave propagated spherically all around it, the vertices of the two hemispheres in front and behind are in opposite motions with respect to the centre. But with regard to that wave of the sphere where the vibrating plate prolonged cuts it, there is evidently no reason why its molecules should approach to or recede from the centre, or, rather, there is as much reason for one as for the other. They will therefore either remain at rest, or move tangentially; so that the motion of the whole sounding surface, or wave, will, in this case, be rather as in fig. 7 than in fig. 8; and a corresponding difference, both in the intensity and character of the Sound heard in different directions, may be fairly expected.

The mathematical theory of such pulses as these is of the utmost complication and difficulty, depending on the integration of partial differential equations with four independent variables, viz. the time and the three coordinates of the moving molecules. It is therefore of much too high a nature to have any place in an Essay like the present. We shall merely content ourselves with stating the following as general results in which mathematicians are agreed.

1st. The velocity of propagation of a sonorous pulse is the same, whether we regard it as propagated in one, two, or three dimensions, i.e. in a pipe, a lamina, or a mass of air. *

2nd. Sounds propagated in a free mass of air diminish in intensity as they advance further from the sonorous centre, and their energy is in the inverse duplicate ratio of this distance, ceteris paribus. Law of the decay of Sound.

3rd. Sounds propagated in a free mass of air diminish in intensity as they advance further from the sonorous centre, and their energy is in the inverse duplicate ratio of this distance, ceteris paribus. Law of the decay of Sound.

We shall not attempt a proof of these propositions in the general cases, but content ourselves with illustrating them in one particular but important case, viz. when the initial impulse is confined to a very small space, and consists in any small radiant motion of all the particles of a spherical surface in all directions equally from the centre.

Since the initial wave is spherical, and similar in all its parts, it will evidently retain this property as it dilates.
by the progress of the impulse. If, then, it be conceived to be divided into its infinitesimal elements by a system of pyramidal disposed plane surfaces, having the common vertex in the centre of the sphere, each of these elements will form the base of one of the pyramids, and its molecules will advance and recede along its axis, as the pulse traverses them, without any change of their relative positions, *inter se*; so that the whole wave may be regarded as broken up into partial waves, each advancing as if confined within a pyramidal pipe, independently of all the rest.

Now in any one of these imaginary pipes the pulse will be propagated from layer to layer of the included particles with the same velocity as if the pipe were cylindrical, for the divergence of the sides of the pipe can only cause a lateral extension, and thence a diminished thickness, of the stratum, and will, therefore, alter the velocity of each of its molecules and the extent and law of its motion from what it would be in a cylindrical pipe. But, if we consider a row of particles situated in the axis of the pyramid, the propagation of a pulse along them depends, as we have seen, neither on the velocity nor extent or law of excursion of the individual molecules, but only on their intrinsic elasticity. The latter, however, is not altered by the shifting of the whole vibrating fibre into a wider or narrower part of the pipe, since, from this cause, (its excursions from its original place being supposed infinitely small,) the whole dilates or contracts together, as if by an external compressing or rarefying force.

Now we have seen that a variation in the general density of the medium in which a pulse is propagated from external pressure makes no change in its velocity. It follows, then, that the pulse will be propagated with equal velocity along the line of molecules in question, whether the pipe be cylindrical or pyramidal, or, indeed, of any shape; and as it runs equally fast in each of the imaginary pyramids into which the sphere is divided, the wave, of which it is an element, will dilate itself spherically with the uniform velocity of Sound in a straight tube. See also Euler, *Comm. Petrop.* 1771, cap. iv. &c., where the general equations for the motions of air in tubes of any figure are deduced, and the above proposition proved therefrom, in the case of hyperbolic tubes (p. 391) and conical or pyramidal ones (p. 418.)

Let us now conceive a spherical wave by any means excited, such that the whole interval, reckoned along its radius, within which the motion to and fro of the molecules is comprised, shall be equal to 2a. This, then, will be the breadth of the wave, and as all the parts dilate equally fast, this will continue to be its breadth throughout its whole progress. Its surface increases in the ratio of the square of the radius, and, therefore, calling r this radius, 2a r will represent the quantity of matter in motion at the moment the Sound has reached the distance r from its origin. Now, as all the air within and beyond the wave is quiescent, the whole impulse, or *vis viva*, originally communicated to the sphere first set in motion, is successively transferred to all the rest without loss or increase, (by the general law of the conservation of the *vis viva*. See *Mechanics.*) And since it is distributed equally over the whole spherical surface, any portion of it, of given magnitude, (that of the aperture of the ear, for instance,) will receive a part of the whole, proportional to \( \frac{1}{2a r^2} \) or to \( \frac{1}{r^2} \). Thus the whole shock or impulse given to the ear, while the wave passes over it, is as the inverse square of the distance from its origin, and the absolute velocity of each molecule in any determinate phase of its motion inversely as the distance itself.

In the theory of Sound, as in that of Light, the intensity of the impression made on our organs is estimated from its origin, as the square of the distance from its origin, and the absolute velocity of each molecule in any determinate phase of its motion inversely as the distance itself. A pulse, then, will be propagated into the solid or fluid matter according to its own laws, but this will not take place without the propagation back again of a pulse in the original medium, which may be regarded as the reflexion or echo of the first. To understand how this happens, let us consider what takes place when a motion is first impressed on any small stratum, whose thickness is 2a (as in Art. 63) of a sounding column, and let its law be as there expressed, \( \phi (x) = 0 \), and \( \psi (x) = 1 \) from \( x = -a \) to \( x = a \), and from \( x = a + a \) to \( x = +a \); while from \( x = -a \) to \( x = +a \) they may have any arbitrary values.

Since \( t \) is always positive, if we take \( x > a \), we have, of necessity, \( x + at > a \), and, therefore, \( \phi (x + at) = 0 \), and \( \psi (x + at) = 1 \), so that the values of \( v \) and \( e \) in equations (i) (j) become

\[
v = \frac{1}{2} \left[ a + \phi (x - at) - \psi (x - at) \right]
\]

\[
e = \frac{1}{2} \left[ \psi (x - at) + \psi (x - at) \right]
\]

§ VII. Of the Reflexion and Refraction of Sound, and of Echos.

As there is no body in nature absolutely hard and inelastic, whenever the particles of a vibrating medium impinge on the solid or fluid matter which contains or limits it, they will agitate those of the latter with motions similar to their own, but modified by their greater or less density and mobility. A pulse, then, will be propagated into the solid or fluid according to its own laws, but this will not take place without the propagation back again of a pulse in the original medium, which may be regarded as the reflexion or echo of the first. To understand how this happens, let us consider what takes place when a motion is first impressed on any small stratum, whose thickness is 2a (as in Art. 63) of a sounding column, and let its law be as there expressed, \( \phi (x) = 0 \), and \( \psi (x) = 1 \) from \( x = -a \) to \( x = a \), and from \( x = a + a \) to \( x = +a \); while from \( x = -a \) to \( x = +a \) they may have any arbitrary values.

Since \( t \) is always positive, if we take \( x > a \), we have, of necessity, \( x + at > a \), and, therefore, \( \phi (x + at) = 0 \), and \( \psi (x + at) = 1 \), so that the values of \( v \) and \( e \) in equations (i) (j) become
which gives
\[ a \varepsilon = a - v, \text{ or } 1 - \varepsilon = \frac{v}{a}. \]

Again, on the negative side of the \( x \) we take \( x < -a \), we have, of necessity, \( x - a T < -a \), and, consequently,
\[ \psi (x - a T) = 0; \quad \psi (x - a T) = 1, \text{ and, consequently,} \]
\[ v = \frac{1}{2} \left(-a + \phi (x + a T) + \psi (x + a T)\right) \]
\[ a \varepsilon = \frac{1}{2} \left(a + \phi (x + a T) + \psi (x + a T)\right) \]
and, therefore, in this case,
\[ 1 - \varepsilon = \frac{v}{a}. \]

Now \( 1 - \varepsilon = 1 - \frac{dy}{dx} = \frac{dx - dy}{dx} \) expresses the condensation the molecule \( d x \) has undergone in its disturbed state. Hence we see, that in each of the two waves into which the primary impulse separates itself, one running towards the positive, the other towards the negative side of the \( x \), there obtains this condition, viz. that the condensations of the aerial molecules are proportional to their actual velocities, the fluid being condensed wherever the molecules are moving from the origin of the first impulse, and dilated when returning to it.

This remarkable relation, which does not of necessity hold good within the limits of the first disturbance, establishes a distinction equally marked between the initial impulse and the waves freely propagated from it. The former is subject to no law, the latter must obey this condition. Any impulse, then, in which this condition is not satisfied, will immediately divide itself into two pulses running opposite ways, in each of which the condition in question holds, but so long as this condition obtains, no subdivision of the pulse will take place. This is easily shown, for if we suppose an initial impulse communicated to any portion \( (2a) \) of the fluid in which this relation is purposely maintained, such supposition is equivalent to making
\[ a (1 - \psi (x)) = \phi (x), \]
which, substituted in \((i)\) and \((j)\), give, for all values of \( x \) and \( t \),
\[ v = a - a \psi (x - a T) \]
\[ a \varepsilon = \psi (x - a T), \]
in which, whenever \( x \) is negative and \( x < -a \), we have \( v = 0 \) and \( 1 - \varepsilon = 0 \); thus indicating that the molecules on the negative side of such a primitive disturbance as supposed will remain constantly at rest, in other words, that the pulse will only be propagated on the positive side.

Whenever, then, in the progress of a pulse through a medium, it receives, by extraneous causes, any modification which disturbs the condition \( 1 - \varepsilon = \frac{v}{a} \), it will undergo subdivision, and a portion will run backward, or be reflected. Similarly this portion may be again subdivided and undergo partial reflexion, and so on \textit{ad infinitum}, giving rise to a continual series of repetitions or Echos of the original Sound.

Let us now examine more closely what passes at the junction of two media when the pulse arrives there; and, first, in the equations \((i)\) and \((j)\) let us write, instead of \( \phi (x) \) and \( \psi (x) \), which are arbitrary, the combinations, equally arbitrary,
\[ \phi (x) = F (x) + f (x) \]
\[ \psi (x) = 1 + \frac{F (x) - f (x)}{x}, \]
when it is to be observed that \( F \) and \( f \) are not the same with the \( F \) and \( f \) of Art. 57, which we shall have no more occasion to refer to. If, then, we put \( s = 1 - \varepsilon \), so that \( s \) shall represent the infinitely small condensation undergone by the molecule \( d x \) in its troubled state, those equations will become
\[ v = f (x - a T) + F (x + a T) \]
\[ a s = f (x - a T) - F (x + a T) \]
\begin{align*}
\text{(A)}
\end{align*}
These represent the state of the molecules of the first medium. Similarly, the state of those in the second will, of necessity, be represented by another system similar in form,
\[ v' = f' (x - a' T) + F' (x + a' T) \]
\[ a' s = f' (x - a' T) - F' (x + a' T) \]
\begin{align*}
\text{(B)}
\end{align*}
where \( a' \) represents the velocity of Sound in the second medium, but the functions \( f' \) and \( F' \) (which are not here intended to represent the derived functions or differential coefficients of \( f \) and \( F \), but others quite distinct) are here no longer arbitrary, because the motion of the particles of the second medium must evidently depend on that of the first, and on their relative elasticities, densities, &c. Let us see, then, what conditions the nature of the case, and their mutual action at their point of junction, will enable us to assign for deducing the forms of these functions from those of \( f \) and \( F \), supposed to remain arbitrary.
Now, first, the condition of continuity of the two media requires that the strata in contact should always have a common motion, or that for the value \( x = l \), corresponding to the place of junction, we should have \( v = v' \), which gives

\[
f(l - at) + F(l + at) = f'(l - at') + F'(l + at');
\]

(C).

Again, they must not only have a common motion, but a common elasticity, at this point. Now, if we call \( E \) the natural elasticity of the first medium and \( E' \) that of the second, the elasticities in the disturbed state will be expressed by \( E(1 + \beta s) \) and \( E'(1 + \beta's') \), where \( \beta \) and \( \beta' \) are constant coefficients depending on the nature of the media and the heat developed in them by compression, and which would each be unity were no heat so developed. Hence we must have \( E(1 + \beta s) = E'(1 + \beta's') \), and since in the state of equilibrium \( E = E' \), we must also have \( \beta s = \beta's' \), that is

\[
\frac{\beta}{\alpha} \left\{ f(l - at) - F(l + at) \right\} = \frac{\beta'}{\alpha'} \left\{ f'(l - at') - F'(l + at') \right\};
\]

or, putting

\[
c = \frac{\beta'}{\beta} \times \frac{\alpha}{\alpha'}
\]

\[
f(l - at) - F(l + at) = c \left\{ f'(l - at') - F'(l + at') \right\};
\]

(D).

Suppose the whole extent of both media to be initially at rest (and, therefore, \( v = v' = s = s' = 0 \)), for every value of \( x \), but those comprised within the region of the primitive disturbance (\( x = \pm a \)), supposed very minute and situated at the origin of the \( x \), we shall have then

\[
f'(x) = 0 \quad \text{and} \quad F'(x) = 0 \quad \text{from} \quad x = l \quad \text{to} \quad x = \infty,
\]

and since \( t \) is necessarily positive, and also \( a' \), therefore

\[
f(l + at') = 0 \quad \text{and} \quad F'(l + at') = 0.
\]

The equations C and D then become

\[
f(l - at) + F(l + at) = f'(l - at')
\]

\[
f'(l + at') = 0 \quad \text{and} \quad F'(l + at') = 0.
\]

and, consequently,

\[
f(l - at) - F(l + at) = c \left\{ f'(l - at') - F'(l + at') \right\}.
\]

(E).

Now this equation is equivalent to \( as = cv \); \( x \) being supposed \( = l \), (equation A.) Consequently, whatever be the motion of the first medium, the existence of a second, in contact with it, establishes at their point of junction a relation between the velocity \( v \) and the condensation \( s \) of its terminal stratum, which is incompatible with the condition \( as = v \), (unless in the very peculiar case where \( c = 1 \),) which we have shown to be essential to the total propagation of the pulse forward. It will, therefore, divide itself conformably to what was said in Art. 129, and a portion will run back in the first medium and cause an Echo.

134. In the second medium, on the other hand, we have constantly \( r > 1 \), and, therefore, \( r + at > 1 \), so that \( F'(r + at') = 0 \), and, therefore, \( x + at' > l \), so that \( F'(x + at') = 0 \), and, therefore, the equations (B) give

\[
v' = a's' = f'(x - at');
\]

(F.)

The condition of the single propagation of the pulse onward in this medium \( v' = a's' \) being therefore satisfied, no further subdivision of the pulse will take place, and each particle of the second medium will be agitated once and no more. The reader who would pursue this discussion (a very delicate one) further, is referred to M. Poisson’s Memoir, Sur le Mouvement des Fluides Elastiques dans des Tuyaux Cylindriques, Mém. Acad. Par. 1818, 1819. See also a very curious Paper by Euler, Sur la Propagation du Son et sur la Formation de l’Echo, Mém. Acad. Berlin, 1765, p. 355; where he shows how an echo may be formed at the open mouth of a tube, by the mere conditions to be satisfied by the arbitrary functions, and without any reflexion properly so called. It is enough that the condition \( as = v \) should be disturbed (as it will by the sudden breaking off of the pipe) to cause an echo. See also Weber, Wellenlehre, § 276, who shows how this disturbance takes place, owing to the greater freedom of motion suddenly attained by the particles when the pulse reaches the free air.

If we suppose a plane wave of indefinite extent to fall obliquely on the surface of a second elastic medium, each particle of this surface may be regarded as being put in agitation by it and becoming a separate and independent centre, from which spherical waves originate and are thence propagated in either medium with the velocity peculiar to it. Now, if we investigate the surfaces which in either medium are common tangents to all these spheres, and which, therefore, will be the form of the general or resulting waves in each, we shall find them to be planes; that is, in the medium of incidence being inclined to the surface at an angle equal to that made with it by the incident wave, and that in the other medium at an angle whose cosine is to the cosine of that made with it by the incident wave as the velocity of propagation of the wave in the first medium to that in the second. For the demonstration of these propositions we shall refer to our article on Light, Art. 566. Thus the reflexion and refraction of Sound at oblique surfaces obeys the same geometrical laws with those of Light. The observation of Messrs. Colladon and Sturm, above cited, Art. 95, shows that this analogy extends to the case of oblique internal reflection at the surface of a less elastic medium, which, at a certain incidence, becomes total.
PART II.

OF MUSICAL SOUNDS.

§ I. Of the Nature and Production of Musical Sounds.

Every impulse mechanically communicated to the air, or other sonorous medium, is propagated onward by its elasticity as a wave or pulse; but, in order that it shall affect the ear as an audible sound, a certain force and suddenness is necessary. Thus the slow waving of the hand through the air is noiseless, but the sudden displacement and collapse of a portion of that medium by the lash of a whip produces the effect of an explosion. It is evident that the impression conveyed to the ear will depend entirely on the nature and law of the original impulse, which being completely arbitrary, both in duration, violence, and character, will account for all the variety we observe in the continuance, loudness, and quality of Sounds. The auditory nerves, by a delicacy of mechanism, of which we can form no conception, appear capable of analyzing every pulsation of the air, and appreciating immediately the law of motion of the particles in contact with the ear. Hence all the qualities we distinguish in Sounds—grave or acute, smooth, harsh, mellow, and all the nameless and fleeting peculiarities which constitute the differences between the tones of different musical instruments—bells, flutes, cords, &c., and between the voices of different individuals or different animals.

Every irregular impulse communicated to the air produces what we call a noise, in contradistinction to a musical Sound. If the impulse be short and single we hear a crack, bounce, or explosion; yet it is worthy of remark, as a proof the extreme sensibility of the ear, that the most short and sudden noise has its peculiar character. The crack of a whip, the blow of a hammer on a stone, and the report of a pistol, are perfectly distinguishable from each other. If the impulse be of sensible duration and very irregular we hear a crash, if long and interrupted, a rattle or a rumble, according as its parts are less or more continuous, and so for other varieties of noise.

The ear, like the eye, retains for a moment of time, after the impulse on it has ceased, a perception of excitement. In consequence, if a sudden and short impulse be repeated beyond a certain degree of quickness, the ear loses the intervals of silence and the Sound appears continuous. The frequency of repetition necessary for the production of a continued Sound from single impulses is, probably, not less than sixteen times in a second, though the limit would appear to differ in different ears.

If a succession of impulses occur, at exactly equal intervals of time, and if all the impulses be exactly similar in duration, intensity, and law, the Sound produced is perfectly uniform and sustained, and has that peculiar and pleasing character to which we apply the term musical. In musical Sounds there are three principal points of distinction, the pitch, the intensity, and the quality. Of these, the intensity depends on the violence of the impulses, the quality on their greater or less abruptness, or, generally, on the law which regulates the excursions of the molecules of air originally set in motion. The pitch is determined solely by the frequency of repetition of Pitch, the impulse, so that all Sounds, whatever be their loudness or quality, in which the elementary impulses occur with the same frequency, are at once pronounced by the ear to have the same pitch, or to be in unison. It is the pitch only of musical Sounds whose theory is susceptible of exact reasoning, and on this the whole doctrine of harmonics is founded. Of their qualities and the molecular agitations on which they depend, we know too little to subject them to any distinct theoretical discussion.

The means by which a series of equidistant impulses, or, to speak more generally, by which an initial impulse of a periodical nature (i.e. capable of being represented by a periodical function) can be produced mechanically, are extremely various. Thus, if a toothed wheel be turned round with uniform velocity, and a steel spring be made to bear against its circumference with a constant pressure, each tooth, as it passes, will receive an equal blow from the spring, and the number of such blows per second will be known, if the velocity of rotation and number of teeth in the wheel be known.

The late Professor Robison devised an instrument in which a current of air passing through a pipe was alternately intercepted and permitted to pass by the opening and shutting of a valve or stopcock. When The Sirene, this was performed with sufficient frequency (which could only be done, we presume, by giving a rapid rotatory motion to the stopcock by wheelwork) a musical tone was produced, whose pitch became more acute as the alternations became more frequent. This is precisely the principle of the Sirene of Baron Cagniard de la Tour. In this elegant instrument the wind of a bellows is emitted through a small aperture, before which revolves a circular disc, pierced with a certain number of holes arranged in a circle concentric with the axis of rotation, exactly equidistant from each other, and of the same size, &c. The orifice, through which the air passes, is so situated, that each of these holes, during the rotation of the disc, shall pass over it and let through the air, but the disc is made to revolve so near the orifice, that in the intervals between the holes it shall act as a cover and intercept the air. If the holes be pierced obliquely, the action of the current of air alone will set the disc in motion: if perpendicular to the surface, the disc must be moved by wheelwork, by means of which its velocity of rotation is easily regulated and the number of impulses may be exactly counted. The Sound produced is clear and sweet, like the human voice. If, instead of a single aperture for transmitting the air, there be several, so disposed in a circle of equal dimension with that in which the holes of the disc are situated, that each shall be
opposite one corresponding hole when at rest, these will all form Sounds of one pitch, and being heard together will reinforce each other. The Sirene sounds equally when plunged in water, and fed by a current of that fluid, as in air; thus proving that it is the number of impulses alone, and nothing depending on the nature of the medium in which the Sound is excited, that influences our appreciation of its pitch.

In general, whatever cause produces a succession of equidistant impulses on the ear, causes the sensation of a musical Sound, whether such periodicity be a consequence of periodical motions in the origin of the Sound, or of the mode in which a single impulse is multiplied in its conveyance to the ear. For example, a series of broad palisades set edgeways in a line directed from the ear, and equidistant from each other, will reflect the Sound of a blow struck at the end of the line nearest the auditor, producing a succession of echos, which (by reason of the equidistance of the palisades) will reach his ear at equal intervals of time, \( \left( \frac{\text{distance of palisades}}{\text{velocity of Sound}} \right) \), and will therefore produce the effect of a number of single impulses originating in one point. Thus a musical note will be heard whose pitch corresponds to a number of vibrations per second, equal to the quotient of the velocity of Sound by twice the distance of the palisades.

A similar account may be given of the singing Sound of a bullet, or other missile, traversing the air with great rapidity. The bullet being in a state of rapid rotation, and not exactly alike in all its parts, presents, periodically, at equal intervals of time and space, some protuberance or roughness first to one side, then to the other. Thus an interruption to the uniformity of its mode of cutting through the air is periodically produced, and reaches the ear in longer or shorter equal intervals of time, according as the rectilinear velocity of the bullet bears a greater or less ratio to the velocity of its rotation about its axis.

The echos in a narrow passage, or apartment of regular figure, being regularly repeated at equal very small intervals, always impress the ear with a musical note; and this is, no doubt, one of the means which blind persons have of judging of the size and shape of any room they happen to be in. But the most ordinary ways in which musical Sounds are excited and maintained consist in setting in vibration elastic bodies, whether flexible, as stretched strings, or membranes; or rigid, as steel springs, bells, glasses, &c. or columns of air of determinate length enclosed in pipes. All such vibrations consist in a regular alternate motion to and fro of the particles of the vibrating body, and are performed in strictly equal portions of time. They are, therefore, adapted to produce musical sounds by communicating that regularly periodic initial impulse to the aerial molecules in contact with them which such sounds require. We shall, therefore, proceed to consider more particularly the principal of these modes of production; but especially, at present, the first and last, being the most simple cases.

§ II. Of the Vibrations of Musical Strings or Cords.

If a string, or wire, be stretched between two fixed pins, or supports, and then struck, or drawn a little out of its straight line, and suddenly let go, it will vibrate to and fro, till its own rigidity, and the resistance of the air, reduce it to rest; but if a bow (which is an instrument composed of a bundle of fibres of horse hair, loosely stuffed, and rendered adhesive by rubbing with rosin) be drawn across it, the vibrations are continually renewed, and may be maintained for any length of time, and a musical Sound is heard corresponding to the rapidity of the vibration.

The mathematical theory of the vibrations of a stretched cord is remarkable, in an historical point of view, as having given rise to the first general solution of an equation of partial differences; and led geometers to the consideration of the nature and management of the arbitrary functions which enter into the integrals of these equations. Such functions, as we have seen, enter into the general expressions for the motion of the air in Sound; and such, as we shall presently show, into that of the molecules of a vibrating cord; and a long and lively discussion, on the degree of generality which ought to be attributed to them, soon arose between Euler, D'Alembert, D. Bernouilli, and Lagrange. It is not, however, our intention in this Article to enter into any points of historical detail, and we shall content ourselves with a reference to the principal Memoirs, &c. on the subject, which the reader may consult for himself; while we proceed to give such a view of the subject as is consistent with the present state of knowledge on this delicate point, and sufficient for the purpose we have in hand. See Taylor, De Motu Nervi Tensi, Phil. Trans. 1718-26; D'Alembert, Mém. Acad. Berl. 1747; Ditto, 1753; Ditto Opuscles, tom. i.; Euler, Mém. Acad. Berl. 1753; Daniel Bernouilli, Ditto; Lagrange, Miscellanea Taurin. vol. i. See also Sauveur, Mém. Acad. for 1713, p. 324; J. Bernouilli, on Vibrating Cords, Petrop. Comm. iii. 13; Daniel Bernouilli, Ditto, p. 62; Ditto, on Vibrations of Unequal Cords, Acad. Berl. 1765, p. 81; Ditto, on Vibrations of Compound Cords, N. Comm. Petrop. xvi. 257; Euler, Acad. Berl. 1748, p. 69; Ditto, Ditto, 1765, p. 307, 335; Ditto, on Unequal Vibrating Cords, N. Comm. Petrop. xvii. 381; Ditto, 1790, iv. ii. 99.

Let M N (fig. 9) be a cord maintained by any means in a constant state of equal tension throughout, and disturbed by any external cause from its rectilinear position, and then left to take its own form and motion in consequence of its tension; its gravity, however, being neglected. Let M A B C D N be the figure of the cord after the lapse of any time \( t \) from the initial disturbance; respecting which we will only suppose that the distance of all its points from the axis VT (the undisturbed rectilinear position of the cord) is extremely small; so that in this theory, as in that of the sonorous vibrations of the air, we concern ourselves only with such excursions of the vibrating molecule as may be considered infinitely minute. Let A B C D be points of the cord infinitely near each other; and erecting the ordinates A P, B Q, C R, D S, and drawing A a, B b, C c, D d, parallel to VT,
Sound. Let the tension of the cord at rest be represented by c, which (since the cord is infinitely little disturbed from its position of repose) will also be its tension in its disturbed state; and will in this, as in the former state, be uniform over its whole length, the curvature being evanescent. The point B of the cord then will be solicited towards the axis by the tension c applied at B, and acting in the direction BA, and whose resolved value is, therefore,

\[ c \cdot \frac{d y}{d x} = c \cdot \frac{d y}{d x} \]

neglecting the higher powers of the quantity \( \frac{d y}{d x} \), which (being the tangent of the inclination of the element AB to the axis) is infinitely small. Similarly the point B will be solicited from the axis by the tension c applied at B in the direction BC, whose resolved part in the direction of the ordinate is equal to \( c \cdot \frac{d y}{d x} \). The resolved parts in directions parallel to the axis, being equal and parallel, destroy each other; consequently, the whole force applied at B will be \( c \cdot \left( \frac{d y}{d x} - \frac{d y}{d x} \right) \); or, supposing \( d x \) constant, \( c \cdot \frac{d^2 y}{d x^2} \) \( d x \), tending to increase the value of y.

Now the motion of the cord will be the same, whether we regard it as a continuous mass, or compound of detached particles situated at A, B, C, D, &c. and connected by filaments AB, BC, &c. without weight. Thus its equation derived and integrated.

\[ y = F(x + at) + f(x - at) \]

The determination of the arbitrary functions in this equation will depend on the conditions we may set out from. Now, first, when the cord is supposed to be of indefinite length, and the part initially disturbed to be comparatively very small; and having an indefinite undisturbed portion on either side. In this case, it is evident by the very same reasoning as that of Articles 63 and 64, that a pulse will run out both ways along the cord from the point of initial disturbance, with a velocity represented by \( a = \sqrt{\frac{2 g c}{c}} \), every molecule of the cord being once agitated during the time the pulse runs over it, and no more. Moreover, a condition similar to that which ensures the single propagation of the pulse when once it has proceeded beyond the limits of the initial disturbance (\( x = \pm a \)) in the theory of Sound, holds good in the present case; for we have

\[ \frac{d y}{d x} = F'(x + at) + f'(x - at) \]

So that on the positive side of the \( x \), when \( x > a \), and therefore \( x + at = a \), and \( F(x + at) \) and \( F'(x + at) \) Condition for the single propagation of a wave.

\[ \frac{d y}{d t} = a F'(x + at) - a f'(x - at) \]

which expresses that the tangent of the obliquity of the cord to the axis in its disturbed state, at any point, is proportional to the absolute velocity of that point in its motion, or putting \( \theta = \angle B A a \),

\[ a \cdot \tan \theta = - v \]

and when this condition ceases to hold good, as it does when the pulse encounters an obstacle either fixed or less movable than the rest of the cord, it will be either wholly reflected, or divide itself into two, one an obstacle, running back, and producing a species of imperfectly echoed or reflected wave, just as in the theory of Sound.
Since, in the above investigation, $c$ represents a force equal to the tension on the same scale that $dx$ represents a weight equal to that of the element $dx$, we have

$$ \text{weight of} \ dx : \text{tension} :: dx : c. $$

Hence $c$ represents the length of a portion of the cord whose weight is equal to the tension, and $\sqrt{2gc}$ the velocity which would be acquired by a body falling freely by gravity through that length. Hence this theorem,

The velocity of a pulse, or undulation propagated along a taut cord, is equal to that which a heavy body would acquire by falling freely through the length of a portion of the cord whose weight is equal to its tension.

Let us next suppose the cord attached at one of its extremities to an immovable point, and let the undulation be supposed to reach this point, at which suppose $x = l$, then, whatever be the value of $t$, $y = 0$, when $x = l$.

So that we must have

$$ F(l + at) + f(l - at) = 0. $$

Since $at$ may have any positive value, and since on the positive side of the $x$ (at which we have supposed the fixed end situated) $x < l$, therefore $l - x$ is in all cases positive, and therefore may be one of the values of $at$.

We may substitute, then, $l - x$ for $at$ in this equation, when we get for positive values of $x$ less than $l$, and for all negative ones

$$ F(2l - x) + f(x) = 0; \quad \text{or} \quad F(2l - x) = -f(x). \quad (p) $$

Now, in general,

$$ y = F(x + at) + f(x - at). $$

If, then, we make $at = x + \omega$, where $\omega$ is any quantity between $+a$ and $-a$, at which values of $x$ both $f(x)$ and $F(x)$ may be supposed to vanish,

$$ y = F(x + \omega) + f(x - \omega), $$

and if we make $at = 2l - x + \omega$, we have

$$ y = F(2l + \omega) + f(2x - 2l - \omega), $$

but by $(p)$

$$ y = -f(-\omega) + f(2x - 2l - \omega). $$

Now since when $t = 0$, we have $y = F(x) + f(x)$ and $\frac{dy}{dx} = F'(x) + f'(x); \quad \frac{dy}{dt} = a \{ F(x) - f'(x) \}$, all these values must vanish unless $x$ lies between the limits $+a$ and $-a$. Consequently, for all values but those comprised within such limits, we now have $F'(x) = 0$ and $f(x) = 0$. From the above equations, then, supposing $x > a$, or $x < -a$; and, therefore, $F(2x + \omega) = 0$, and $f(2x - 2l - \omega) = 0$, we see that for values of $at$ between $x + a$ and $x - a$, $y$ will have real values; and that when $at$ attains any value between $2l - x + a$, and $2l - x - a$, $y$ will again have real values, the same as the former, only with contrary signs.

Thus the reflected pulse runs back with the same velocity as the direct, and is in all respects similar and equal to it, only that it lies on the opposite side of the axis. A reasoning precisely similar applies to the case of an aerial pulse reflected from the bottom of a stopped pipe, supposed perfectly rigid.

If the cord be fixed at both ends, the two pulses into which the initial pulse has separated itself, will each be totally reflected, and will run along the whole length, being reflected again at the other end, and thus run backwards and forwards for ever, at least if we neglect the effect of the stiffness of the cord and resistance of the air; crossing each other at each traverse.

Suppose the whole length of the cord to be $l + l' = L$, of which $l$ lies on the positive, and $l'$ on the negative side of the origin of the $x$. That portion of the subdivided primitive pulse which runs towards the positive side of the $x$ will describe the length $l$ in a time $\frac{l}{a}$, being then reflected it will describe the whole length $l + l'$ in a time $\frac{l + l'}{a}$; and being again reflected, it will describe $l'$ in a time $\frac{l'}{a}$, so that after a time

$$ \frac{l}{a} + \frac{l + l'}{a} + \frac{l'}{a} = \frac{2L}{a}, $$

it will reach its first starting point; and having been twice inverted by reflexion, will lie now on the same side of the axis it originally was. Similarly, the negative portion of the original pulse will describe $l'$, $l' + l$, and $l$, and reach its starting point after two reflexions in the time

$$ \frac{l'}{a} + \frac{l' + l}{a} + \frac{l}{a} = \frac{2L}{a}, $$

the same as the other, and will also have recovered its original situation with respect to the axis. Thus at the end of this time the two pulses will precisely reunite, and constitute a compound pulse in all respects similar to the initial impulse. The state of the cord, then, after the lapse of the time $\frac{2L}{a}$, will (abstracting the effects of resistance, &c.) be precisely what it was at first; and so again, after the lapse of time $\frac{4L}{a}, \frac{6L}{a}, \&c.$ the same state will recur, so that if left to itself it will continue to vibrate for ever.
Thus we see that what in an indefinite cord was merely a pulse running along it and never returning, becomes, by the reaction of the fixed extremities of a finite one, a regular vibration, in which each molecule repeats its motion to and fro on either side of the axis, at equal intervals, for ever. In the foregoing reasoning no particular assumption has been made respecting the value of \( a \). It has not been supposed small with respect to \( l, L \), and, consequently, the above conclusion applies equally to the case where the initial disturbance is confined to a minute portion of the cord, and where a large portion, or even its whole length, is disturbed at once. Only in the former case the motions of the individual molecules of the cord will be performed by starts interrupted by intervals of absolute rest in the axis. In the latter there will be no moments of rest but those when the direction of the motion changes at the extreme points of their excursions.

Hence we conclude that when a stretched cord, whose length = \( L \), is struck, or forcibly drawn out of its straight situation into any form and let go, it will continue to vibrate to and fro, and that the time of one complete vibration, after which it resumes its initial state, is represented by

\[
\frac{2L}{a} = \frac{2L}{\sqrt{\frac{2g}{c}}},
\]

being equal to the time of a pulse running over double the length of the cord, or to the time in which a body would describe such double length with the velocity acquired by falling down a height equal to the length of a portion of the cord whose weight is the tension.

Hence the times of vibration of different cords are, as their lengths directly, and the square roots of the tending forces inversely, and the number of vibrations, dato tempore, as the lengths inversely, and the square root of the tensions directly.

The equations which express the conditions arising from the immobility of the ends of the cord so far limit the arbitrary functions \( F \) and \( f \), that when the figure of the cord between its two extremities is given it may be prolonged beyond them to any extent. To show this, let \( y \), represent the ordinate \( P, M, \) of the curve supposed to be continued beyond \( B \), one of the fixed extremities, at a distance, \( B, P \), beyond that end equal to \( B, P \), the distance from it of the ordinate \( y \), and, for simplicity, suppose \( l = 0 \), or let the origin of the \( x \) be at the other fixed extremity, \( A \), (fig. 10.) Then we have

\[
y = F (x + at) + f (x - at),
\]

\[
y = F (2L - x + at) + f (2L - x - at).
\]

Now the condition of Art. 155, derived from the fixity of the point \( B \), viz.

\[
F (2L - x) + f (x) = 0,
\]

gives, if we write for \( x \) successively \( x - at \) and \( 2L - x + at \), the following equations,

\[
F (2L - x + at) + f (x - at) = 0,
\]

\[
F (x + at) + f (2L - x - at) = 0,
\]

whose sum is no other than

\[
y + y = 0, \text{ or } y = -y.
\]

Thus we see that the curve \( A M B \) will be continued beyond \( B \) by merely reversing it from right to left and transferring it to the other side of the axis. Again, if we put \( y \), for the ordinate \( P, M, \) at a distance = \( x \) beyond \( C \), we have

\[
y = F (2L + x + at) + f (2L + x - at),
\]

\[
F (2L + x + at) + f (- x - at) = 0,
\]

\[
F (- x + at) + f (2L + x - at) = 0,
\]

On the other hand, the condition of the immobility of the point \( A \) gives, as we have seen,

\[
F (x) + f (- x) = 0,
\]

in which, writing successively for \( x + x + at \), and \( - x + at \), we get

\[
F (x + at) + f (- x - at) = 0,
\]

\[
F (- x + at) + f (x - at) = 0,
\]

and subtracting the sum of these from that of the two former, we find ultimately

\[
y - y = 0, \text{ or } y = y.
\]

so that the portion of the curve \( C M, D \) is the very same with the first portion \( A M B \). And thus we may go on as far as we please, repeating the same curve alternately in a direct and reverse position, and the same manifestly holds good on the other side of the point \( A \).

A very simple consideration will show that such ought to be the case; for if we conceive two equal and similar cords, \( A M B, B M C \), (fig. 10,) both attached to the same point, \( B \), and vibrating simultaneously, the strain on \( B \), from both their tensions, will be always equal and opposite, provided the curves be so related as above described, and \( B \), therefore, will be retained in equilibrium, independently of its attachment to any extraneous body, so that were it detached, or if the two cords, instead of being fixed to one immovable point, were merely linked together at \( B \), so as to form one cord of double the length, their vibrations would be the same.

Some curious and important consequences follow from this. And, first, a cord, although vibrating freely, may yet have any number of points, equally distributed at aliquot parts of its whole length, which never leave the axis, and between which the vibrating portions are equal and similar, and lie alternately above and below the...
Firstly, if a string in the act of vibration be touched in any point so as to reduce that point to rest and retain it in the axis, then if, after the contact, it vibrate at all, it will divide itself into a certain number of ventral parts similar to each other and separated by nodes, and each of these will vibrate as if the others had no existence, but instead the nodes were fixed points of attachment. Hence, if $L$ be the whole length of a cord, $n$ the number of ventral segments into which it divides itself, and, therefore, $n - 1$, the number of its nodes, the time of one complete vibration (going and returning) will be \( t = \frac{2L}{n\sqrt{2g\rho}} \) and the number of vibrations per second will be represented by the reciprocal of this fraction.

Experience confirms this. If the string of a violin, or violoncello, while maintained in vibration by the action of the bow, be lightly touched with the finger or a feather exactly in the middle, or at one-third of the length, it will not cease to vibrate, but its vibrations will be diminished in extent and increased in frequency, and a note will become audible, fainter but much more acute than the original, or, as it is termed, the fundamental note of the string, and corresponding in the former case to a double, in the latter to a triple rapidity of vibration. The note heard in the former case being the octave, in the latter the twelfth, above the fundamental tone (See Index, Musical Intervals.) If a small piece of light paper, cut into the form of an inverted V, be set astride on the string, it will be violently agitated and, probably, thrown off when placed in the middle of a ventral segment, while at a node it will ride quietly as if the string were (as it really is at those points) at perfect rest. The Sounds thus produced are termed harmonics.

But, further, any number of the different modes of vibration, of which a cord is thus susceptible, may be going on simultaneously, or be, as it were, superposed on each other. This is a consequence of the principle of mechanics of “the superposition of small motions,” which, when the excursions of the parts of a system from their places of rest are infinitely small, admits of any or all the motions of which, from any causes, they are susceptible, to go on at once without interfering with or disturbing each other. In the particular case before us it is easily shown, for since the general integral of the equation

\[
\frac{d^2y}{dt^2} = a^2 \frac{dy}{dx^2}
\]

is

\[
y = F(x + a t) + f(x - a t),
\]

where $F$ and $f$ denote arbitrary functions, we may suppose

\[
F(x) = F_1(x) + F_2(x) + F_3(x) + \&c.
\]

\[
f(x) = f_1(x) + f_2(x) + f_3(x) + \&c.
\]

where $F_1, F_2, \&c.$, and $f_1, f_2, \&c.$, denote functions equally arbitrary, and we get

\[
y = \{F_1(x + a t) + f_1(x - a t)\} + \{F_2(x + a t) + f_2(x - a t)\} + \&c.
\]

Now each of the expressions within brackets is the integral of an equation exactly similar to the original one. Therefore, if we put

\[
\frac{d^2y_1}{dt^2} = a^2 \frac{d^2y_1}{dx^2} ; \quad \frac{d^2y_2}{dt^2} = a^2 \frac{d^2y_2}{dx^2} ; \quad \&c.
\]

we shall have

\[
y = y_1 + y_2 + y_3 + \&c.
\]

Thus, if the several particular modes of vibration, $y = y_1, y = y_2, \&c.$, be possible, $y = y_1 + y_2 + \&c.$ will also be possible: the ordinate of the curve into which the cord at any moment forms itself in virtue of the compound vibration will be the sum (algebraically understood) of the ordinates it would have in virtue of each simple one, separately: the compound curve will be formed by first constructing on the abscissa, as an axis, any one of the simple ones, then on that curve, as an abscissa, any other, on the new curve thence arising any other, and so on.

Hence it is evident that if we suppose the curve, whose ordinate is $y$, to be of the form, fig. 11, (a) having no node, and that, whose ordinate is $y_1$, to have, for instance, one node, as fig. 11, (b) the corresponding modes of vibration, when coexisting, will produce a curve, such as (c). On these we may superpose a third mode of vibration, where the string divides itself into three ventral segments, as (d), and the result will be a curve, such as (e), and so on to any extent. The reader may exercise himself in tracing the variations of form in these curves as they go through the several phases of their periodic excursions during one complete period of a vibration of the whole string as one cord.

Experience again confirms this result of theory. It was long known to musicians that, besides the principal or fundamental note of a string, an experienced ear could detect in its Sound when set in vibration, especially when very lightly touched in certain points, other notes, related to the fundamental one by fixed laws of harmony, and which are called, therefore, harmonic sounds. They are the very same which, by the production of distinct nodes, may be insulated, as it were, and cleared from the confusing effect of the coexistent Sounds, as in Art. 163. They are, however, much more distinct in bells, and other sounding bodies, than in strings, in which only delicate ears can detect them.

The monochord is an instrument well adapted to exhibit these and all other phenomena of vibrating strings. It is nothing more than a single string of catgut fixed at one end immovably, and at the other strained over a well-defined edge, which effectually terminates its vibrations, either by a known weight or by screws. A similar well-defined edge is also interposed between its fixed end and the vibrating portion, and the interval between the two edges is graduated into aliquot parts, or in any other convenient way, and it is provided with a movable
brider, or piece of wood capable of being placed at any division of the scale, and abutting firmly against the string so as to stop its vibrations, and divide it into two of equal or unequal lengths, as the case may be.

By the aid of this instrument we may ascertain the number of vibrations which belongs to any assigned musical note, or which correspond to the notes of any musical instrument, as a piano-forte, &c. For when we have ascertainment the weight of a known length of the catgut, of which the string is formed, and the weight which must be applied to stretch the cord, so as to make its fundamental tone coincide with any given note, (as the middle C of a piano-forte,) then by the formula

$$\sqrt{\frac{2g}{cL}}$$

we know the number of complete vibrations going and returning, and by the formula

$$\frac{2g}{cL}$$

the number of oscillations from rest on one side of the axis to rest on the other, that is, the number of impulses made on the ear per second corresponding to that fundamental tone. To determine the same for any note sharper, higher, or more acute than the fundamental note, we have only to apply the bridge, and move it backwards and forwards till the sound of the vibrating part of the string is in unison with that of the note to be compared, of which the ear judges with the greatest precision; then if the length of this part, read off on the divided scale, be called \( l \), the number of its vibrations per second will be to that of the whole string \( L \); \( L : l \), and is therefore known.

The production of harmonic Sounds from cords, and their division into aliquot parts, was first noticed, in 1673, by Wallis, (Opera J. Wallisii, fol. li. p. 466, cap. cvii,) but the subject remained unattended till taken up by Sauveur, in a valuable Memoir, published among those of the French Academy for 1701, which first put this part of the doctrine of Acoustics in a clear point of view. The contact of a solid obstacle is not the only means of producing them. If two cords equally tended, and in all other respects similar, but one only half, one third, or other aliquot part of the length of the other, be placed side by side, and the shorter be struck or sounded, the vibration will be communicated to the longer by the intervention of the air, which will thus at once be thrown into a mode of vibration, in which the whole length is divided into ventral segments, each equal to the shorter string.

To understand how this may happen, let us conceive first two strings of equal length, one at rest the other vibrating, and let them be placed parallel, and side by side, then the sonorous pulses diverging at any instant from each point of the moving string, will arrive at once at each corresponding point of the other. The aerial molecules in their progress, while condensed, will press on the string and give it a very slight motion in their own direction; in their retreat they will be followed by the string, whose vibrations by hypothesis are synchronous with their own, but it will not follow them so fast as they retreat, and it will, therefore, urged and accelerated by those behind. It will, however, come to rest, in its furthest point of excursion, at the same time with the aerial molecules, when its elasticity will begin to urge and accelerate it in the contrary direction. But now also the direction of the motion of the air has changed, and again conspiring with that of the cord still continues to accelerate it, and so on, till, after a very great number of repetitions of this process, the cord will be set in full vibration and will become itself a source of Sound. But its Sound will always be much fainter than that of the original vibrating cord, for this reason, viz. that its acquired motion is perpetually dissipated, laterally, into the surrounding air, for no cord is so exactly uniform, or so equally tended in every part of its transverse section, that it can vibrate rigorously in one plane. Hence it will inevitably begin to rotate, or to describe vibrations whose plane is continually shifting, (see Art. 171,) and thus it will throw off laterally a great part of the motion it receives from the air; just as a body exposed to the radiation of a hot fire never acquires a temperature equal to that of the fire, part of the heat communicated being dissipated by lateral radiation.

Just as a small pull, repeated exactly in the time of its natural swing, will raise a great bell, or a trifling impulse a heavy pendulum, so the molecules of the air, in a state of sonorous vibration, will impress on any body capable of vibrating in their own time an actual vibratory motion, and if a body be susceptible of a number of modes of vibration performed in different times, that mode only will be excited which is synchronous with the aerial pulsations. All other motions, though they may be excited for a moment by one pulsation, will be extinguished by a subsequent one. Hence, if two cords have any mode of vibration in common, that mode may be excited by sympathy in either of them when the other is sounded, and that only. For example, if the length of one cord be that of the other as \( 2 : 3 \), and if either be set vibrating, the mode of vibration, corresponding to a division of the former into two, and of the latter into three ventral segments, will, if it exist in the one, be communicated by sympathy to the other. Nay, if it do not originally exist, it will, after a while, establish itself; for all accidental circumstances which may favour such a division have their effects, however minute, continually preserved and accumulated, till at length they become sensible.

In the vibrations of cords, which from their small surface can receive but a trifling impulse from the air, the Sounds and motions excited by this sort of sympathetic communication are feeble, but in vibrating bodies, which present a large surface, they become very great. It is a pretty well authenticated fact performed by persons of clear and powerful voice, to break a drinking-glass by singing its proper fundamental note close to it. (See Chladni, Acous. § 224.) Looking-glasses also are said to have been occasionally broken by music, the excursions of their molecules in the vibrations into which they are thrown being so great as to strain them beyond the limits of their cohesion.

The coincidence of the theory above stated, of the propagation of a wave along a stretched cord, with experiment, has been put to careful trial by Weber. (See his Wellenlehre auf Experimente Gegrundet, Svo. Leipzig, 1822, a most instructive work.) He stretched a very equal and flexible cotton thread, 51 feet 2 inches in length, weighing 864 grains, horizontally, by a known weight. The thread was struck at 6 inches from one end at the instant of letting go a stop-watch of peculiar and delicate construction, marking thirds, (sixtieths of
SOUND.

Sound. whose motion was instantaneously arrested when the wave had run a certain number of times over the length of the string backwards and forwards. The mean of a great many observations, agreeing well with each other, gave as follows:

<table>
<thead>
<tr>
<th>Tension in Grains</th>
<th>Length run over by the Wave</th>
<th>Time of its description in 4 in.</th>
<th>Time of running over the length 102 f. 4 in. in Thirds, by observation</th>
<th>The same time calculated from the formula $V = \sqrt{\frac{g}{2T}}$</th>
</tr>
</thead>
<tbody>

</table>

A completer coincidence could not have been wished for. The slight discrepancies may, perhaps, arise from the want of uniformity in the tension of so long a thread, which would, of course, form a catenary of sensible curvature. We should observe, however, that M. Weber has reckoned here the weight (864 grains) of the thread as part of the tension, a proceeding whose legitimacy may be questioned.

The way in which the permanent or vibratory oscillations of a cord arise by reflexion at its fixed extremities from a wave propagated along it progressively, may be rendered a matter of ocular inspection if we take a long and pretty thick cord, fasten it at one end, and holding the other in our hands, give it a regular motion to and fro, transverse to the length of the cord. Progressive waves will thus arise, which, as soon as they reach the fixed end, and are reflected, will be observed to interfere with those still on their way, and, as it were, to arrest them, producing a series of nodes and ventral segments, whose number will depend on the tension and frequency of the alternate motion communicated to the movable end. In this arrangement the continual periodic renewal of the primary impulse by the hand supplies the place of a reflecting obstacle at that end.

The pitch of the Sound of a vibrating string depends only on the number of vibrations made dat tempore, its quality will depend partly on the nature of the string, and especially on its equality of thickness, besides which, much may depend on the form and extent of the wave excited, or of the curve into which it is thrown. In instruments, like the violin or violoncello, played with a bow, or the guitar or harp, where the string is drawn softly out of its position and suddenly let go, this curve is, probably, single, and occupies the whole length of the string; but in the piano-forte, where the strings are struck, near one extremity, with a sharp sudden blow, there can be little doubt that the vibration consists in an elevation or bulge, more or less extensive, running backwards and forwards. Fig. 12 represents the different phases of a single complete vibration of a string so struck. The first wave (1) is a single elevation, it divides in (2) into two running contrary ways; in (3) that nearest the end A is reflected and takes a reversed position; in (4) they advance the same way towards B; in (5) the unreflected portion reaches B, is there reflected and reversed, as in (6). In (7) it meets and coincides with the former reflected portion, there forming a depression equal and similar to the original elevation in (1), and as far distant from the end B as the former from A. After this the same steps are repeated in the reverse direction, till the original elevation is reproduced again, as in (1). The waves, however, must be supposed to bear a much more considerable ratio to the whole string than in the figure. It is evident that the magnitude of this ratio must influence the quality of the tone, and thus a difference of character in the tone, according as the keys are struck with quick short brilliant blows, or gently pressed, and the duration of the contact of the hammers with the strings prolonged for an instant of time, giving rise to a more moderate but sustained tenuto effect, by bringing a larger portion of the string, or even the whole into motion at once.

But whether the portion disturbed at once be large or small, whether it occupy the whole string, or run along it like a bulge in its line, whether it be a single curve, or composed of several ventral segments with intervening nodes, we must never lose sight of the fact that the motion of a string with fixed ends is no other than an undulation or pulse continually doubled back on itself and retained constantly within the limits of the cord, instead of running out both ways to infinity.

It is very seldom (for the reasons mentioned in Art. 170) that the vibrations of a string actually lie in one plane. Most commonly they consist of rotations more or less complicated, except when produced by the sawing of a bow across the string, when they are forcibly limited to the plane of motion of the bow. The real form of the orbit described by any molecule may be made matter of ocular inspection, by letting the sun shine through a narrow slit as to form a thin sheet of light. Let a polished wire be placed so as to penetrate this sheet perpendicularly to its plane, and the point where it cuts the plane will, at rest, be seen as a bright speck, but when set vibrating it will form a continued luminous orbit, just as a live coal whirled round appears as a circle of flame. Fig. 13 exhibits specimens of such orbits, observed by Dr. Young.

A very curious case of a mode of vibration, by which a string may be made to produce a Sound graver than its fundamental tone, is mentioned by M. Biot. If an obstacle be placed below the middle point of a vibrating string so as just to touch, but not to press against, it, and the string be then drawn up vertically and let go, it will strike at every oscillation upon this obstacle, and bend over it, as in fig. 14, at every blow; thus resolving itself into two, of half the length. Thus the first semi-oscillation will be performed as a whole, the
§ III. Of the Vibrations of a Column of Air of Definite Length.

The general equation representing the motions of the molecules of a tended cord of indefinite length is, as we have seen, precisely similar in its form, and in that of its complete integral, to that of the particles of air in a sounding column. There subsists, of course, a perfect analogy between the two cases, and, mutatis mutandis, all propositions which are true of a vibrating cord are also true of a vibrating cylindrical volume of air.

Thus, if such a cylindrical column be enclosed in a pipe, whose length $= l + l = L$, stopped at both ends by perfectly immovable stoppers, and if we suppose any single impulse communicated to one of its sections at the distance $l$ from one of its extremities (A), this will immediately divide itself into two pulses running opposite ways; they will be totally reflected at the two extremities, the one, after describing the space $l$ before and $l$ after reflexion, will meet the other which has described $l$ before and $l$ after reflexion, at a distance $= l$ from the other extremity B, and produce a compound agitation in the section at that place similar to the primitive disturbance; hence the partial pulses will again diverge, and after each undergoing another reflexion will again unite in their original point of departure, constituting a repetition of the first impulse, and so on, till the motion is destroyed by friction and by the imperfect fixity and rigidity of the stoppers, allowing some of it to pass into them and be lost at each reflexion.

But if the section first set in motion be maintained in a state of vibration synchronous with the return of the reflected pulse, it will unite with and reinforce it at every return, and the result will be a clear and strong musical sound resulting from the exact combination of the original periodic impulse with all its echos. This will be transmitted through the pipe to the outer air, and thus dissipated and lost.

For simplicity, let us suppose the section primitively set in vibration and so maintained, to be situated just in the middle of the pipe. Then, when once the regular periodic pulsation of the contained air is established, it is evident that the motion of the column will consist of a constant and regular fluctuation to and fro within the pipe of the whole mass, the air being always condensed in one half of the pipe while it is rarefied in the other. The greatest excursions from their place will be made by the molecules in the middle, while those at the extremities, being constantly abutted against the stoppers, remain unmoved, and the excursions made by each intermediate molecule will be greater the nearer it is to the middle. On the other hand, the rarefactions and condensations are greatest at the extremities, and diminish as we approach the middle of the pipe, where there is neither condensation nor rarefaction. The analogy of this case with the case of the vibrating cord will be evident if we consider that the condensation in the former is represented by the angle of inclination of the vibrating curve to its abscissa in the latter, and that the mode of vibration now contemplated in the aerial molecules is analogous to that of a cord vibrating as a whole, and having its two halves symmetrical.

In the same way as a vibrating cord is susceptible of division into its several aliquot parts all vibrating simultaneously, so may the aerial column in our stopped pipe vibrate in distinct ventral segments. The manner in which this may take place will be evident on inspection of figs. 15 and 16, where the arrows denote the directions of the motions of the vibrating molecules, and where we see the immobility of the nodal sections is secured by the equal and opposite pressures of the molecules on either side of them. At these nodal sections, too, the same thing holds good as at the stopped extremities, their molecules remain constantly at rest while yet they undergo greater vicissitudes of compression and dilatation than those in any other parts of the column.

Precisely, too, as in the vibrations of strings, any number of these modes of vibration may go on simultaneously. Such combined modes may be produced by an expert flute player, by a nice adjustment of the force of his breath; at least the octave of any note may be obtained without difficulty, and distinctly heard with the fundamental tone.

Half way between two nodes (regarding the stopped ends as nodes) the condensations and rarefactions are evanescent, and the amplitudes of the molecular excursions are at a maximum. Now at such a point let us conceive a narrow ring of the cylindrical pipe in which the vibrating column is contained to be cut away, so as to open a free communication with the outer air. There will be no tendency for air to pass in or out, because the air within is constantly, at these points, in its natural state as to density; neither will its motion be impeded, being parallel to the axis of the column and without any lateral bias. The detachment then of such a ring will no way alter the vibrations of the column, nor, a fortiori, will the opening of a hole in the pipe at this place affect...
Sound. Suppose, now, at this hole, a vibrating body placed, whose vibrations are executed in equal times with those in which the excursions to and fro of the included aerial sections are performed in the stopped pipe. They will be communicated to them, and thus the Sound of the pipe will be excited and maintained. Such an aperture is called an embouchure.

But let us now conceive the one half (A) of the pipe entirely removed, and in its place a disc substituted exactly closing the aperture, and maintained, by some external cause, constantly in a state of vibration, such, that the performance of one complete vibration, going and returning, shall exactly occupy as much time as a sonorous pulse would take to traverse the whole length of the stopped pipe (A + B), or double that of the open one (B). Its first impulse on the air will be propagated along the pipe (B) and reflected at the stopped end, and will again reach the disc just at the moment when the latter is commencing its second impulse. But the absolute velocity of the disc in its vibrations being excessively minute compared with that of Sound, the reflected pulse will undergo a second reflexion at the disc as if it were a fixed stopper. It will, therefore, in its return exactly coincide and conspire with the second original impulse of the disc, and the same process being repeated on every impulse, each will be combined with all its echoes, and a musical tone will be drawn forth from the pipe vastly superior to that which the disc vibrating alone in free air would produce. This is, in fact, the simplest instance of the resonance of a cavity, of which more hereafter. (See Index, Resonance.) Now, it is manifestly of no importance whether the pulses reflected from the closed end of the pipe (B) undergo a second reflexion at the disc, and are so returned back by the pipe, or whether we regard the disc as penetrable by the pulse, (i.e. a mere imaginary vibrating section,) and suppose the pulse to run on and be reflected at the extremity of the other half (A) of the bisected pipe (A + B), and on its return again to pass freely through the disc and be again reflected at the stopped extremity of (B). The Sounds produced will be the same, on the principle of the superposition of vibrations. Thus we see that the fundamental Sound of a pipe open at one end is the same with that of a pipe closed at both ends, and of double the length.

The mode here supposed of exciting and maintaining the vibrations of a column of air in a pipe is easily put in practice. Let any one take a common tuning-fork and on one of its branches fasten with sealing-wax a circular disc of card of the size of a small wafer, or sufficient nearly to cover the aperture of a pipe. The sliding joint of the upper end of a flute, with the mouth-hole stopped, is very fit for the purpose; it may be made to "speak" perfectly well by holding close to the embouchure a vibrating tuning-fork while the fingering proper to the note of the fork is at the same time performed. We shall have further occasion to refer to this point. (Resonance, Index.)

But the most usual means of exciting the vibrations of a column of air in a pipe is by blowing into, or rather over it, either at its open end or at an orifice made for the purpose at the side, or by introducing a small current of air into it through an aperture of a peculiar construction called a reed, provided with a "tongue" or flexible elastic plate which nearly stops the aperture, and which is alternately forced away by the current of air and returns by its elasticity, thus producing a continual and regularly periodic series of interruptions to the uniformity of the stream, and, of course, a Sound in the pipe corresponding to their frequency. Except, however, the reed be so constructed as to be capable of vibrating in unison, or nearly so, with, at least, one of the modes of vibration of the column of air in the pipe, the Sound of the reed only will be heard, the resonance of the pipe will not be called into play, and the pipe will not speak; or will speak but feebly and imperfectly, and yield a false tone.

But of reeds more hereafter; (see Index, Reeds;) at present let us consider what takes place when the vibrations of a column of air are excited by blowing over the open end of a pipe or an aperture in its side. To do it effectively the air must be directed in a small current, not into, but across the aperture, as in fig. 18, so as to graze the edge of the aperture. By this means a small portion will be caught and turned aside down the pipe, thus giving a first impulse to the contained air and propagating down in a pulse in which the air is slightly condensed. This will be reflected at the end as an echo, and return to the aperture where the condensation goes off, the section condensed expanding into the free atmosphere. But in so doing, it lifts up, as it were, and for a moment diverts from its course the impinging current, and thus, while it passes, suspends its impulse on the edge of the aperture. The moment it has escaped the current resumes its former course, again touches the edge of the aperture, creates there a condensation, and propagates downwards another condensed pulse, and so on. Thus the current passing over the aperture is kept in a constant state of fluttering agitation, alternately grasping and passing free of its edge, at regular intervals, equal to those in which a sonorous pulse can run over twice the length of the pipe; or, more generally, in which the condensations and rarefactions recur at its aperture in virtue of any of the modes of vibration of which the column of air in the pipe is susceptible.

In general, wherever there is a communication opened between the column of air in a pipe and the free atmosphere, that point will become a point of maximum excursion of the vibrating molecules, or the middle of a ventral segment. In such a point the rarefactions and condensations vanish, the air reducing itself constantly to an equilibrium of pressure with the free atmosphere with which it is in contact. Hence, if the pipe speak at all, it will take such a mode of vibration as to satisfy this condition, but, consistently with this, it may divide itself into any number of ventral segments. But here there is a point of practical difference between the affections of a vibrating aerial column and those of a tending cord. The tension of the cord can only be maintained steadily in practice, by fixing its two ends; so that the case of one extremity fixed, the other free, can have no existence but in imagination, where the cord may be conceived as of indefinite length in one direction, so that the running pulses may lose themselves, or, at least, never return. It is true they might be stifled by wrapping one
end of a very long cord in cotton, but whether, under such circumstances, any mode of producing and maintaining
an initial periodical impulse sufficiently regular to produce musical Sounds could be found remains to be
tried. The nearest approach to the case in question is when one end of a long cord is held in the hand and
agitated while the tension is maintained, as in Art. 173.

In cords with fixed extremities, however, all the ventral segments must, of necessity, be complete, no half
segments can exist. In pipes it is otherwise. The air in a pipe closed at one end vibrates as a half, not the
times and whole of such a segment. It is owing to this that a pipe open at both ends can yield, if properly excited, a
vibration in modes of musical Sound. The column of air in it vibrates in the mode represented in fig. 19, where there is a node in the
middle and each ventral segment is only half a complete one. In general it is easy to represent, in an algebraic
formula, the time of vibration, or the number of vibrations per second corresponding to any mode of vibration. Fig. 19.

For, in a pipe open at both ends, let the number of nodes be n, then there will be n – 1 complete ventral
segments between them, as in fig. 20, and a moiety of one at each end. If, then, we call L the whole length of Fig. 20.
such a pipe in feet, V the velocity of Sound in feet per second, the length of one complete ventral segment will
be \( \frac{L}{n} \). This length is traversed by a sonorous pulse in a time \( \frac{1}{n} \cdot \frac{L}{V} \), and this is the time of vibration of the
middle section of it to which the Sound corresponds. The pipe, then, vibrating according to this mode, will
yield a Sound whose pitch is that of a cord making \( \frac{V}{L} \) vibrations per second; and the series of tones it can
produce is expressed by the following series of numbers of vibrations,

\[ 1, \frac{V}{L}; 2, \frac{V}{L}; 3, \frac{V}{L}, \text{etc.} \]

In the case of a pipe closed at one end, the stopped end must be regarded as a node. (Fig. 21.) Calling the
whole number of nodes, thus included, n, the number of complete ventral segments will be n – 1, and one half of
segment will terminate at the open end. Therefore \( \frac{2n + 1}{2n + 1} \) \( \frac{L}{V} \), will be the number of such halves contained in the length L, and \( \frac{2n + 1}{2n + 1} \)
will, therefore, be the length of each complete one; so

that each will make \( \frac{2n + 1}{2} \cdot \frac{V}{L} \) vibrations in one second, and thus the series of tones such a pipe can yield
will be expressed by the series of vibrations,

\[ \frac{1}{2} \cdot \frac{V}{L}; 3 \cdot \frac{V}{L}; 5 \cdot \frac{V}{L}, \text{etc.} \]

Lastly, the number of nodes, including the two stopped ends of a pipe closed at both ends, being n, the
number of segments (all complete) into which it will be divided will be n – 1, and the length of each will be \( \frac{L}{n - 1} \).

so that the series of Sounds, of which such a pipe is susceptible, is represented by the series
of vibrations,

\[ 1, \frac{V}{L}; 2, \frac{V}{L}; 3, \frac{V}{L}, \text{etc.} \]

Taking, therefore, unity for the number of vibrations per second in the fundamental tone, the series of harmonics
will run as follows:

In a pipe stopped at both ends ................. 1, 2, 3, 4, 5, \&c.

----- open at both ends .................. 1, 2, 3, 4, 5, \&c.

stopped at one end, open at the other.... 1, 3, 5, 7, 9, \&c.

It being recollected, however, that in the last series the fundamental note 1 is an octave lower than in the others,
\( i.e. \) performs its vibrations only half as rapidly.

To produce these Sounds by blowing into a pipe, it is only requisite to begin with a gentle blast as will
make the pipe speak, and to augment its force gradually. The fundamental tone will be heard first; and as
the strength of the blast increases, will grow louder, till at length the tone all at once starts up an octave, \( i.e \).
exciting the interval between notes whose vibrations are as 1 : 2. By blowing still harder, the next harmonic, 1 : 3, or
as it is called in Music, the octave of the fifth, or the twelfth of the fundamental tone, is heard; but no adap-
tation of the embouchure, or force of the wind, will produce any note intermediate between these. The next
harmonic is 1 : 4, and corresponds to the double octave, or fifteenth of the fundamental tone; and the next, or
1 : 5, to the seventeenth, or major third above the double octave. (See the explanation of these terms in
Art. 210, et seq.) The next, 1 : 6, corresponds to the sixteenth, or double octave of the fifth, and so on. All the
series of harmonic tones here enumerated are very readily produced on the flute, without changing the fingerings, from the lower C
or D upwards, by merely varying the force of the blast, and a little humouring the form of the lips and their
position with respect to the embouchure. The reader may consult on this subject D. Bernouilli, Sur le Son et
sur les Tons des Tuyaux d'Orgues, Mém. Acad. Paris, 1762; in which the true theory of wind-instruments is

Vol. IV.
Sound.

compared with the dimensions of the pipe, a power of mutual accommodation subsists, and a mean tone is produced, less powerful and less pure and pleasing, however, as the pipe is more forced from its natural pitch, until it ceases to sound altogether, and the note produced, if any, is that of the reed alone. In this respect there is, however, a great difference in pipes of different sizes. In large organ-pipes the reed vibrates with nearly the same force as the open air, and will, therefore, speak when the pipe has ceased to resound; but in smaller and narrow pipes, as in oboes, and other similar wind-instruments, a much closer correspondence between the pitches of the reed and pipe is required, or the reed will not vibrate. Messrs. Biot and Hamel adapted to a glass pipe a reed of the ordinary construction represented in fig. 23, in which the vibrating tongue L (by whose oscillations the opening of the reed at R is alternately opened and closed) could be lengthened or shortened at pleasure by thrusting in or withdrawing a wire F; which bears with a slight spring against the tongue at f. The blast of wind being maintained constant, the reed was made to yield its gravest note, by withdrawing the wire as far as possible, after which, by pushing it in, the pitch of the reed was gradually raised. It was observed that the note of the reed grew constantly more acute, but that after a certain point, it began to diminish in intensity, till at length no Sound could be heard. At this point, the note of the reed, being narrowly examined through the glass, was observed to be still in rapid vibration; but its vibrations were performed entirely in the air, so as not to strike upon and close the orifice. A constant passage then being left for the air, the vibrations of the pipe could not be excited. But this state of things continued only so long as the tongue was of that precise length. The moment the wire was pushed in by the smallest quantity, the Sound sprung forth and of a pitch still corresponding with the shortened state of the tongue.

The instrument called the German harmonica is a reed, on M. Grenié's principle, consisting of nothing but a very thin lamina of brass, of the form of an oblong parallelogram fixed by one of its narrow ends in a frame of its own shape, but just so much larger as to allow of its free motion. This instrument vibrates by a blast urged through it yielding a clear musical tone of a very pleasing character and fixed pitch. If placed at the end of a pipe it performs the office of a reed, and its tone commands, or is commanded, by the pipe according to circumstances, as above explained.

When the action of the embouchure of a pipe is so decided as to be incapable of being, to any sensible extent, commanded or influenced by the resonance of the pipe; as, for instance, when the column of air in a stopped pipe is set in vibration by a tuning-fork furnished with a clapper described in Art. 119, the pipe will sound, and reinforce the Sound of the tuning-fork, but more and more feebly, as the pitch of the latter departs more from that of the pipe. The experiment is easily made by tuning the upper joint of a flute with the mouth-hole stopped exactly in unison with a fork, and then moving the piston of cork at the end of the pipe to and fro, or loading the fork with wax, so as to put it more or less out of tune. The fork and aerial column vibrate as a system, in which the former has so much the preponderance as to command the latter completely.

We may here notice a very remarkable experiment, which we do not remember to have seen elsewhere.

* As we have heard it done by M. Eulenstein.
SOUND.

§ IV. Of Musical Intervals, of Harmony, and Temperament.

Our appreciation of the pitch of a Musical Sound depends, as we have seen, entirely on the number of its vibrations performed in a given time. Two Sounds whose vibrations are performed with equal rapidity, whatever be their difference in quality or intensity, affect the ear with a sentiment of accordance which we term a unison, and which irresistibly impresses on us the conviction of a perfect analogy, or similarity between them, which we express by saying that their pitch is the same, or that they sound the same note. In fact, their impulses on the air, and on the ear, through its medium, occurring with equal frequency, blend, and form a compound impulse, differing in quality and intensity from either of its constituents, but not in the frequency of its recurrence; and, therefore, the ear will judge of it as of a single note of intermediate quality.

But when two notes not in unison are sounded at once, the ear distinctly perceives both, and (at least with practice, and some ears more readily than others) can separate them, in idea, and attend to one without the other. But besides this, it receives an impression from them jointly, which it does not acquire when sounded singly, even in close succession, an impression of concord, or dissonance, as the case may be; and is irresistibly led to regard some combinations as peculiarly agreeable and satisfactory, and others as harsh and grating. Now it is invariably found that the former are those, and those only, in which the vibrations of the individual notes are in some very simple numerical proportion to each other, as 1 to 2, 1 to 3, 1 to 4, 2 to 3, &c., and that the concord is more satisfactory and more pleasing, the lower the terms of the proportion are, and the less they differ from each other. While, on the other hand, such notes as vibrate in times bearing no simple numerical ratio to each other, or in which the times of the ratio are considerable, as 8 : 15, for example, when heard together produce a sense of discord, and are extremely unpleasant. This simple remark is the natural foundation of all harmony.

Next to a unison, in which the vibrations of the two notes are in the ratio of 1 : 1, the most satisfactory concord is the octave, where the vibrations are as 1 : 2, or one note performs two vibrations to each single one of the other. The octave approaches in its character to a unison, and indeed two notes so related when played together can hardly be separated in idea; and when singly, appear rather as the same note differently modified, than as independent Sounds. The reason of this will be evident on inspecting fig. 29, where the dots in the upper line represent the periodically recurring impulses on the ear produced by the vibrations of the acuter note, while those in the lower represent the same impulses as produced by those of the graver; as the ear receives these all in the order they are placed, it will be the same thing as if they were produced by two Sounds both of the graver pitch, but one of a different intensity and quality from the other; the one having its impulses (represented by \( \cdots \)) the sum of two separate impulses of the octave Sounds; the other consisting of the alternate impulses (\( \cdots \)) of the acuter only.

In like manner the octave of the octave, or the fifteenth, as it is called in Music, which consists of notes whose
vibrations are as 1 : 4, is a very agreeable and perfect concord; as are, indeed, all the scale of octaves 1 : 8, 1 : 16, &c. they all partake of the peculiar character of the octave, a sense of perfect adjustment or identity.

The next in order is the combinations 1 : 3, where the vibrations of the graver note are triated by those of the acuter, as in fig. 30, which gives a concord called the twelfth, a very agreeable one. In this, if we substitute for the note 1 its octave 2, we shall have the concord whose vibrations are in the ratio of 2 : 3; or, as we shall call it for brevity, the concord 2 : 3, whose pulsations are represented in fig. 31. This concord is termed the fifth, and is a remarkably perfect and agreeable one, even more so than the twelfth, which although simpler in a numerical estimate, yet from the greater interval between its component notes allows them to be more readily distinguished, while the notes of the fifth blend much more perfectly.

If, instead of substituting for 1 its octave 2, we substitute its double octave 4, we get the concord 4 : 3, or the fourth, which may be regarded as a sort of complement of the fifth, and is also very agreeable.

The concords 1 : 5, 2 : 5, and 4 : 5, especially the latter, in which the tones approach pretty near to each other, are all remarkably agreeable. The last is called a major third, and the two former are regarded rather as varieties of it than as independent concords. The concord 8 : 5 (which is its complement in the same sense, as 4 : 3 the fourth is to 2 : 3 the fifth) is called the minor sixth, and is almost equally agreeable with the major third, to which it is related.

The concord 3 : 5 is called the major sixth, and, as well as its complement 6 : 5, or the minor third, though pleasing, is decidedly less satisfactory than the foregoing; and, as we see by casting our eyes on the figure, the periods of recurrence of their combined pulses in the same order is longer and more complex.

Higher primes than 5 enter into no harmonic ratios. Such combinations, for instance, as 1 : 7, 5 : 7, or 6 : 7, are altogether discordant. The same may be said of the more complicated combinations of the lower primes 1, 2, 3, 5. The ear will not endure them, and cannot rest upon them. When sounded, a sense of craving for a change is produced, and this is not satisfied but by changing one or both of the notes so as to fall as easily as the case will permit into some one of the concords above enumerated. This is called the resolution of a discord; and such is the constitution of our minds in this respect, that a concord agreeable in itself is rendered doubly so by being thus approached through a discord. For example, let us take the ratio 5 : 9, which is called a flat seventh, a combination decidedly discordant. If we multiply the terms of this ratio by 5, we get 25 : 45. A small change in one of the notes will reduce this to 27 : 45, or 3 : 5, a major sixth—an agreeable concord. Now this will be done, if, retaining the lower note 5 or 25, we change the upper from 45 to 45 x 3/4; that is to say, to a note whose vibrations are to its own as 25 : 27. This ratio corresponds to a musical interval called a semitone. Hence the discord in question will be satisfactorily resolved by holding on its lower note, and making its upper one descend a semitone.

On the proper alternation of concords and discords the whole of musical composition depends, but though the principle above stated must be satisfied in the resolution of every discord, there are other rules to be attended to by which our choice is limited to some modes rather than others; for example, in the foregoing instance it is the upper note which must descend a semitone. The ascent of the lower by the same interval, which would equally change the ratio as above indicated, would offend against other precepts with which we have here nothing to do.

The interval, as it is called in Music, between the two notes of which any simple concord or discord consists, depends not on the absolute number of vibrations which either makes in a given time, but on their relative proportion. For it is no matter how slowly, or how rapidly, the vibrations take place, provided the order in which their impulses reach the ear be the same. Hence, if the vibrations 4 and 5 produce on the ear the agreeable effect of a major third; two notes, each an octave higher, or having their vibrations respectively 8 and 10; or in general any two having their vibrations in this ratio, will produce the same effect. This is a matter of experience, but the inspection of the figures representing the order of succession of the individual vibrations enables us to understand its reason.

If we take any note for a fundamental Sound, and tune a string or a pipe so as to vibrate with the degree of rapidity corresponding to that Sound, and represent by unity the number of vibrations it makes per second; and if we also tune other strings to make in the same time respectively the numbers of vibrations represented by

\[
\begin{align*}
\frac{5}{4},& \quad \frac{3}{2},& \quad \frac{5}{3},& \quad 2; \quad \text{and then sound all these strings in succession, beginning with the fundamental note,} \\
\end{align*}
\]

we shall perceive that two of the sequences, the first and last, are much wider than the rest, and would admit the interpolation of a note between each. But it is no longer possible to choose for these interpolated notes such as will make concordant intervals with any of the rest, or their octaves. But in order to obtain as many concords as possible in the scale, so as to produce the most harmonious music, they are made to harmonize with that note which bears the nearest relation to the fundamental one, (for its octave is regarded as a mere repetition of itself) i.e. the fifth. The vibrations of a note a fifth higher than the fifth are represented by

\[
\left(\frac{3}{2}\right)^2 \times \frac{3}{4}; \quad \text{and as this is greater than 2, it lies beyond the octave. We must, therefore, tune our interpolated string an octave lower, or to the vibration } \frac{9}{8}; \quad \text{and thus we get the second. Again, if we tune another to The second.} \\
\]

the vibration \(\frac{15}{8}\), or \(\frac{5}{4} \times \frac{3}{2}\), it will form, with the fifth of the fundamental note \(\left(\frac{3}{2}\right)^2\), a major third—the next most harmonious interval on the scale. The note thus interpolated is the seventh.
The interpolation scale, with the vibrations of its respective notes, will stand thus:

<table>
<thead>
<tr>
<th>Signs</th>
<th>(1), (2), (3), (4), (5), (6), (7), (8).</th>
</tr>
</thead>
<tbody>
<tr>
<td>Names of intervals</td>
<td>1st.</td>
</tr>
<tr>
<td>Ratios of vibration</td>
<td>1</td>
</tr>
</tbody>
</table>

or multiplying all by 24, to avoid fractions, 24, 27, 30, 32, 36, 40, 45, 48.

This is called the natural, or diatonic scale; when all its notes are sounded in succession, whether upwards or downwards, the effect is universally acknowledged to be pleasing. The ear rests with perfect satisfaction on the fundamental note, and the intervals succeed each other gracefully, with sufficient variety to avoid monotony. Accordingly all ages and nations have agreed in adopting this scale as the foundation of their music.

This scale consists of seven distinct notes, for the eighth being the octave of the first is regarded as a mere repetition of it. And if we add to it on both sides the octaves of all its tones above and below, and again the octaves of these, and so on, we may continue it indefinitely upwards and downwards. Not that the ear will follow these additional tones, to an unlimited extent. When the vibrations are so fast as to be heard about 16 per second, the ear loses the impression of a continued sound; and perceives, first, a fluttering noise, then a quick rattle, then a succession of distinct sounds capable of being counted. On the other hand, when the frequency of the vibrations exceeds a certain limit all sense of pitch is lost; a shrill squeak, or shrill, only is heard; and, what is very remarkable, many individuals, otherwise no way inclined to deafness, are altogether insensible to very acute sounds, even such as painfully affect others. This singular observation is, due to Dr. Wollaston. (See his paper on sounds inaudible to certain ears, Phil. Trans. 1820.) Nothing can be more surprising than to see two persons, neither of them deaf, the one complaining of the penetrating shrillness of a sound, while the other maintains there is no sound at all. Thus while one person mentioned by Dr. Wollaston could but just hear a note four octaves above the middle E of the piano-forte, others have a distinct perception of sounds full two octaves higher. The chirp of the sparrow is about the former limit; the cry of the bat about one octave above it; and that of some insects, probably, more than another octave. Dr. Wollaston's sense of hearing terminated at six octaves. The whole range of human hearing comprised between the lowest notes of the organ and the highest known cry of insects, seems to include about nine octaves.

It is probable, however, that it is not the frequency of the vibrations which renders shrill sounds inaudible. There is no reason why an impulse, if strong enough single, should affect the ear, should lose its effect if repeated many thousand times in a second. On the contrary such repetition would render the noise intolerable. But this is not the case with musical sounds; their individual impulses would, probably, be quite inaudible singly, and only impress by repetition. Now, as vibrating bodies have only a certain degree of elasticity, extreme swiftness of vibration can only take place when their dimensions are very minute, and consequently the excursions of their molecules from rest, and their absolute velocities, excessively minute also. Thus in proportion as sounds are more acute their intensity (which depends wholly on the extent and force of their vibrations) diminishes. No doubt, if by any mechanism a hundred thousand hard blows per second could be regularly struck by a hammer on an anvil, at precisely equal intervals, they would be heard as a most deafening shriek; but in natural sounds the impulses lose in intensity more than they gain in number, and thus the sound grows feebler and feebler till it ceases to be heard.

"As there is nothing in the nature of the atmosphere (remarks Dr. Wollaston) to prevent the existence of vibrations incomparably more frequent than any of which we are conscious, we may imagine that animals like the Gryllus, whose powers appear to commence nearly where our ears terminate, may have the faculty of hearing still sharper sounds, which we do not know to exist; and that there may be other insects hearing nothing in common with us, but endowed with a power of exciting, and a sense which perceives vibrations of the same nature indeed as those which constitute our ordinary sounds, but so remote that the animals who perceive them may be said to possess another sense agreeing with our own solely in the medium by which it is excited." The same may, no doubt, be true of aquatic animals. The shrimp and the white may have no Sound in common.

By the aid of the ascending and descending series of sounds in the natural scale thus obtained, pieces of music perfectly pleasing, both in point of harmony and melody, may be played; and they are said to be in the key of that which is assumed as the fundamental note of the scale, or whose vibrations are represented by 1. If such a piece be analyzed, it will be found to consist entirely, or chiefly, of triple and quadruple combinations, or chords, such as the following:

1. The common, or fundamental chord, or chord of the tonic, or the 1st, 8d, and 5th, (1, 3, 5,) or the 8d, 5th, and octave (3, 5, 8) sounded together. This is the most harmonious and satisfactory chord in music, and when sounded the ear is satisfied, and requires nothing further. It is, therefore, more frequently heard than any other; and its continual recurrence in a piece of music determines the key it is played in.

2. The chord of the dominant. The fifth of the key-note is called, by reason of its near relation to the fundamental note, the dominant. The chord in question is the common chord of the dominant, or the notes (2, 5, and 7) sounded together.

3. The chord of the subdominant, or the note 4, consisting of the notes 1, 4, 6, being the common chord of 4 as a fundamental note.

4. The false close, or the combination (1, 3, 6) or (3, 6, 8) which is, in fact, the common chord of the note 6, only with a minor third (6, 8) instead of a major. The term false close arises from this, that a piece of music, frequently before its final termination, (which is always on the fundamental chord,) comes to a momentary close.
on this chord, which pleases only for a short time, but requires the strain to be taken up again and closed as usual to give full satisfaction.

5. The discord of the 7th, or (3, 4, 5, 7.) It consists of four notes; and, in fact, the common chord of the dominant, with the note immediately below it, or the seventh in order above it. The interval, however, between the notes (4) and (5), or between (5) and the octave of (4) next above it, is represented by the ratio

\[
\frac{2 \times 4}{3} = \frac{3}{9} = 16.
\]

or (taking 24 as the number of vibrations in a unit of time corresponding to the note (1)) = \(42\frac{2}{9}\). This interval, then, is less than the seventh of the diatonic scale, and is about half-way intermediate between the sixth and seventh of that scale. It is, therefore, called the flat seventh. (See Arts. 231 and 232.) This discord resolves itself into the chord (3, 5, 8;) and unless that combination, or one equivalent to it, follows, the ear is not satisfied. The notes (4) and (5) are the essential ones of this discord, and the others are regarded as accompaniments. If played together, the ear requires that in the next chord 4 should descend or be succeeded by (3) while the note 7 is required to rise or be succeeded by (8).

With these chords and a few others, such as the chord of the 9th, whose essential notes are 1 and 2, or 1 and 9, may a great variety of music be played, but it would be found monotonous. The ear requires, in a long piece, a variety of key. The fundamental note occurs so often that it seems to pervade the whole of the composition, and must therefore be changed. But this change of key, which is called modulation, is not possible without introducing other notes than those already enumerated. It is true the chord (2, 5, 7) is the perfect fundamental chord in the key of (5;) but the other chords in that key corresponding to those already enumerated cannot be formed, with the exception of its sub-dominant, which is, in fact, the common chord of 1. Take, for instance, its dominant. This would be formed, if it could be formed at all, of all the notes (2, 4, 6) or (4, 6, 9.) But if we come to analyze the intervals of these notes, we find that

\[
\begin{align*}
&\frac{4}{2} = \frac{32}{27}; \quad \frac{6}{2} = \frac{40}{27}.
\end{align*}
\]

Now these differ from the ratios \(\frac{5}{4}\) and \(\frac{3}{2}\) which exist between the notes (3, 1) and (5, 1) of the perfect common chord. Consequently, if we would play equally well in tune in the key (5) we must introduce these new ratios; and, in fact, we ought to have for that purpose notes corresponding to all the ratios

\[
\begin{align*}
&\frac{3}{2} \times \frac{9}{8}, \quad \frac{3}{2} \times \frac{5}{4}, \quad \frac{3}{2} \times \frac{4}{3}, \quad \text{&c.}
\end{align*}
\]

and similarly for every other key we might choose to play in. But this would require an enormous number of notes, and would render the generality of musical instruments too complicated. It becomes necessary, then, to consider how the number may be reduced, and what are the fewest notes that will answer.

Let us take for example, as above, the dominant of the note (5.) The number of its vibrations is \(36 \times \frac{3}{5}\), or 54, the half of which (because it surpasses the octave of 1) is 27. This is correctly the number corresponding to (2.) Now, taking this for a key-note, the major third of (2) has \(27 \times \frac{5}{4} = 34 \frac{1}{4}\) for the number of its vibrations in a unit of time. Now in the scale as it stands we have 32 and 36, so that the note in question is almost just half-way between them, and must therefore be interpolated. It will stand between (4) and (5) on the scale, and is denoted in Music by the sign \(\sharp\) sharp, or \(\flat\) flat; thus it is written either as (4) sharp, (4)\(\sharp\), or as (5) flat, (5)\(\flat\). With regard to the fifth of the new fundamental note (2) its representative number is

\[
27 \times \frac{3}{2} = \frac{81}{2} = 40 \frac{1}{2}.
\]

This comes so near 40, that the ear hardly perceives the difference; and though a small error of one vibration in 80 is introduced by using the note (6) as the dominant of (2), yet it is not fatal to harmony; and there is no necessity for enumbering ourselves with new names of notes, and additional pipes or strings to our instruments for its sake. In practice these errors are modified and subdued by what is called temperament, of which this is the origin, and of which more presently.

The interval \(\frac{81}{80}\) being the difference of two notes, one of which is the octave of the perfect sixth of the fundamental note, and the other arises by reckoning upwards three perfect fifths from the same origin, is called a comma. The former note is represented by

\[
2 \times \frac{5}{3} = \frac{10}{3}, \quad \text{the latter by} \left(\frac{3}{2}\right)^3 = \frac{27}{8}, \quad \text{and} \quad \frac{27}{8} + \frac{10}{3} = \frac{81}{80}.
\]

In like manner, if we would choose any other note for the fundamental one, similar changes will be required,
and no two keys will agree in giving identically the same scale. All, however, will be nearly satisfied by the interpolation of a new note half-way between each of the larger intervals of the scale, thus

\[
\begin{array}{cccccccc}
1^\# & 2^\# & 4^\# & 5^\# & 6^\#
\end{array}
\]

and the scale so interpolated is called the chromatic scale.

Musicians have long been at issue on the most advantageous method of executing this interpolation. If, indeed, it were intended to give such a preference to the natural scale 1, 2, 3, 4, &c. as to make it perfect, to the sacrifice of all the other keys, there would be little difficulty, as a mere bisection of the intervals would, probably, answer every practical purpose: thus 1\# or 2\# might be represented by \( \sqrt{\frac{9}{8} \times \frac{5}{4}} \), and so on; but as in practice no preference is given to this particular key, (which is denoted in

Music by the letter C,) but, on the contrary, variety is purposely studied, it is found necessary to depart from the pure and perfect diatonic scale, even in tuning the natural notes; and to do so with the least offence to the ear is the object of a perfect system of temperament. If the ear absolutely required perfect concords there could be no music, or but a very limited and monotonous one. But this is not the case. Perfect harmony is never heard, and if heard would probably be little valued, except by the most refined ears; and it is this fortunate circumstance which renders musical composition, in the exquisite and complicated state in which it at present exists, possible.

In order to judge of the limits, however, to which the ear will bear a deviation from exact consonance of musical vibrations, we must first see what takes place when two notes nearly, but not quite, in unison or concord are sounded together. Conceive two strings exactly equal and similar, and equally drawn out from the straight line, to be let go at the same instant; and suppose one to make 100 vibrations per second, the other 101; let them be placed side by side, and at the same distance from the ear. Their first vibrations will conspire in producing a Sound-wave of double force, and the impression on the ear will be double. But at the 50th vibration one has gained half a vibration on the other, so that the motions of the particles of air, in virtue of the two coexistent waves emanating from either string, are now not in the same but in opposite directions; and the two waves being by supposition of equal intensity, they will instead of conspiring exactly destroy each other, and this will be very nearly the case for several vibrations on either side of the 50th. Consequently, in approaching the 50th vibration, the joint Sound will be enfeebled; there will be a moment of perfect silence, and then the Sound will again increase till the 100th; when the one string having gained a whole vibration on the other, the motions of the particles of air in the two waves will again completely conspire, and the Sound will attain its maximum. The effect on the ear will therefore be that of an intermitting Sound alternately loud and faint. These alternate reinforcements and subsidences of the Sound are called beats. The nearer the Sounds of the strings approach to exact unison, the longer is the interval between the beats. If we call \( n \) the number of vibrations in which one string gains or loses exactly one vibration on the other, and \( m \) the number of vibrations per second made by the quicker, \( \frac{n}{m} \) will be the interval between two consecutive beats. When the unison is complete, no beats are heard. On the other hand, when it is very defective they have the effect of a rattle of a very unpleasant kind. The complete destruction of the beats affords the best means of attaining by trial a perfect harmony.

Beats will likewise be heard when other concords, as fifths, are imperfectly adjusted. Suppose one string to make 201 vibrations, while the other makes 300; then, at and about the 100th of one, and the 150th of the other, the former will have gained half a vibration, and those vibrations of the one which fall exactly on those of the other, (see fig. 31,) being performed with contrary motions will destroy each other; those which fall intermediate only partially. The beats then will be heard, but with less distinctness than in the case of unisons.

This seems the proper place to notice an effect which takes place in perfect concords, and only in those which are very perfect, viz. the production of a grave Sound by the mere concurrence of two acute ones. If we examine the figure 212, which represents the succession of vibrations in a perfect fifth, we shall see that every third of the one coincides exactly with every second vibration of the other. These coincidences (so delicate is the ear) are remarked by it, and a Sound is heard, besides the two actually sounded, of a pitch determined only by the frequency of the precise coincidences; that is, in this case, a precise octave below the lowest tone of the concord.

In general, if one note makes \( m \) vibrations and the other \( n \), while another, of which they may both be regarded as harmonics, makes one, that one will be the resultant tone, provided \( m \) and \( n \) be prime to each other; so that the only difficulty in determining the resultant of two notes, is to determine of what they are both harmonics. This will be done by reducing \( m \) and \( n \), if fractions, to a common denominator \( \frac{m'}{N} \) and \( \frac{n'}{N} \); then, if \( m' \) and \( n' \) have no common factor, \( \frac{1}{N} \) will represent the fundamental tone. If, then, \( m \) and \( n \) be integers, and without any common factor, the resultant will be represented by 1.
Hence follows a very curious fact, viz. that if several strings, or pipes, be tuned exactly to be harmonics of one
of them, or to have their vibrations in the ratios 1, 2, 3, 4, 5, &c., then if they be all, or any number of them,
from the first onward, sounded together, there will be heard but one note, viz. the fundamental note. For they
are all harmonics of the first note; and, moreover, if we combine them all two and two, we shall find compa-
ratively but few which will give other resultants, so that these will be lost, as well as the individual Sounds of
the strings, all but the first in the united effect of all the resultant unit Sounds. But to produce this effect, the
strings, or pipes, must be very perfectly tuned to the strict harmonics. The effect can never take place by touching
the keys of a piano-forte corresponding to the harmonic notes, because they are always of necessity tempered.

To return to our temperament. If we count the semitones in the chromatic scale between (1) and (8) we
shall find the number of such intervals 12. If, then, we would have a scale exactly similar to itself in all parts,
and which should admit of our playing equally perfectly in every key, we have only to compute the values of
the fractions

\[ 1 = 2^0, 2^{\frac{1}{2}}, 2^{\frac{1}{3}}, 2^{\frac{1}{4}}, \ldots, 2^{\frac{7}{12}}, 2. \]

which may readily be done by logarithms, and we shall find the ratios of the vibrations which will give what
may be termed the scale of equal intervals.

If we examine the chromatic scale, and consider it as approximatively composed of equal, or nearly equal,
intervals called semitones, the following will be the number of semitones in each interval:

<table>
<thead>
<tr>
<th>In the semitone</th>
<th>In the major fifth or fifth</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>7</td>

<td>12</td>
</tr>
</tbody>
</table>

If then we reckon upwards from the note (1) by fifths, viz. from (1) to (5), from (5) to (9), (or, which comes to
the same, descending an octave, to (2)), from (2) to (6), from (6) to (10), that is to (10 − 7), or (3), and so on,
we shall find that after taking twelve such steps as these we shall have fallen upon every note in the scale, and
come back to the fundamental note or its octave. But, since no power of 2 is exactly the same with any power of
\( \frac{3}{2} \), it is evident that no series of steps by perfect fifths can ever bring us to any one of the octaves of the
fundamental note. Were the chromatic scale perfect, twelve fifths should exactly equal seven octaves, and three
major thirds should precisely make one octave. Neither of these, however, can be true of perfect fifths or thirds,
for \( \left( \frac{3}{2} \right)^7 = 129.74 \), and \( \left( \frac{5}{4} \right)^7 = 1.953 \), instead of 2. Thus, if we reckon upwards by perfect fifths, we surpass the octaves; if by thirds, we fall continually
below them. In this dilemma it has been proposed to diminish all the fifths equally, making a fifth instead of
\( \frac{3}{2} \), to be equal to \( 2^{\frac{1}{2}} \); and tuning regularly from the note (1) upwards by such fifths and from the notes
so tuned downwards by perfect octaves. This constitutes what has been called the system of equal temperament.

It is evident that in this system the notes will all of necessity be represented by powers of \( 2^{\frac{1}{12}} \); and that
therefore the scale resulting from this system is identical with that of equal intervals, or the iso-harmonic scale
described in the last article. Theoretically speaking, it is the simplest that could be devised; and, practically,
(though stolid ears may profess to be offended by it,) it must produce no contemptible harmony. It has, how-
ever, one radical fault, it gives all the keys one character. In any other system of temperament some intervals, though
of the same denomination, must differ by a minute quantity from each other; and this difference falling in one
part of the scale in one key, in another in another, gives a peculiarity of quality to each key, which the ear seizes
and enjoys extremely. This fact, in which, we believe, all practical musicians will agree, is alone sufficient to
prove, that perfect harmony is not necessary for the full enjoyment of music. Most practical musicians seem
to have no fixed or certain system of temperament; at least very few of them when questioned appear to have
any distinct ideas on the subject.

It is a mistake to suppose, as some have done, that temperament applies only to instruments with keys
and fixed tones. Singers, violin players, and all others who can pass through every gradation of tone, must all
temper, or they could never keep in tune with each other or with themselves. Any one who should keep on
ascending by perfect fifths, and descending by octaves or thirds, would soon find his fundamental pitch grow
sharper and sharper till he could at last neither sing nor play; and two violin players accompanying each other,
and arriving at the same note by different intervals, would find a continual want of agreement.

Musical intervals may be numerically represented by the logarithms of the fractions expressing the ratios of
the vibrations of the notes between which the intervals are comprised; for the interval depending only on this
ratio, and the sum of any two intervals corresponding to the product of their respective ratios, the logarithms
of the latter are the proper measures of the magnitudes of the former. Thus an octave corresponds to a ratio
of 2 : 1 of the vibrations of its extreme Sounds; two octaves to the ratio 4 : 1 or 2^2 : 1; three to 8 : 1 or 2^3 : 1,
and so on; so that log. 2, log. 2, log. 2, log. 2, &c. or any numbers in that proportion, are proper numerical
representatives of these intervals. The intervals of the diatonic scale will, therefore, be represented logarithmically
as follows.
The approximate values of the intervals being all true to a 500th of a tone, an interval far too minute for the nicest ear to appreciate, may be used in all musical calculations where high multiples of them are not taken.

It will be observed that the diatonic scale so constructed, consists of three different intervals between consecutive notes. Thus, the interval from (1) to (2) is 51 parts of a scale on which the octave measures 301. This interval is called a major tone, \( \tau \), and the same interval occurs again between (4) and (5), and between (6) and (7), as will appear by referring to the column of differences. Again, the interval from (2) to (3) is 46 such parts only, and this, which occurs again between (5) and (6), is called a minor tone, \( \sigma \). Lastly, the interval between (3) and (4) and between (7) and (8) is 28 such parts, and is called (but more improperly) a semitone, \( \delta \), being in fact much more than the half of either a major or a minor tone. The term limma, which has been used by some authors, is much preferable.

This is the origin of what is called the enharmonic diesis, and of the distinction existing between the sharp of one note and the flat of that next above it; a distinction essential to perfect harmony, but which cannot be maintained in practice, except in organs and complicated instruments, which admit a great variety of keys and pedals, or in stringed instruments or the voice, where all gradations of tone can be produced, and then only when used without a fixed accompaniment. To explain this distinction, suppose, in the course of a piece of music, commenced in the key of (1), we should modulate, as it is called, into the key of (4), its sub-dominant; that is, change our key, and adopt a new scale, having (4) for its fundamental tone. To make the new scale perfect, the intervals should be the same, and succeed each other in the same order as in the original key (1). That is, setting out from (4) we ought to have for our sequence of intervalstttt \( \tau \) tt, \( \sigma \) \( \delta \). Now, this sequence does not take place in the unaltered scale of (1), when we set out from any note but (1), and if we prolong it backward to (4), they will stand thus,

\[
\begin{array}{cccccccc}
(4) & (5) & (6) & (7) & (1) & (2) & (3) & (4) \\
\tau & \sigma & \delta & \sigma & \tau & \sigma & \delta & \sigma \\
\end{array}
\]

whereas they ought to stand thus,

\[
\begin{array}{cccccccc}
(4) & (5) & (6) & (7) & (1) & (2) & (3) & (4) & \&c. \\
\tau & \sigma & \delta & \sigma & \tau & \sigma & \delta & \sigma & \&c. \\
\end{array}
\]

The first two intervals are the same in both. The two next will also agree if we flatten the note (7), so as to make \( (7)\) \(-\& (6) = \delta \) and \( (1) - (7) = \tau \), which leaves the interval \( (1) - (6) \) the same as before, viz. \( \tau + \theta \), or a perfect minor third. The quantity by which (7) must be flattened for this purpose, or \( (7) - (7) = \delta \), is equal to \( \tau - \theta = 51 - 28 = 23 \), and this is the amount by which in this case a note differs from its flat. As to the remaining three intervals, the difference between \( \tau \) and \( \theta \) being small, amounting only to 5, (which is the logarithmic representative of the ratio \( \frac{51}{50} \) or a comma,) the sequence \( \tau \theta \delta \) is hardly distinguishable from \( \tau \theta \), and if the note (2) be tempered flat by an interval \( \tau - \theta = \frac{\tau}{2} \), or half a comma, this sequence will in both cases be the same, and our two scales of (1) and (4) will be rendered as perfect as the nature of the case will permit, by the interpolation of only one new note. But, on the other hand, suppose we would modulate into the key (7). In this case the scales will stand thus:

\[
\begin{array}{cccccccc}
(7) & (1) & (2) & (3) & (4) & (5) & (6) & (7) \\
\theta & \tau & \sigma & \delta & \tau & \sigma & \delta & \tau \\
\end{array}
\]

This change will require the interpolation of no less than five new notes; the notes (7) and (3) being the only ones that remain unchanged. But to confine ourselves to the change from (6) to (6)\( \# \), we have \( (7) - (6) = \tau \) and \( (7) - (6)\# = \delta \). Consequently \( (6)\# - (6) = \tau - \theta = 23 = (7) - (6)\), as before determined. But since the whole interval between (6) and (7), or \( (7) - (6) \), which is \( \tau = 51 \), is more than double of this quantity, the flattened note (7)\# will lie nearer to the higher note (7), and the sharpened one (6)\# nearer to the lower one (6) than a note arbitrarily interpolated half way between them, to answer both purposes approximately, would do, and thus a gap, or, as it is termed, a diesis, would be left between (6)\# and (7)\#.

The diesis in this case amounts only to a comma \( (= 5) \), or the tenth part of a major tone, \( \tau \) \( (= 51) \), in
other cases it would be greater. But in all cases the interval between any note and its sharp is considered to be equal to that between the same note and its flat. Assuming this as a principle, a variety of systems of temperament have been devised for producing the best harmony by a system of 21 fixed Sounds, viz. each note of the seven in the scale, with its sharp and flat, (regarded as different).

The first and most celebrated is that of Huygens. He supposes the octave divided into 31 equal parts. Of these a whole tone, whether \( r \) or \( 4 \), (for he makes all his tones equal,) consists of 5, a limma (or an approximate, or tempered value of \( \theta \) = 3, the interval between each note and its sharp or flat = 2, and the diesis = 1. This gives the following scale of intervals:

\[
\begin{align*}
(1) & \quad (2) \quad (2) \quad (3) \quad (4) \quad (4) \quad (5) \quad (5) \quad (6) \quad (6) \quad (7) \quad (7) \\
2 & \quad 2 & \quad 2 & \quad 2 & \quad 2 & \quad 2 & \quad 1 & \quad 1 & \quad 1 & \quad 1 & \quad 1 & \quad 1 \\
\end{align*}
\]

and by picking our notes among these, we may obtain a scale approaching extremely near to a perfect diatonic scale, whichever we may choose for our key-note.

Instead of dividing the octave into 31 equal parts, Dr. Smith proposes to divide it into 50, of which 8 shall constitute a tempered tone, and 5 a limma, or tempered value of \( \theta \), and the interval between each note, and its sharp or flat, shall = 3. This will give the sequence of intervals as below.

\[
\begin{align*}
(1) & \quad (2) \quad (2) \quad (3) \quad (3) \quad (4) \quad (4) \quad (5) \quad (5) \quad (6) \quad (6) \\
3 & \quad 2 & \quad 2 & \quad 2 & \quad 2 & \quad 2 & \quad 2 & \quad 2 & \quad 2 & \quad 2 & \quad 2 \\
\end{align*}
\]

This scale, he observes, approximates insensibly near to what he terms the system of equal harmony, a system, in our opinion, uselessly refined, and founded on principles for which the reader is therefore referred to his Work on Harmonics. (Cambridge, 1749.)

Either system, no doubt, will give very good harmony; but as on the piano-forte only 12 keys can be admitted, and as this instrument is now become an essential element in all concerts, and indeed the chief of all, a temperament must be devised which will accommodate itself to that condition. Of the division of the octave into 21 equal parts we have already spoken. Its fifths are all too flat, and its major thirds all too sharp; and the harmony is equally imperfect in all keys. But it has generally been considered preferable to preserve some keys more free from error, partly for variety, and partly because keys with five or six sharps or flats are comparatively little used, so that these may safely be left more imperfect, (which is called by some throwing the wolf into these keys.)

Dr. Young recommends as a good practical temperament to tune downwards six perfect fifths from the fundamental note, and upwards six fifths equally imperfect among themselves. Or, as he observes is more easily executed, to make the third and fifth of the natural scale perfectly correct, to interpose between their octaves the second and sixth, so as to make three fifths equally tempered, and to descend from the key-note by seven perfect fifths, which will complete the scale. (Lectures on Natural Philosophy, vol. i. lect. 33.)

The system called by Dr. Smith that of mean tones, or the vulgar temperament, supposes the octave divided into five equal tones and two equal limmas, succeeding each other in the order \( a a \ a a a 3 a a a a a 3 \) instead of \( t t 6 t t 9 t t 6 t t 9 \) as in the diatonic scale, and such that the third shall be perfect and the fifth tempered a little flat. These conditions suffice to determine \( a \) and \( \beta \), for we have

\[
\begin{align*}
5 a + 2 \beta & = 1 \text{ octave} = 3 r + 2 t + 2 \theta, \\
2 a & = 1 \text{ third} = \tau + \frac{t}{2}, \\
\end{align*}
\]

and consequently

\[
\begin{align*}
a & = \frac{\tau + t}{2}; \\
\beta & = \frac{\theta + \tau - t}{4};
\end{align*}
\]

or, (since \( \tau + t = 00961 \), and \( \tau - t = 00540 \)) \( a = 04845 \) and \( \beta = 02938 \). And since the interval from the first to the fifth of the scale in this system is \( 3 a + \beta = 2 \tau + t + \theta = \frac{\tau - t}{4} \), it appears that this is flatter than a perfect fifth by the quantity \( \frac{1}{4} (\tau - t) \), or a quarter of a comma. In this system the sharps and flats may be inserted by bisecting the larger intervals.

Mr. Logier has lately, in a Work of great practical utility and very extensive circulation among musical students, endeavoured to place the interpolation of the intermediate notes between those of the natural scale on a priori grounds, by assuming the flat seventh \( (7) b \) as the seventh harmonic of the fundamental note \( (1) \), that is to say, the note produced by subdividing into seven equal parts the length of a string whose fundamental tone is \( (1) \), or at least one of the octaves of that note. There is something ingenious in this idea. In the first place it completes the series of the 10 first harmonics or notes, whose vibrations are multiples by \( 1, 2, 3, 4, 5, 6, 7, 8, 9, 10 \), of those of the fundamental tone, which would thus be, in their order, \( (1), (1), (5), (1), (3), (5), (7) b, (1), (2), (3) \), or octaves of these, and thus derives five out of the twelve notes of the octave from one uniform principle. Again, it gives something like a plausible reason for the prominent importance of the chord of the flat seventh (see Art. 230.) in music. This chord, in fact, which, if we take \( (1) \) for a fundamental note, consists of the notes \( (1), (3), (5), (7) b \), becomes in this point of view a perfect concord, consisting entirely of harmonics of \( (1) \), and its pulses will succeed each other on the ear in a cycle comprising four vibrations of the fundamental tone \( (1) \), five of the next \( (3) \), six of the next \( (5) \), and seven of the essential note \( (7) b \), as represented in fig. 35. The succession of pulses in the common chord is also represented in the same figure, and its regularity and pleasing variety, even to the eye, explains its agreeable effect on the ear. It is for musicians to say, whether they can make up their minds to regard the discord of the seventh in the light of a perfect concord or no. There is certainly nothing at all discordant in the vulgar sense of the word, i.e. unpleasant in its Sound, and so far it may be regarded as at least "discordia concors," but so far from possessing the essential character of a concord, that the ear is satisfied in hearing it, and expects and desires no more; there is no discord which calls so urgently for resolution. But, although it be true, that the seventh harmonic of the fundamental note lies between its natural

8 5 2
sound, seventh and its octave, (it must lie somewhere,) yet, in fact, it is materially too flat a sound to be used as a good flat seventh (7)#. Its actual sound coincides much more nearly with the (6)# of Huygens and Smith; and this defect, though it might be tolerated in quick compositions, and especially in piano-forte music where the notes are not held on, but degrade rapidly in intensity, would be at once felt in a slow piece on the organ. It is still worse if we derive from it, by a similar process, the intermediate note between (5) and (6), or (6)b, and thence again (5)b, and complete the chromatic scale of twelve notes by deriving (3)b according to the same principle from (4), and (2)b from (3)b, according to Mr. Logier's system as laid down by him.* The (2)b thus derived would hardly be distinguished from (1) natural, or the (5)b from (4) natural, as the following scale will show, where the fractions represent the ratios of the vibrations of the notes above them to those of the fundamental tone (1).

(1), (2)b, (2), (3)b, (3), (4), (4), (5)b, (5), (6)b, (6), (7)b, (7), (8).

Sevenths, then, tuned on Mr. Logier's principle, will require a much more violent temperament than either fifths or thirds, either of which might be used as a means of introducing the intermediate notes; and the system must in consequence be abandoned, as must every system which professes to render musical arithmetic anything more than a matter of convention and approximation.

We annex here, for comparison, a Table of the logarithmic values of the intervals from (1) the fundamental tone to all the other notes in the several scales of 21, or of 12 notes, according to the different systems and principles above mentioned.

The numbers marked thus (*) are what would be given by pushing the application of Mr. Logier's principle through the whole scale, and are inserted only to show the rapid progressive effect of flattening by a series of untempered harmonic sevenths.

</table>

* System of the Science of Music and Practical Composition, p. 50. We should, however, remark that the powerful descending tendency of the chord of the flat seventh is necessarily much augmented by tuning the (7)b too flat.
The last column contains a scale derived by taking the mean of all those in the other columns which differ in the principle of their origin, (excepting those in the tenth column, for obvious reasons.) It approaches through its whole extent so near to the system of mean tones in col. 6, as to be quite indistinguishable from it; the deviation in no case exceeding a single unit, or a fifty-fifth part of a tone. This system, then, though the most artificial, is probably as good as any which the nature of music admits, holding a sort of mean between the advantages and defects of all the rest. Consult on Temperament and on Musical Scales, Salinas, de Musici, (1577;) Zarlino, Dimostrazione Armoniche; and Institution Armoniche; Deschales, Cursus Mathematicus de Progressu Musico; Sauveur, Mem. Acad. Par. 1700; Smith, Harmonics; Pepusch, Phil. Trans. Lond. 1746; Farey, Phil. Mag. xxviii.; Young’s Lectures and his Catalogue of Authors in vol. ii.

For one purpose, that of explaining to beginners the notes, intervals, and rules of music, the system of equal temperament, which supposes the octave divided into 12 equal parts, which in this system only are really semi-tones, has the advantage of avoiding all discussions and puzzling explanations on the nature of harmony, as it makes all intervals which are called by the same name strictly alike. Regarding the octave as consisting of 12 semi-tones, and designating its notes in succession, beginning with the fundamental note, by 0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, &c. it will not be amiss if we write down in this notation the principal scales, chords, &c. which occur in music.

These are all the chords, consisting of four different notes (or tetrachords) in common use in music. As to pentachords, such as what have been called the major and minor ninth, and compound sharp sixth, whose notes are respectively 0, 2, 4, 7, 10; 0, 1, 4, 7, 10, and 0, 4, 6, 7, 10, (Logier, Ex. 212, 158, and 292) they are, in fact, only chords of the seventh (0, 4, 7, 10) with a fifth note violently forced in; the effect being to distract the ear by a harsh discord, out of which it is but too glad to escape, to be very nice about its resolution. In like manner the pentachord 0, 2, 5, 7, 11, or the chord of the eleventh, is the chord of the seventh accompanied by the sub-dominant of its radical note, and thus anticipating its resolution; as is easily seen by adding 5 to each of its component numbers, when it becomes 5, 7, 10, 12, 16, or, which is the same thing, 5, 7, 10, 0, 4, or 0, 4, 5, 7, 10 (since the addition or subtraction of 12 semi-tones, or an octave, does not alter the character of the sounds;) and in the same way may other pentachords be formed, as 0, 3, 4, 7, 10; 0, 4, 7, 8, 10; (Ex. Clementi's Sonatas, Op. 22. son. 1. bars 68, 69.) 0, 4, 7, 9, 10. As to such combinations as the hexachord 0, 2, 5, 7, 9, 11, or “the chord of the 13th,” (Logier, Ex. 273.) in which only one note of the whole natural scale (4) is wanting, they are abominable jangles, as offensive to a simple and unvitiated ear, as the mixed flavors and haut-gouts of the palled epicure are to an appetite not spoiled by artificial excitement.

The reader who would try these chords on the piano-forte, has only to place his finger on any black or white key as a radical note, and also on the keys distant from that one by the numbers of semi-tones (reckoning upwards) marked in the designation of the chord as above. Thus to produce the chord of the sharp sixth having Db for its radical note. The note 0 corresponds to Db, 2 to Eb, 6 to Gb, and 8 to Ab, which are, therefore, the notes to be struck together, (to whatever octaves of the instrument they may be afterwards transferred, as the rules of composition may dictate,) and so of others.

Any of these chords is said to be inverted, when, instead of taking 0 for the initial note, we regard any other of its component Sounds as such. As to the system of notation here employed, (which we will term the system of Chromatic numbers to distinguish it from those in Art. 234, to which the term Diatonic numbers may be applied,) nothing is easier than to represent the inversions of a chord. Take, for instance, the major concord, 0, 4, 7. The addition of 12 (the octave of 0) does not change the chord; so that it may be written thus, 0, 4, 7, 12, or, leaving out the first note, and adopting 4 for the initial note, 4, 7, 12. If, now, we choose to regard the note 4 as an initial one, and count upwards from it, we have only to subtract 4 from each of these numbers, and we get 0, 3, 6 for a first inversion. Appending 12 to this again, and rejecting the initial 0, it becomes 3, 8, 12, from each of which numbers subtracting 3 we get the second inversion, 0, 5, 9. If we repeat the same process on this we fall back on the original combination. Thus we see that this chord admits of only two inversions. Again, suppose we would find the inversions of the chord of the added sixth, or 0, 4, 7, 9. The process will stand thus:

* 8, 11, 12, according to Logier and others. 

For, thenotestobe strucktogether, (towhateveroctavesoftheinstrumenttheymaybe afterwardstransferred, as therulesofcompositionmaydictate,)and sofothers.
Thus we see that this chord admits of three distinct inversions. In general, a triad admits of three forms, or one original, and two inversions, a tetrachord of 4, a pentachord of 5, and so on; though it may happen, as in the case of the triad 0, 4, 8, or the tetrachords 0, 2, 6, 8, and 0, 3, 6, 9, that some or all of the inversions reproduce the original chord.

260. If we go through the same process for other triads and tetrachords, we get their inversions as follows:

261. **Remarks.**

These chords, thus figured and arranged, afford room for some remarks of importance. In the first place we observe that they all, with the exception of the triad 0, 4, 8, and the tetrachords 0, 2, 6, 8, and 0, 3, 6, 9, contain a major or minor concord, 0, 4, 7, or 0, 3, 7. This seems necessary to give any chord a decided character; for the excepted cases above specified have all an equivocal effect and leave the ear in suspense whether the modulation will lead. For with respect to the chords 0, 4, 8, and 0, 3, 6, 9, they divide the octave equally, the one into three major thirds, the other into four minor, as is immediately seen if we write them thus, 0, 4, 8, 12, and 0, 3, 6, 9, 12. In consequence, all their inversions are similar to the original chords, and they are equally related, the former to three, and the latter to four different keys, and may lead into either of them, according as a
The transitions thus produced by means of the tetrachord $0, 3, 6, 9$, are peculiarly graceful. It is otherwise with the equivocal triad $0, 4, 8$, which is essentially harsh and unpleasant, (in spite of the perfect harmony which, if we were to leave out the octave and tune its thirds perfect, its members must produce with each other, since it would be in that case an absolute concord.) Whether this chord, or that which we have called the triple fifth, has ever been or can be used in music, we know not, though perhaps, properly handled, it might become a source of modulation; which, however, is for practical musicians to consider.

The chord of the sharp sixth $0, 2, 6, 8$ is also equivocal, arising from a double aliquot division of the octave, and the two last of its inverted forms being therefore merely repetitions of the two first. Like the diminished seventh, then, it holds the ear in suspense, till the addition of another note decides the course the modulation shall take, and the chord so arising is the compound sharp sixth. (See the inversions of this latter chord compared with those of the former.)

In like manner the major ninth contains both a ninth and a seventh, though not the other accompaniments of the seventh. The tetrachord which (for want of another name, we have called the minor added sixth, from its being a minor concord with a sixth added) is related to this compound ninth in the same way as has just been pointed out with respect to the chords of the diminished seventh and minor ninth, and to those of the sharp sixth and compound sharp sixth; the character of the tetrachord, which is undecided of itself, and admits of more than one resolution, being determined by the note added in the pentachord so as to form a dominant seventh with some one or other of its other members.

The chord of the eleventh offers room for a remark analogous to what we have before observed (Art. 262.) respecting the equivocal triad $0, 4, 8$. It contains within itself three fifths and a major third; as is obvious if we take its fifth form $0, 2, 6, 7, 9$, and transfer the notes $2, 6$, and $9$ to the next octave above, when it will become $0, 14, 18, 21$, or $0, 7, 14, 18, 21$. The notes $0, 7, 14, 21$, in this arrangement, make fifths with each other, and the note $18$ forms with $14$ a major third; if, then, the intervals were tuned perfect, their vibrations would succeed each other in a regular cycle, but if the cycle formed by two perfect thirds, which requires only $25$ vibrations of its highest note, or $16$ of its lowest to complete it, is too complex for the ear to relish, the cycle of three perfect fifths, which requires $77$, will already be too complex; and if we add to this a major third, the ear will lose all sense of recurrence, and only discord will result.

But to place this in clearer evidence, we need go no further than the chord of the ninth, which, when written thus, $0, 4, 7, 14$, manifests a major third, ($0, 4$) a fifth, ($0, 7$) and a double fifth, ($0, 7 + 7$), of the fundamental note, and therefore, if tuned perfect, would excite a sense of perfect concord, were not the period of recurrence of the vibrations too long for the ear to seize; and a similar remark applies to the discord of the seventh, which consists of a major third, a fifth, and a double fourth, from the fundamental tone ($0, 4, 7, 5 + 5$). It may be that the harshness of the triad $0, 4, 8$, and of the tetrachord $0, 2, 7, 9$, the former consisting, if tuned perfect, of a third and double third, the latter of a fifth, a double fifth, and a triple fifth, may arise from an imperfect, or obscure, and therefore unsatisfactory, perception of the cycles of their vibrations by the ear, the former, as before remarked, occupying $25$, and the latter $27$, single vibrations of the highest note. But it is time to leave these speculations.

§ V. Of the Sonorous Vibrations of Bars, Rods, and Plates

The vibrations of all bodies, if of a proper degree of frequency, and of sufficient force to be communicated through the air, or any other intermedium, to our organs of hearing, produce Sounds whose pitch depends on their frequency; and their force and quality on the extent and other mechanical circumstances of the vibrations, and the nature of the vibrating body. The mathematical investigation of these vibratory motions is altogether foreign to our purpose. It is a branch, and one of the most intricate and least manageable branches, of Dynamics, and we shall, therefore, refer our readers for its theory and details to the writings of the various eminent authors who have discussed it. See Bernouilli, Com. Petrop. vol. xiii. On the Vibrations of Laminae; and Nov. Com. Petrop. vol. xv.; Euler, Com. Petrop. vol. vii., Nov. Com. vol. xvii., and Act. Petrop. vol. iii. On the Vibrations of Plates; Riccati, Soc. Ital. vol. i. p. 444; Lexell, On the Vibrations of Rings, Act. Petrop. 1781; Lambert, On the Sounds of Elastic Bodies, N. Act. Helv. vol. i.; J. Bernouilli, On the Vibrations of Rectangular Plates, N. Act. Petrop. 1757; Biot, On the Vibrations of Surfaces, Mem. Inst. vol. iv.

A solid body may vibrate, either in consequence of its inherent elasticity, by which it tends to return to its own proper figure and state when forcibly deranged, or in consequence of an external tension. To the former sort of vibrations belong those of rods, tuning-forks, plates, rings, bells, gongs, and vessels of all shapes, or generally, of all solid masses which ring when struck. To the latter, those of vibrating strings and membranes, such as the parchment of a drum or tambourin, &c. But, further, a solid may vibrate by its own proper elasticity in two very different ways. First, an undulation may be propagated through it, as through an elastic compressible medium, and, in this case, the waves will consist of alternate strata of condensed and rarefied solid matter, precisely similar to those of an elastic fluid. If the solid be homogeneous, such as the metals, glass, &c., the elasticity being the same in all directions, the waves will be propagated from the centre of disturbance, according
to exactly the same laws as in a mass of air of the same shape. But if crystallized, this may not be the case, or
the vibrations instead of being in the direction of the propagated wave, may be transverse, or oblique to it, or
may even not be confined to one plane, but may be performed in circles or ellipses. See Article Light.

If a straight rod of glass, or a metal, to be struck at the end in the direction of its length, or rubbed
with a moistened finger, it will yield a musical Sound, which, unless its length be very great, will be
of an extremely acute pitch; much more so than in the case of a column of air of the same length. The reason
of this is the greater velocity with which Sound is propagated in solids than in air. Thus the velocity of
propagation in cast-iron being $10^{4}$ times that in air, a rod of cast-iron so excited will yield for its fundamental
note a Sound identical with that of an organ pipe of $\frac{1}{10^{4}}$ of its length stopped at both ends, or $\frac{1}{10}$ of its length
if open at one end. See § III., all the details of which are applicable to the present case. To such vibrations,
Chladni, who first noticed them in long wires, has applied the term longitudinal. (Art. Acad. Erfurt, 1796.) To
produce the harmonics of such a rod or wire he held it lightly at the place of one of its intended nodes between
the finger and thumb, and applied the friction in the middle of one of the vibrating segments. If the rod be of
metal, the friction which he found to succeed, was that of a bit of cloth sprinkled with powdered rosin, if of
glass, the cloth, or the finger, may be moistened and touched with some very fine sand or pumice powder. It
may be observed here, that, generally speaking, a fiddle-bow well rosined is the readiest and most convenient
means of setting solid bodies in vibration. To reduce their gravest or fundamental tones, the bow must be
pressed hard and drawn slowly, but for the higher harmonics, a short swift stroke with light pressure is most
proper. In all cases the point intended to be a node must be lightly touched with the finger, and the vibration
must be excited (as above said) in the middle of a ventral segment. Such is the case analysed by Chladni.
In general, however, the vibrations of a cylindrical rod or tube so excited are more complex. See Art. 266, Index,
Art. Longitudinal Vibrations.

But by far the most usual species of vibration executed by solid bodies is that in which their external form is
forcibly changed, and recovered again by their spring. The simplest case is that of a rod executing vibrations
to and fro in a direction transverse to its length. This case has been investigated mathematically by D. Bernoulli
and Euler, as also by Riccati; (see the list of authors above cited, Art. 266;) and their results have been
compared with those of experiment by Chladni, Acoust. sec. 5, and found correct. The cases enumerated by
Chladni are six in number.

1. When one end of the rod is firmly fixed in a vice or let into a wall, the other quite free. In this case the
curve assumed by the rod in its vibrations must of necessity have its axis or position of rest for a tangent, as
fig. 36.

2. One end applied or pressed perpendicularly against an obstacle, the other free. In this case, the
excursions of the applied end to and fro are prevented by the friction and adhesion to the obstacle, but the axis is
of necessity a tangent. See fig. 37.

3. Both ends free. Fig. 38.

4. Both ends applied. Fig. 39.

5. Both ends fixed. Fig. 40.

6. One end fixed, the other applied. Fig. 41.

All these cases have been examined by Chladni at length. We shall, however, select only the fourth case
where both ends are applied, because it will afford room for an important remark. In this, the several modes
of vibration corresponding to 1, 2, 3, 4, 5 vibrating or ventral segments of the rod will be as in fgs. 39, 43, 44.
Now these are similar to the curves which would be assumed by a vibrating string under the same circumstances
of subdivision. But the notes produced are very different. For whereas in the case of a string the
vibrations of the successive harmonics are represented by 1, 2, 3, 4, 5, &c.; in that of a rod they are represented
by the squares of these numbers 1, 4, 9, 25, &c., which correspond to double the former intervals. In all the other
cases the series is still less simple.

This alone suffices to shew the insufficiency of any attempt to establish, as some have wished to do, the whole
theory of harmony and music on the aliquot subdivision of a vibrating string. Had vibrating rods or steel
springs (which yield an exquisite tone) been always used instead of stretched chords, such an idea would never
have suggested itself, yet no doubt 'our notions of harmony would have been what they now are. The same
remark applies still more forcibly to the modes of subdivision of vibrating surfaces, which in many cases have
their harmonics altogether irreducible to any musical scale.

A rectangular plate may be regarded as an assemblage of straight rods of equal length, ranged parallel to each
other. Supposing such an assemblage all set in vibration similarly and at once, they will retain their parallel
juxtaposition during their vibration, and may, therefore, be supposed to adhere, and form a plate. Consequently,
among the possible series of vibrations of a rectangular plate will be found all those of a rigid rod. Accordingly,
when fixed, (for instance,) by one of its edges in a vice, with its plane parallel to the horizon and strewn over
with sand, if it be set in vibration by a fiddle-bow and touched in one of its possible nodes, its subdivisions will
be rendered visible to the eye, by the sand being thrown away from the vibrating parts and accumulating on
those at rest. Thus the plate will be crossed transversely by a series of nodal lines marked in sand, and whose
distances from each other and from the ends of the plate may be measured at leisure.

But besides these, rectangular plates are susceptible of other modes of subdivision, having two sets of nodal
lines, straight or curved, crossing at right angles, or otherwise, and dividing the plate into smaller plates, each
vibrating in its middle, and at rest at its edges, and every two contiguous plates separated by a nodal line
making their simultaneous excursions on contrary sides of their state of rest.

To produce these subdivisions, and to render them visible, take a rectangular plate (for simplicity we will
Suppose it a square) of glass, or metal, of an even thickness, not too thick, and holding it firm between the points of the finger and thumb of the left hand, or between two points of a clamp-screw covered with cork or leather so as not to jar, taking care to keep the pressure confined to as small a space as possible, draw a rosined bow over the edge, which should be smoothed and a little rounded. If then the point where it is held be the centre of the plate, and the bow be applied close to one of the angles, sand strewed over it will arrange itself on the two diameters which divide it into four equal squares as in fig. 44. Each of these, in the act of vibration, becomes a surface of double curvature, and their motions are contrary to each other; those marked + making their excursions on one side of the plane of repose, while those marked — are on the other. This mode of vibration corresponds to the gravest tone produced by the plate.

If the plate being still held in the centre, the bow be applied at the middle of one side, the sand will occupy the diagonals of the plate, which are the nodal lines corresponding to this mode. In this, as in the former case, the plate subdivides itself into four equal vibrating segments as in the fig. 45, but the tone is different, being a fifth higher than in the former case, the distribution of the inertia with respect to the elastic power of the plate being such as to admit a quicker motion.

If the plate be held at a, the intersection of two nodal lines fig. 46, and the bow be still applied at the middle of one side, or at the angle adjacent to a, the plate will vibrate as there represented. In this subdivision, the four small squares at the angles and the large one at the centre vibrate on one side, or negatively, while the four intermediate oblong rectangles adjacent to the sides vibrate positively.

These instances may serve to show the mode of proceeding in more complicated cases, and with plates of other figures. Among these, circular ones hold the chief place both for symmetry and variety. The examples, figs. 47—93, are selected from those described by Chladni, who has determined by experiment the tones corresponding to each mode of division in plates of a great variety of figures. Of these we shall only give some examples in the case of a square plate, of which we shall suppose the gravest or fundamental tone to be represented by 1. This premised, if we regard the plate as subdivided into \( n \times n' \) rectangles by \( n \) nodal lines parallel to one side, and \( n' \) parallel to the other, the notes corresponding will be as in the following Table:

The vibrations of triangular, hexagonal, elliptic, and semicircular plates have also been investigated by Chladni, and fig. 94—123 exhibit some out of a great variety of nodal figures, to which they give rise in their various modes of vibration.
PART III.

§ 1. Of the Communication of Vibrations and of the Vibrations of Systems.

The subject of the sonorous vibrations of solids has recently been taken up in a more general and extended point of view by M. Felix Savart, in a series of Memoirs communicated by him to the Royal Academy of Sciences of Paris, and of which copies, or copious extracts, are printed in the Annales de Chimie. We regret that the narrow limits which remain to us in this volume will allow little more than a slight sketch of the contents of the principal of these most interesting papers, the whole of which are models of experimental research, and indeed, so full of new, curious, and instructive matter, that it is next to impossible either to condense or abstract them; for which reason we earnestly recommend our readers, who may be led to take an interest in the subject of this Essay, not to content themselves with the meagre statements here offered, but to procure and study diligently the original Memoirs.

In order to a regular analysis of this intricate subject, it was first requisite to obtain some certain mode of communicating to any given point of a solid vibrations confined to one plane, and whose period of recurrence, as well as the plane in which they were performed, and the amplitude of their excursions, could be varied at pleasure. The vibrations of a stretched string set in motion by a fiddle-bow, afford the means of doing this. Such are necessarily confined to the plane in which the motion of the bow is performed, because any vibratory motion out of this plane is prevented, or immediately stifled by the pressure of the bow; and as the plane of its motion may be varied at pleasure, and the amplitude of excursion may be increased or diminished by a change of pressure, and velocity of stroke, all the requisite conditions are here obtained. Accordingly, if the vibrating part of such a string be brought to press on a solid not too massive, or if the end of the string be attached to a point in the solid, M. Savart has found that the regularly repeated impulses of the string are transferred to the solid with perfect fidelity.

A familiar example of this communication of impulses is found in the violin. In that instrument, fig. 124, the strings which are stretched from end to end of it, are divided into two unequal parts by the bridge, A, on which they all press strongly, and at the same time rest in small notches, so as not to slip laterally on it. The portion, B, of the string which lies towards the handle, C, of the instrument, is free, and is set in vibration by the bow in its own plane; but that on the other side of the bridge, D, is loaded with a mass of horn or whalebone, E, to which all the other strings are also attached, and which, being only tied to the wood-work, cannot propagate the vibrations of any one string sounding separately, by reason of the contradictory and unequal tensions of the other three. Thus the bridge is in effect acted on only by the vibrations of that part, A B C, of the string which is crossed by the bow, as if it terminated abruptly at its point of pressure, A. These vibrations constantly tend, therefore, to tilt the bridge laterally backwards and forwards, and to press up and down alternately the two little prominences or feet, F G, by which it rests on the belly of the violin. It, therefore, sets the wood of the upper face in a state of regular vibration, and this again is communicated to the back through a peg set up in the inside of the fiddle, and through its sides, called the soul of the fiddle, or its sounding post. In consequence, if the upper surface be strewed with sand, it will assume a regular arrangement in nodal lines when the bow is drawn; and the same subdivision is also observed in the wood of the under surface, if the sounding-post be exactly placed in the centre of symmetry of the nodal figures. The experiment can hardly be made, however, with a common fiddle, by reason of the convexity of its surface, on which sand will not rest; but if one be constructed with plane boards, or if, abandoning the fiddle, a string be stretched on a strong frame over a bridge, which is made to rest on the centre of a regularly formed plate or disc of metal or wood, strewed with sand, the surface thus set in vibration by the string will be seen to divide itself by regular nodal figures.

Now M. Savart has observed this remarkable fact, viz. that if the tension or length of the string thus placed in vibratory communication with a plate, be changed, so as to vary the note it speaks, the nodal figures on the plate undergo a corresponding variation, and the plate still vibrates in unison with the string; or, which is the same thing, the two, together with the interposed bridge, form a vibrating system, in which, though the vibrations of the several parts are necessarily very different in their nature and extent, yet they have all the same periods. This experiment is very important. It shows that the Sounds of such thin plates are not like those of strings confined to certain fixed harmonics, but, according to the forms of their nodal lines, and the proportions of the vibrating areas in opposite states of excursion, may assume any assigned period; in other words, given the vibrating plate and the pitch, a nodal figure may be described on it, which shall correspond to that pitch, and the plate (with more or less readiness, however) is always susceptible of such a vibration as shall yield that note, and produce that nodal figure. How far this proposition is general, and with what limitations it is to be understood, we shall soon see. Meanwhile this remark, it will be observed, furnishes a complete explanation of the effect of sounding-boards in musical instruments. It is not, as some have supposed, that there exist in them fibres in every state of tension, some of which are therefore ready to vibrate in unison with any proposed Sound, and therefore, reinforce it. Such a cause could at best produce but a very feeble effect. It is the whole board which vibrates as part of a system

\[804\]
Sound. With every note, and (as vibrations may be supposed to any extent) the same sounding-board may at once form a part of any number of systems, and vibrate in unison with every note of a chord. Still some modes will always be more difficult than others, and no sounding-board will be perfectly indifferent to all Sounds.

The longitudinal vibrations of a rod of glass, excited by rubbing it with a wet cloth, may also be used to excite vibrations in a given point of a solid perpendicular to its surface, by applying its end to it, or connecting it to the solid by mastic. In this way Chladni applied it to draw forth the Sounds of glass vessels, (which when hemispherical, and of sufficient size and even thickness, are remarkably rich and melodious,) in an instrument which he called the Euphone, exhibited by him in Paris and Brussels. The principle of this instrument was at the time concealed; but the enigma was subsequently solved by M. Blanc, who, on his part independently made the same remark, and applied it to a similar purpose.

If the solid (a circular glass disc for instance) to which such a vibrating rod or tube is fastened, be of small comparative dimensions, its vibrations are commanded by those of the rod, and the Sound yielded will be that of the rod alone; and vice versa, if the disc be large, and the rod small, the note sounded will be that of the disc, which will entirely command the rod; but in the intermediate cases, both M. Savart and M. Blanc have observed, the note will be neither that of the disc or the rod separately, but the two will vibrate together as a system, each yielding somewhat to the other. It is a case exactly analogous to that of a reed-pipe, in which the reed and column of air mutually influence each other’s note. See Art. 199. This mutual influence of propagated motion, by which two periodically recurring impulses affect each other’s period, and force themselves into synchronism, extends to cases where at first sight it would hardly be suspected. Thus Ellicot observed that two clocks fastened to the same board, or even standing on the same stone pavement, beat constantly together, though when separated their rates were found to differ very considerably; and Breguet has since made the same remark on watches. Thus also two organ-pipes vibrating side by side, if very nearly in unison, will under certain circumstances force themselves into exact concord, as has been observed by Hudleston, (Nicholson’s Journal, i. 329.) and lately recalled to notice by some experiments made in Copenhagen. The experiment with the disked tuning-fork and pipe, related in Art. 204., may here again be referred to.

The longitudinal vibrations of a rod have also been used by M. Savart, to communicate vibrations from one solid to another; as for instance, from the upper to the under of two circular discs cemented at their centres to the two ends of the rod, at right angles to their planes, as at fig. 125. If the two discs be of the same dimensions and materials, so as to yield, when separately vibrating, the same note, the vibrations of one of them, (the upper for instance,) excited by a bow, will be exactly imitated by the other, and sand strewed over both will immediately excite vibrations of similar form in both discs, and that, into whatever number of vibrating segments that plates by a rod.

The state of vibration in which the molecules of the connecting rod are thrown in such cases, deserves a nearer examination. For simplicity let us suppose the discs equal, the rod cylindrical, and the vibration of the system such that each disc shall subdivide itself into four quadrantal segments. In this case it is clear that as the form assumed at any instant by the upper disc is undulated or wrinkled, as represented in fig. 126, the section of the rod in immediate contact with it, and which obeys all its motions, must assume a similar form, and so of all the rest. Thus if we conceive the rod split into infinitesimal columns, parallel to its axis, all the columns in two opposite quadrants will be ascending, while those in the other two are descending; and thus the two corresponding opposite quadrants of the lower disc will be drawn upwards, while the alternate ones are forced downwards, giving a similar distortion to its figure, and disposing it to a similar vibration only. It will depend on the length of the rod, and the time taken by an undulation to run over its length, compared with that of a vibration of either disc, whether the phases of vibration in the two discs shall be the same at the same instant or not. It may happen that, for instance, the quadrant, D B, of the upper disc shall have completed its downward motion, and begun to return before the pulsation propagated through the rod has arrived at the lower disc; and in that case the corresponding quadrants of the two discs will be always in opposite phases of their periodic motion. But the nodal lines will of necessity correspond in both.

When the two discs are unequal, the propagation of the pulses through the rod must of course cease to be uniform, and each section of it down its whole length will have its own peculiar law of form and motion, which it is beyond our power to investigate. In that case its molecules must have lateral as well as vertical motions, and its vibrations must be partly longitudinal and partly transverse, in a way easier imagined than described. If the discs be dissimilar in form as well as unequal in dimension, the vibrations of the connecting rod will of course be very complicated.

These principles have been applied by M. Savart, and apparently with success, (as appears by the very able report of M. Biot on his Paper,) to the improvement of violins, and the construction of these delicate instruments on scientific and experimental grounds. Everyone is aware of the difficulty of procuring perfect violins, and the enormous prices they bear, so that fixed rules, by which any ordinary artist can with certainty produce an excellent one, are evidenly highly valuable. We long to see M. Savart’s construction tried in this country, but must refer to his Paper (Annales de Chimie, vol. xii. p. 225, &c.) for the details.

It appears from what we have said, that the motions of the molecules of a rod which communicates the vibrations of one disc to another, or, more generally, which vibrates longitudinally by any exciting cause, are not of necessity analogous to those of the air in a cylindrical pipe, at least not to that simple case of the latter vibrations, which we have heretofore considered in our 3d Section. The several transverse sections of such a rod, in the act of vibration, do not necessarily merely advance and recede longitudinally, but may become curves of double curvature; in short, such a rod may be considered as an assemblage of vibrating discs, ranged along a common axis, along which...
they may, it is true, be also carried backwards and forwards with a vibratory motion, while at the same time their flexure is changing from convex to concave, and vice versa. Now it may happen that a point, or a line, (straight or curved,) in any one of such discs, may be advancing in the direction of the axis in consequence of the bodily motion of the whole disc, while, in virtue of its flexure in the act of changing its figure, it may be receding; and this advance and recess may so balance each other, that the point or line shall be at rest. If this be true at one instant, it will be so at all instants, because the vibrations have all one period, and follow the same law of increase and decrease in their phases. Thus we have a nodal point, or a nodal line; and as each disc, by reason of the law of continuity, must have a similar one, the assemblage of such lines will mark out within the rod a nodal surface, dividing it into separate solids whose molecules on either side of such surface are in opposite phases of their motion.

This is here said of rods, applies of course to solids of any figure and dimension, neither is there the slightest reason why it should not apply to vibrating masses of air, or any other elastic fluid. Any such mass may be conceived as cut up into two or more oppositely vibrating portions pervading it according to certain laws. Where these surfaces out-crop or intersect the external surface of the mass, there will be a nodal line.

Such nodal lines, formed on the surfaces of bodies by the longitudinal vibrations of their molecules, (i.e. by vibrations parallel to their surfaces,) may be detected and rendered visible to the eye by fine dry sand, or the powder of Lycoperdon, strewed over them; and the motions of the particles in the act of forming them will easily distinguish such vibrations as are executed parallel to the surface (in which, of course, the surface is not thrown into waves) from such as take place at right angles to it, where the surface itself leaps up and down. In the latter case, the particles of sand dance, and are violently thrown up and down over the whole extent of the vibrating portions, till, at length, they are entirely dispersed from them. In the former, they only glide along close to the surface, and meet and settle on the nodal lines, and that, sometimes, with incredible swiftness.

The reason why they retreat to the nodal lines is easily understood. The amplitude of the excursion of the vibrating molecules of the surface diminishes as we approach a nodal line. Hence a particle of sand anywhere situated, if thrown by an advancing vibration towards this line, will not be thrown quite so far back by the subsequent retracting vibration, because its then situation is one less agitated. Thus the motion of each particle of sand is one of alternate advance towards the node and recess from it, but the advances are always greater than the recesses. In consequence, it creeps along the surface, and will not rest till it has attained the node. When a large disc of glass is set vibrating vigorously by a bow, perpendicular to its plane, the grains of sand will fly up some inches from it and be scattered in all directions. M. Savart has distinguished by the name tangential vibrations all such motions of the superficial particles of a body as are performed parallel to the surface; while those executed at right angles to it, in virtue of which the surface itself heaves and sinks, he calls transverse; and to motions compounded of both these, where the surface both swells and falls and shifts laterally backwards and forwards, he gives the term "oblique vibrations." In this we shall follow him.

This acute experimenter has investigated with great minuteness the tangential vibrations of long flat rods or rulers of glass, as well as of cylinders and tubes. They are extremely complicated, and offer most singular phenomena, some of which we shall now describe. If we take a rectangular lamina of glass 0.70 (= 27.56) long, 0.0015 (= 0.059) broad, and 0.0015 (= 0.006) thick, and holding it by the edges in the middle between the finger and thumb with its flat face horizontal, strewed with sand, and, at the same time, set it in longitudinal vibration, either by rubbing its under side near either end with a bit of wet cloth, by tapping it on the end with light blows, or by rubbing lengthwise a very small cylinder of glass, cemented on to its end in the middle of its breadth, and parallel to its length; in whatever way the vibration be communicated, we shall see the sand on its upper surface arrange itself in parallel lines, at right angles to its longer dimension, and always, in one or the other of the two systems, represented in figs. 127 and 128. Now it is very remarkable that although the same one of these two systems will always be produced by the same plate of glass, yet among different plates of the above dimensions, even though cut from the same sheet, side by side, one will invariably exhibit one system, and the other the other, without any visible reason for the difference. Moreover, in the system, fig. 127, the disposition of the nodal lines is unsymmetrical, one of them, a, being nearer to one end, and the closer pair, ff, not being situated in the middle; and this too is peculiar to the plate, for wherever it be rubbed, whichever end be struck, still the line a will always be formed nearest to the same extremity.

Now let the positions of the nodal lines be marked on the upper surface, and then let the plate be turned till the lower surface becomes the upper, and this being saund, let the vibrations again be excited just as before. The nodal lines will now be formed quite differently, and will fall on the points just intermediate between those of the other surface; i.e. on the points of greatest excursions of its vibrating molecules. In a word, if n, n, n, n, &c. in fig. 129, or 130, represent the places of the nodes on the one surface, then will n', n', &c. be those of the other. Thus all the motions of one half the thickness of the lamina are exactly contrary to those of the corresponding points of the other half. This property, indeed, is general, whatever be the material, length, breadth, or thickness of the lamina.

If, the other dimensions remaining, the thickness be increased, the Sound will remain the same, but the number of nodal lines will be less. This fact alone is sufficient to prove an essential difference between the vibrating portions of such a plate, and the vertical segments of an organ-pipe harmonically subdivided.

If the breadth of a plate of the above length be greater than 0.006 the nodal lines cease to be straight, and ranged across the breadth at right angles to the sides. They pass into curves, and, when the breadth is increased to 0.004, ( = 1.57) they assume the former representation of the lines on the upper, the latter those on the under surface. If the breadth be enlarged to 0.006, ( = 2.56) the figures on the two faces will be as in figs. 133, 134. If the dimensions be so varied as to convert the plate into a square, the nodal figures will assume the forms in figs. 135, 136. If the form of the plate pass into the circular or triangular, the
Part III.

Of still broader vibration.

§ II. Of the Communication of Vibrations from one Vibrating Body to another.

We have already seen that a rod placed between two discs, one of which is set in vibration, becomes the means of communicating its vibrations to the other. But it may be announced as a general fact, that whenever a vibrating body is brought into intimate contact with another, it communicates to it its own vibrations, more or less effectually as their union is more perfect. This proposition has been carried still further by M. Savart, whose experiments show that all the particles of the body thus set in vibration by communication are agitated by motions not merely similar in their periods, but actually parallel in their directions, to those of the original source of the motion. Examples will best explain the meaning of this.

Example 1. Let A, fig. 142, be a long flat glass ruler or rod, cemented with mastic to the edge of a large bell-glass, such as is used for the harmonica, or musical glasses, or a large hemispherical drinking-glass, perpendicular to its circumference. Let it be very lightly supported in a horizontal position on a bit of cork at C, and, when the cylinder is turned, then let the bell-glass be set in vibration by a bow, at a point opposite the place where the rod meets it. It will a bell-glass.
vibrate transversely, i.e. the motions of its molecules will be perpendicular to its surface; and these motions will be communicated to the rod, without any change in their direction, whose vibrations will be longitudinal-tangential, as will be rendered evident by strewing its surface with sand, when the nodal lines will be formed as in Art. 293, and, if the apparatus be inverted, and the sand strewed on the under side of the rod, the nodal lines will be seen to correspond to the points of greatest excursion on the other side, as in that article.

In this combination the original tone of the bell-glass is altered, and the note produced differs both from that yielded by it, or by the glass rod vibrating alone. The two vibrate as a system together and, what is singular, the Sound of the glass is considerably reinforced by the combination.

Example 2. Let A' be a rectangular strip of glass firmly cemented at right angles to another strip, A, across its breadth. Let the latter be lightly supported on two bits of cork, C, fastened to a wooden piece, B, so as just to touch A in the places of two of its nodes when vibrating transversely. Then, if A be held horizontally, and strewed with sand, and A' be set in longitudinal-tangential vibration, either by rubbing with a wet cloth, or by any other means, A will vibrate transversely, as will be known by the dancing of the sand and its settling on the nodes C C. On the other hand, if A be held vertically, and agitated transversely by a bow, while A' is horizontal and strewed with sand, the latter will indicate longitudinal-tangential vibrations, both by the creeping of the sand, and by the difference of the nodal figures on its two faces.

Example 3. Let M be a rectangular plate (fig. 144) mounted like A in the last example, but instead of carrying a simple plate A', let it carry a system of circular discs traversed by a lamina, as in the figure. Then, if the faces of these discs and of the lamina M be horizontally placed and strewed with sand, and the lamina M be set in longitudinal-tangential vibration, all the discs will be so too, and the sand will arrange itself in figures which, on every alternate disc, 1, 3, 5, &c. will be of one species, (such as at a for instance,) but on every other, 2, 4, 6, &c. will be of a different species, as b. Now if the whole apparatus be inverted, so as to place the lamina M uppermost, and let the system of discs hang down, the then upper surfaces of the discs will exhibit the same system of nodal figures, but in the reverse order: i.e. the discs 1, 3, 5, &c. will give the figure b, and 2, 4, 6, &c. the figure a. In this apparatus, if the connecting piece which traverses all the discs be examined, it will be found to vibrate transversely, while the discs and lamina M vibrate tangentially, and vice versa.

Example 4. Let A be a strong frame of wood of the form [], across the extreme edges of which is stretched a strong guttural or other chord, and let L L' be a circular disc of glass, or metal, retained between the chord and back of the frame by the pressure of the former. Then, if the chord be set, in vibration by a bow drawn transversely across it in one steady direction, the vibrations of the chord will all lie in the plane of the bow, and will be communicated in the same direction to the disc, which will execute tangential vibrations, each of its molecules moving to and fro in lines parallel to the bow through the whole extent of the disc. This is easily verified by the direction in which sand strewed on it creeps. Conceive the whole apparatus placed with the chord vertical, and projected on the plane of the horizon. If, as in fig. 145, a, F F' be the projection of the bow, the surface of the disc will be marked with nodal lines parallel to it, the sand there being left, while that in the intermediate spaces creeps along to the edges, as marked by the arrows, and runs off. If the projection of the bow F F' be oblique to the line joining the points of support of the disc, as in fig. 145, c, the nodal line will be curved, as there shown, but the motion of the molecules of sand going to form it will still be parallel to FF'. Finally, if the bow be drawn parallel to the line joining the points of support, as in fig. 145, d, the nodal line will be formed of two arcs making a cusp, but the same law of molecular motion will still hold good, as the arrows indicate.

Example 5. Let L L' be a rectangular plate of the form [], fastened at one end into a block, T, and at the other attached to a chord, c c, stretched parallel to its length, over a bridge, e, and put in vibration by a bow perpendicular to it, F F'. Then, if the plane of the bow and string coincide with the plane of the surface of the lamina, the latter will execute tangential vibrations across its breadth, and will exhibit on its upper surface a single nodal line, n n', as in fig. 147, but on its under none, all the sand being driven off. Now incline the bow to the surface of the lamina as represented in fig. 146, e, at an angle of about 20°, still keeping it perpendicular to the string, and the nodal line will assume the curvature represented in fig. 148. If the bow be still more inclined, the curve breaks up, and at 45° of inclination becomes changed into transverse and oblique lines, as in fig. 149; and it is now observed that the sand not only runs in the direction of the arrows, but also begins to leap, indicating an oblique vibration of the surface. Lastly, when the bow is inclined 90° to the plane of the lamina, as in fig. 150, the vibration becomes altogether transverse, the nodal lines are similarly disposed on both sides of the plate, and the sand merely leaps up and down till it is danced off the vibrating parts, without any tendency to creep.

Example 6. If a very thin membrane be stretched horizontally over the orifice of a circular bowl, as a drinking-cup, or harmonica-glass, (extremely thin paper wetted and glued to the edges, and then suffered to become tight by drying, answers very well,) and if fine sand be strewed on it, it becomes a most delicate detector of aerial vibrations. Suppose now a circular disc of glass held concentrically over it with its plane parallel to that of the membrane, and set in transverse vibration so as to form any of Chladni's acoustic figures, as for instance fig. (99). Then will this figure be imitated exactly by the sand on the membrane. Now let the vibrating disc be shifted laterally, so as no longer to have its centre vertically over that of the membrane, but keeping its plane, as well as that of the membrane, horizontal. Still the figures marked out on the latter will be fac-similes of those on the disc, and that, whatever be the extent of lateral removal, till the vibrations become too much enfeebled by distance to have any effect at all.

But, in place of shifting the disc laterally, let its plane be inclined to the horizon. Immediately the figures on the membrane will change though the vibrations of the disc remain unaltered, and the change will be the greater, the greater be the inclination of the plane of the disc to that of the membrane. And when the former plane is perpendicular to the horizon, the nodal figure on the membrane is found to be transformed into a system of straight lines parallel to the common intersection of the two planes, and the particles of sand
instead of dancing, creep in opposite directions to meet in these lines. One of these always passes through the
centre, and the whole system is analogous to what would be produced by attaching a cord to the centre of a
disc, and having stretched it very obliquely, setting it in vibration by a bow drawn parallel to the surface. In a
word, the vibrations of the membrane are now tangential, and they preserve this character unchanged, however
the disc be now shifted laterally, provided its plane be not turned from the vertical position. If the disc be
made to revolve about its vertical diameter, the nodal lines on the membrane will rotate, following exactly the
motion of the disc.

Nothing can be more decisive or instructive than this experiment. We here see evidently, that the motions of
the aerial molecules in every part of a spherical wave, propagated from a vibrating body as a centre, instead
of diverging like radii in all directions so as to be always perpendicular to the surface of the wave,
are all parallel to each other; in a word, they are disposed, not as in fig. 8, but as in fig. 7; and thus the
hypothesis of Art. 118. is found to be completely verified. And the same thing holds good not only in air, but
in liquids, as the experiments hereafter to be related (due, like all those just cited, to M. Savart) satisfactorily
demonstrate.

This experiment is also remarkable in several other points of view. So long as the Sound of the disc, and its
mode of vibration, as well as its inclination to the plane of the membrane, and the tension of the latter, continue
unchanged, the nodal figure on the membrane will continue the same; but if either of these be varied, the mem-
brane will not cease to vibrate, but the figure will be modified accordingly. Let us consider separately the effect
of each of these changes.

And first, ceteris immutatis, let the pitch of the Sound whose vibrations, communicated through the air to the
membrane, excite its motions, be altered, as by loading the disc, or increasing or diminishing its size, (or, if the Sound be excited by any other cause, as a pipe, the voice, &c., then by varying its pitch by any appropriate
means.) The membrane will still vibrate, differing in this respect from a rigid lamina, which will only vibrate
by sympathy with Sounds corresponding to its own subdivisions. The membrane, be it observed, will vibrate in
sympathy with any Sound, but every particular nodal figure, and as the pitch varies the figure varies. Thus if a slow air be played on a flute near it, each note will call up a particular form, which the next will efface, to establish its own.

Secondly. Suppose the exciting cause be the vibration of a disc, or lamina of any form. If its mode of vibration
be varied so as to change its nodal figures, those on the membrane will vary; and if the same note be pro-
duced by different subdivisions of different sized discs, the nodal figures on the membrane will be different.

Again, if the tension of the membrane be varied ever so little, most material changes will take place in the
figures it exhibits. If paper be the substance employed, mere hygrometric changes affect it to such a degree,
that if moistened by breathing on it, and allowed to dry while the exciting Sound is continued, the nodal forms
will be in a constant state of fluctuation, and will not acquire permanence till the paper is so far dried as the state
of the surrounding atmosphere will permit. Indeed, this fluctuation is so troublesome in experiments of this kind, that to avoid them it is necessary to coat the upper or exposed side of the paper with a thin film of varnish.

All substances which can be employed for the exhibition of these beautiful experiments, M. Savart observes,
by far the best is such a varnished paper stretched on a frame and moistened on the under side. The moisture
of the cohesion of the fibres, and renders them nearly independent of each other, and indifferent to all
impulses. As a proof of this, he observes, that he has frequently obtained, on a circular membrane of paper so
prepared, a nodal figure composed of no fewer than twenty concentric annuli, which is far beyond what can be
obtained in any other way.

In some cases, a very curious and instructive phenomenon is observed in these experiments. Between the
nodal lines formed by the coarser and middle-sized grains of sand, others will be occasionally observed, formed
only of the very finest dust, of microscopic dimensions. This phenomenon will be seen to greater advantage if a
little dust of Lycoperdon be mixed with the sand. These intermediate lines M. Savart explains, by referring
them to different and higher modes of subdivision, coexisting with that by which the principal figure is formed.
The more minute particles are proportionally more resisted by the air than the coarser ones, and are thus pre-
vented from making those great leaps which throw the coarser ones into their nodal arrangement. They, there-
fore, rise and fall with the surface, to which they are so it were pinned down. But they are affected by the
motion of the disc.

Nothing can be more decisive or instructive than this experiment. We here see evidently, that the existence
and mode of vibration of the exciting cause.

First, the pitch of the Sound.

Secondly, the nature and mode of vibration of the exciting cause.

Thirdly, the tension of the membrane.

Effect of hygrometric changes on paper membranes.

Secondary nodal figures.

Secondary figures often appear as concentric rings between the primary ones, and not unfrequently the centre of the whole system is occupied by a secondary point.

Figures 151—161 are specimens of the nodal figures thus formed on circular membranes. Of these, fig. 161
shows the modification which is apt to take place when the tension of the membrane is not quite equal. Figs.
162, 168, are figures exhibited by square membranes, and fig. 164—166 by triangular ones.

A very important application of these properties of streched membranes has been made by M. Savart, by
employing such a one as an instrument for detecting the existence and exploring the extent and limits of con-
tinuous and oppositely vibrating portions of masses of air. For, since such a membrane is thrown into vibration
by all aerial vibrations of a certain force, the fact of the existence or not of a vibratory motion in any point of the
air, of a chamber for instance, or a box, or large organ-pipe, may be ascertained by observing whether sand strewn
on it is set in motion, and arranged in regular forms, on holding the membrane at that point. Thus if an organ-pipe
be made to sound with a constant force, and the exploring membrane be so far removed from it that the mem-
brane shall just cease to be agitated visibly, the force of the Sound being increased by a quantity not sensible to
the ear, the sand will recommence its motion. Nay, if two such pipes, placed close together, be made to beat,
(see Index, Beats,) the membrane will be seen to be agitated at the coincidences, and at rest in the interferences
of their vibrations. We shall presently return to this part of our subject.
Another highly interesting application of the same properties, is the view which M. Savart has taken of the use of the "membrana tympani" in the ear. Of all our organs, perhaps, the ear is one of the least understood. It is not with it as with the eye, where the known properties of light afford a complete elucidation of the whole mechanism of vision, and the use of every part of the visual apparatus. In the ear every thing is on the contrary obscure; anatomists, it is true, have scrupulously examined its construction, and many theories have been advanced of the mode in which Sounds are conveyed by it to the auditory nerve, (where of course, as with the optic nerve in the eye, all inquiry terminates, for to trace the progress of sensation along the nerve to the brain, and thence to the sentient soul, it is needless to remark, is altogether beyond our reach.) But nothing certain can be said to be known, though it is to M. Savart that we owe the most rational hypotheses hitherto proposed.

Fig. 167 represents the auditory apparatus. It consists externally of a wide, conch-shaped opening, KL, which contracts into a narrow pipe, AB, defended from the entry of dust and insects by hairs, and a viscous exudation which is slowly secreted, and terminated by a thin elastic membrane, called the Tymanum, F, or drum of the ear. Behind this there is a cavity which communicates with the mouth by a small duct called the Eustachian tube, H G I. If this be stopped, deafness is said to ensue, but, as Dr. Wollaston has shown, only to Sounds within certain limits of pitch. In the cavity behind the tympanum is placed a mysterious and complicated apparatus, B C P S, represented complete, and on an enlarged scale, in fig. 168, consisting of four little bones, of which the first, S C, is called the hammer, and rests with its smaller end in contact with the tympanum, and is larger on the second bone, B F, called the anvil, between which, and the last, V, called the stirrup, a little round bone, P, forms a communication. These bones form a kind of chair, and no doubt vibrations excited in the tympanum by vibrating air, as in the experiments above detailed, are somehow or other propagated forward through these; but they are so far from being essential to hearing, that when the tympanum is destroyed, and the chain in consequence hangs loose, deafness does not follow. The last of this chain of bones, however, is attached to another membrane, P, which closes the orifice of a very extraordinary system of canals, excavated in the bony substance of the skull, called the Labyrinth, represented separately in fig. 169, which consists of three semicircular arcs, (1, 2, 3,) originating and terminating in a common canal, which is prolonged into a spiral cavity (4) called the cochlea. The whole cavity of the labyrinth is filled with a liquid, in which are immersed the branches of the auditory nerve, in which, no doubt, resides the immediate seat of the first impression of Sound, as that of sight does of the brain, and thence to the sentient soul, it is needless to remark, is altogether beyond our reach. But nothing certain can be said to be known, though it is to M. Savart that we owe the most rational hypotheses hitherto proposed.

To understand how the vibrations of a disc may be conceived to be communicated by the air to a membrane in M. Savart's experiments, let us take a simple case, and suppose A B C D to be a horizontal circular disc, vibrating in that mode which gives a subdivision into four quadrantal segments, A C, C B, B D, D A; and let a b c d be an infinitely thin circular membrane placed under it, which we will suppose to be barely coherent so as...
SOUND.

322. Effects of tension and thickness of the membrane.

323. General theorem respecting forced vibrations.

324. Demonstration.

325. Natural elasticity, and let \( \nu = \frac{2\pi}{\theta} \), so that \( A \cos \nu t \) would denote the general term of a series expressing the velocity of any one of its molecules in a state of unforced vibration, and let \( F(t) \) be a function expressive of the law of diminution of the vibrating motion by friction, resistance, and imperfect elasticity. So that if \( t \) be the time since a certain velocity \( V \) was communicated to it, \( V \cdot F(t) \cdot \cos \nu t \) will be its velocity after the expiration of \( t \) as it will then subside, modified by the elastic forces and mechanical state of the membrane.

Conceive the aerial impulse to act not continuously, but at equal infinitesimally small intervals of time \( \tau \), (infinitely small relative not only to \( T \) but to \( T \) and \( \theta \).) Then, first, the impulse \( A \cdot \cos \nu t \), acting during the time \( \tau \), will produce the velocity \( A \cdot \nu \cdot \cos \nu \tau \).
Sound.

Secondly. The impulse $A \cdot \cos(n(t - \tau))$ which acted at the moment immediately preceding, produced in the first instance the velocity $A \cdot \cos(n(t - \tau))$. But this, once produced, was immediately modified by the inherent elasticity of the membrane, and in the subsequent moment became

$$A \cdot \cos n(t - \tau) \cdot F(\tau) \cdot \cos n\tau.$$

Similarly the impulse $A \cdot \cos n(t - 2\tau)$ acting at the instant preceding this generated the velocity $A \cdot \cos n(t - 2\tau)$, which, in like manner, (being regarded as an arbitrary initial disturbance,) was modified by the time $2\tau$ to $A \cdot \cos n(t - 2\tau) \cdot F(2\tau) \cdot \cos 2n\tau$. And so on. Thus, the whole accumulated velocity at the instant $t$, arising from all the preceding impulses, will be expressed by

$$A \cdot \{\cos n t + \cos n(t - \tau) \cdot \cos n\tau \cdot F(\tau) + \cos n(t - 2\tau) \cdot \cos 2n\tau \cdot F(2\tau) + \&c.\},$$

which series, since the function expressed by $F(\tau)$ is supposed to decrease constantly as $t$ increases, and since the whole number of vibrations is supposed so great that the terms of the series $F(\tau), F(2\tau), F(3\tau), &c.$ shall at length become perfectly insensible, may be regarded as continued ad infinitum.

In fact, whatever supposition we may make as to the law of degradation of the motion within the limit of a single period, it must evidently diminish in geometrical progression in similar phases of successive periods, so that we must have

$$F(\tau + \theta) = q \cdot F(\tau); F(\tau + 2\theta) = q^2 \cdot F(\tau) + \&c.;$$

and, moreover, since $\nu \theta = 2\nu \tau$, therefore $\cos \nu \theta = 1$, and $\cos 2\nu \theta = 1, &c.$ Consequently the above expression becomes

$$A \cdot \{\cos n t + \cos n(t - \tau) \cdot \cos n\tau \cdot F(\tau) + \cos n(t - 2\tau) \cdot \cos 2n\tau \cdot F(2\tau) + \&c.\}.$$

Now, each of these series is readily summed, for we have by well-known trigonometrical formulæ

$$\cos n t = q \cdot \cos(n(t - \nu \theta)) + q^2 \cdot \cos(n(t - 2\nu \theta)) + \&c.;$$

so that we have, first, $F(\nu \theta) = 1, F(2\nu \theta) = q, &c.;$ and, moreover, since $\nu \theta = 2\nu \tau$, therefore $\cos \nu \theta = 1$, and $\cos 2\nu \theta = 1, &c.$ Consequently the above expression becomes

$$A \cdot \{\cos n t + \cos n(t - \tau) \cdot \cos n\tau \cdot F(\tau) + \cos n(t - 2\tau) \cdot \cos 2n\tau \cdot F(2\tau) + \&c.\}.$$

As the series are continued ad infinitum, we may regard them as constants independent of $t$, if we call them $M$ and $N$, our series will become

$$A \cdot \{M \cdot \cos n t + N \cdot \sin n t\} + \frac{1 - q \cdot \cos \nu \theta \cdot \sin n(t - 2\nu \theta) + \sin n t \cdot q \cdot \sin \nu \theta}{1 - 2q \cdot \cos \nu \theta + q^2}.$$

Each of the fractions being constant, and independent of $t$, if we call them $M$ and $N$, our series will become

$$A \cdot \{M \cdot \cos n t + N \cdot \sin n t\} + \frac{1 - q \cdot \cos \nu \theta \cdot \sin n(t - 2\nu \theta) + \sin n t \cdot q \cdot \sin \nu \theta}{1 - 2q \cdot \cos \nu \theta + q^2}.$$

Let us now consider the area of a curve whose abscissa, $x$, is divided into equal elements each equal to $\tau$, while its successive ordinates, $y$, are represented by $\phi(o), \phi(\tau), \varphi(2\tau), &c.$ It is evident that its area $\int y \, dx$ will be equal to

$$\int \phi(o) \, dx + \int \phi(\tau) \, dx + \int \phi(2\tau) \, dx + \&c.;$$

and, therefore, the sum of this series, from the term $\tau \times \phi(o)$ to $\tau \times \phi(\tau)$, will be equal to the integral $\int \phi(x) \, dx$, from $x = 0$ to $x = \tau$. Thus our series will assume the form of a definite integral, viz.

$$A \cdot \{M \cdot \cos n(t - x) \cdot N \cdot \sin n(t - x)\},$$

expressing in the manner now pretty general the limits of the integral by indices attached to the integral sign. Resolving now the sines and cosines of $n(t - x)$, this becomes $(x$ and $t$ being independent of each other)

$$A \cdot \{M \cdot \cos nx - N \cdot \sin nx\} + \int A \cdot \sin n t \cdot \cos n x \cdot dx \cdot F(x) \{M \cdot \cos n x - N \cdot \sin n x\},$$

Now, whatever be the law of degradation denoted by the function $F$, it is clear that these definite integrals must at last reduce themselves to certain constants independent of $t$, which, if we call $P$ and $Q$, the whole takes the simple form

$$P \cdot \cos n t - Q \cdot \sin n t,$$

which is a periodic function having the same period as the primary vibrations.*

In the limiting case, when the elasticity of the body on which the forced vibrations are impressed is perfect, and resistance, friction, and every other cause of loss of motion is prevented, $F$ represents a constant, and is equal to unity. In this case both the constants $P$ and $Q$ in the above expressions vanish, and the whole motion

* This demonstration being general, we may here observe, that, on the undulatory theory of light, rays of one refrangibility can never excite by any combination of their own vibrations with those of the bodies they may traverse or impinge on, any resultant rays of a different refrangibility, at least so long as the exciting light continues in action. When it has ceased, the case may be otherwise.
of the body, after a great number of vibrations have elapsed, is zero. In this case then, the elastic body is completely incapable of vibrating in sympathy with any other not having a common mode. In all others, \( P \) and \( Q \) have finite values, which will be greater, or less, according to the circumstances of the case.

Thus we see that imperfect elasticity, or other equivalent causes of the gradual loss and dissipation of the impressed impulses, is the essential condition on which forced vibrations in general depend, and that in proportion as a disc or membrane is devoid of tension it should be more readily susceptible of such vibrations: precisely what M. Savart has shown to be really the case in fact.

It may be objected to what is said in Art. 321, that it would follow from that reasoning that the Sound of a vibrating disc should be inaudible whenever the ear is situated in a plane passing through one of its nodal diameters, and at right angles to the disc. But, in the first place, what is there said applies only to such motions of the aeriform particles as are performed in those planes. But, in fact, a lateral motion, or one parallel to the disc's surface, must also exist, by reason of the alternate tilting up and down of adjacent ventral segments, which must give the whole body of air terminated by them a small reciprocating rotary motion about the nodal line separating them as an axis. Thus, though the transverse vibrations are here destroyed, the sensation of Sound may still be excited by tangential ones. And, secondly, though alternate motion were altogether destroyed, condensations and rarefactions still subsist.

But, in fact, there is observed a difference in the intensity of Sound emanating from vibrating bodies in certain cases, according to their angular position with respect to the line joining them and the ear. We have already (Art. 117.) described Dr. Young's remarkable experiment of the tuning-fork. It is precisely a case in point, and a circumstantial explanation of it will be at once interesting for its own sake, and illustrative of the general argument. Let then \( A, B \), fig. 171, be sections of the two branches of the fork in its state of rest, and since when set to vibrate the disc approaches to and recedes from each other, let us consider them first in their state of approach, as at \( \alpha \). In this state they compress the air between them, and squeeze it out laterally in the direction of the arrows \( P, Q \); while, at the same instant, the aural particles adjacent to the flat outward faces of the two branches, and which of necessity follow their motions, are urged inwards as indicated by the arrows \( R, S \). Thus the four quadrants of the initial circular wave propagated round the fork, are alternately in opposite states of motion, the molecules at \( P, Q \) receding from the centre, while those at \( R, S \) approach to it, and vice versa, when the branches of the fork having closed to the utmost begin to open again. In this case the lateral air will rush in to fill the gap, while that in contact with the broad faces will be forced outwards. If then we consider any intermediate point \( C \), about 45° distant from \( Q \) and \( R \), this, in virtue of both impulses, will acquire a maximum of intensity, at a point where their intensity is nearly equal to that close to the source of Sound. Removing the membrane yet further, a new point of indifference is found, and so on till we reach the end of the chamber. If we walk along the same line, keeping the ear in the plane of the horizontal axis of the resonant cylinder, we shall perceive the Sounds to be much louder in the places where the vibrations of the membrane attain their maxima, than at the intermediate points where they are at a minimum. At these latter, a very curious phenomenon has been observed by M. Savart. When the auditor moves his head away from such a point, towards the right, (always supposing it to remain in the line of the axis above mentioned,) the Sound will appear to come from the right, and if towards the left, it will seem to come...
Sound. from the left, whether the original source of Sound be to the one or the other side. This singular effect shows that the aerial molecules on either side of the point of indifference, are in opposite states of motion at any given instant. In making this experiment, it should be so turned, that the axis of the resonant cylinder prolonged shall pass through both ears. Suppose, for instance, the Sounding apparatus to be to the observer’s left, and that his head be very near it. The Sound will appear to enter at his left ear. As he removes further away, so as to pass one of the nodes, it will seem as if the Sound had changed sides, and now came from the right. When another node is passed, it will appear to have again shifted to the left, and so on.

335. But, if we quit the axis of the cylinder, and carry an exploring membrane, such as already described, about the apartment, noting all the points where it vibrates most forcibly, allowing ourselves, as it were, to be led from spot to spot by its indications, we shall trace out in the air of the room a curve of double curvature marking the maxima of the excursions of the aerial molecules. If the experiment be made in a gallery, or passage, whose length is its principal dimension, this curve will be found to be a kind of spiral, creeping round the walls, floor, and ceiling, obliquely to the axis of the gallery, thus presenting a marked analogy to the disposition of the nodal lines in a long rod vibrating tangentially, (vide Art. 313.); which are also, it should be remarked, imitated, with modifications more or less complicated, in square or rectangular rods.

336. A still more remarkable effect was observed by M. Savart, in thus exploring the vibrations of the air in an apartment with an open window. The spiral disposition of the vibrating portions was found to be continued out of the window into the open air, the lines of greatest intensity running out in great convolutions which seemed to grow wider, on receding from the window, and could be traced to a great distance from it.

337. The vibrations of the air in an organ-pipe were explored by M. Savart, by lowering into the pipe, placed vertically with its upper end open, a thin membrane stretched on a light ring, and suspended by a fine silk thread, and strewed with sand. Thus ocular demonstration of the existence of its subdivision into distinct ventral segments was obtained, the sand remaining undisturbed when the membrane occupied precisely the place of a node. By this means, too, the influence of the embouchure on the places of the nodes, a curious and delicate point in the theory of pipes, which we have not before alluded to, may be subjected to exact examination. Thus, for instance, when the column of air in the pipe vibrates in the manner described, Art. 196, fig. 19. having two half ventral segments, and one node in the middle, it is found that the node is only approximately so placed, being always, in fact, nearer to the embouchure than to the open end.

338. It is well known that if we sing near the aperture of a wide-mouthed vessel, some one note (which in unison with the air in the vessel) will be reinforced and augmented, and sometimes to a great degree. This is what is meant by the resonance of the mass of air contained in the cavity of the vessel, or as it may be termed, the resonance of the cavity. This has been known from the earliest times. The ancients are said to have placed large brass jars under the seats of their immense theatres to reinforce (one does not well see how) the voices of the actors. Any vessel or cavity may be made to resound by placing opposite its orifice a vibrating body, having a surface large enough to cover the aperture, or at least to set a considerable portion of the aerial stratum adjacent to it in regular oscillation, and, at the same time, pitched in unison with the note which the cavity would of itself yield. The experiment of the disked tuning-fork, in Art. 204, is a case exactly in point. The pipe which resounds in that experiment, may be pitched precisely in unison with it by its stopper, and in proportion as it departs from a perfect unison the resonance is feeble. A series of disked tuning-forks, or vibrating steel springs, thus placed over the orifices of pipes carefully tuned, constitutes a very pretty musical instrument, capable of a fine swell and fall according as the discs are brought nearer to, or further from, the orifices of the pipes, or inclined to their axes, and of remarkable purity and sweetness of tone. A similar adaptation of resonant cavities to a series of harmonics glasses fixed on a common revolving axis, has been recommended by M. Savart as the principle of a musical instrument, whose effect, should it be found to answer the expectations his description of the tones thus drawn forth is calculated to excite, would probably surpass that of all others yet invented. See Art. 333. The cavities best adapted to this purpose are short cylinders of large diameters with movable bottoms fitting by tight friction by which they may be tuned.

339. Such cavities may be regarded as short organ-pipes. When the diameter of a pipe is greatly increased in proportion to its length, so that it becomes a box, the law of the proportionality of the time of vibration to the length ceases to hold good, and the note yielded is flatter than that of a narrow pipe of equal length, and the more so the wider the pipe. Thus M. Savart found that a cylinder of 4½ inches in length, and 5 in diameter, resounded in unison with a narrow pipe 6 inches long, making 1024 vibrations per second. That sagacious experimenter has found, that cubical boxes speak with surprising promptitude and facility, and yield Sounds extremely pure, and of a peculiar quality, on which account, and by reason of the little height in which they may be packed, he recommends them for organ-pipes. A cube of 53 or 54 lines (= 4½") in the side yields the same note as a pipe 10 or 11 inches long, and 2 or 2½ inches diameter. They may be excited by an embouchure at one of their lower edges, precisely similar to that of an organ-pipe. But they will also speak if the embouchure be situated in the middle of the side. M. Savart has also examined the vibrations of a great variety of different-shaped pipes, boxes, or cavities, for which see Annales de Chimie, vol. xxix. p. 404.

340. There is yet another remarkable case of vibrations communicated between the different members of a system of which we have not yet spoken, though offering a good example of the verification of the general law of equality of period and parallellism of direction of the vibratory motions of all the molecules of a system laid down in Art. 302. It is when vibrations are communicated through a liquid. The following experiments of M. Savart will show in which this is effected. He took a cylindrical tinned iron vessel whose bottom was placed parallel to the horizon, and having cemented its centre a glass rod, so as to hang perpendicularly down from it, he covered the bottom to the depth of about an inch and a half with water, on which was floated a thin disc of varnished wood, covered on its upper
Sound. The apparatus thus prepared, he impressed on the glass rod a longitudinal-tangential vibration, (Art. 296,) which of course became normal when communicated to the bottom of the vessel, and observed the sand on the upper face of the disc to be also agitated with normal motions, and to assume nodal figures according to the laws of that species of motion. To show more clearly the nature of the communication, he threw out the water, and supported the wooden disc by a small solid stem perpendicular to its surface, and the bottom of the vessel, and attached to the centres of both, when it was found that the disc was affected precisely in the same way as before.

On a vessel of water, whose rim is maintained in a state of normal vibration by a bow drawn perpendicularly across it at any point, let a thin rectangular lamina of wood be floated, having its length parallel to the bow, and its extremity opposite to the point of the circumference excited. The lamina will be seen (as usual by sand strewn on its upper face) to execute longitudinal-tangential vibrations, and will be crossed by nodal lines at right angles to its length. But if, instead of directing the axis or longer edges of the lamina perpendicularly to the vibrating point of the side of the vessel, we incline it obliquely to the direction of the vibrations, still the sand on its upper face will continue to glide in the same direction as before, that is, parallel to the vibrations of the side of the vessel, so that, if the floating lamina be made to revolve slowly in a horizontal plane, the direction of the creeping motion of the sand on its surface will continually vary with respect to the position of its edges, though constant with regard to the sides of the vessel.

Not only are the vibrations thus faithfully transferred through the water to bodies floating on its surface, but even to such as are totally immersed in it. The experiment is easily made by suspending in such a vessel as above described under the water, and not in contact with the sides or bottom, a disc of glass, by means of fine silk threads, and strewn sand on the surface of the water which sinks and spreads evenly on the disc. This will be observed to be agitated with very decided normal, or tangential motions, according as the former or latter of the modes of excitement used in the experiments, Arts. 341, 342, is employed; and to arrange itself in nodal figures accordingly.

From these and similar experiments it appears that vibratory motions are communicated through liquids precisely as through gases and solids, without change of character or direction. This, observes M. Savart, explains how the nerves of hearing, extended throughout the convolutions of the labyrinth and immersed in the liquid which fills it, transmit to the sensorium, not only the general impression of Sound, but of the direction in which it comes.

These remarkable and striking results all tend to confirm and strengthen the analogy between Sound and Light. The luminiferous ether, like air and liquids, transmits vibrations without altering their direction, as the phenomena of polarized light demonstrate. The additional weight of evidence thus thrown into the scale of the undulatory theory of light did not escape the penetrating mind of Dr. Young, to whom that theory was so deeply indebted. Doubtless the analogy thus ascertained would not have remained idle in his hands, had not death snatched him too from science while in the vigour of his intellect, and when so much might have yet been hoped from him. It has been our unprecedentedly unfortunate lot, while composing these Essays on the sister sciences of Light and Sound, to have to deplore the loss of nearly all the great modern contributors to their advancement. A Frauenhofer, a Fresnel, a Wollaston, and a Young, names forming an epoch in the history of human knowledge, have been snatched away in quick and alarming succession, not enfeebled by age or with faculties weakened by disease, but all in the meridian of their intellectual powers, or in that rich maturity when practice had only familiarized them with their resources, and perfected them in their use. To Dr. Young the theory of Sound is in many respects deeply indebted, and it richly repaid the attention he devoted to it by furnishing him with the pregnant idea of the establishment which alone would suffice to place him in the highest rank of scientific immortality, even were his other almost innumerable claims to such distinction disregarded.

§ III. Of the Voice.

Almost every animal has a voice or cry peculiar to itself, originating in an apparatus destined for that purpose of more or less complexity. The voice is most perfect and varied in man and in birds, which, however, differ extremely in the degree in which they possess this important gift. In quadrupeds, it is limited to a few uncouth screams, bellows, and other noises, perfectly unmusical in their character, while in many birds it assumes the form of musical notes of great richness and power, or even of articulate speech. In the human species alone, and that only in some rare instances, we find the power of imitating with the voice every imaginable kind of noise, with a perfect resemblance, and of uttering musical tones of a sweetness and delicacy attainable by no instrument. But in all, without exception, (unless, perhaps, the chirp of the grasshopper, or cricket, be one,) the Sounds of the voice are produced by a wind instrument, by the column of air contained in the mouth, throat, and anterior part of the windpipe, set in vibration by the issue of a stream of air from the lungs through a membranous slit in a kind of valve placed in the throat. In man and in quadrupeds, this organ is single, but in birds, as M. Savart has shown, it is double; a valve of the kind abovementioned being placed at the opening of each of the two great branches into which the trachea first divides itself as it enters the lungs, just before they unite into one common windpipe.

The organs of the voice, in man, consist of

1. The thorax, which, by the aid of the diaphragm and the 24 intercostal muscles acting on the lungs within, and alternately compressing and dilating them, performs the office of a bellows. The thorax.
The trachea, a cartilaginous and elastic pipe which terminates in the lungs by an infinity of roots, or bronchies, and whose upper extremity is formed into a species of head called the larynx situated in the throat, composed of five elastic cartilages, of which the uppermost is called the epiglottis, whose office is to open and shut, like a valve, the aperture of the exterior glottis, and which constitutes the orifice of the larynx.

3. The epiglottis, where it adheres to the larynx, is also united to the tongue, and forms a somewhat concave valve, of a parabolic form, whose base is towards the tongue, and which, by its convexity, resists the pressure of the food and liquids as they pass over it in the act of swallowing.

4. Within the larynx, rather above its middle, between the thyroid and arytenoid cartilages, are two elastic ligaments like the parchment of a drum slit in the middle, and forming an aperture making a right angle with the exterior glottis, and which is called the interior, or true glottis. This slit, in adults, is about four-fifths of an inch long, and a twelfth of an inch broad. This aperture is provided with muscles which enlarge and contract it at pleasure, and otherwise modify the form of the larynx.

5. The tongue, the cavity of the fauces, the lips, teeth, and palate, with its column pendulum, and the uvula, a pendulous, conical, muscular body, which performs the office of a valve between the throat and nostrils, as well as, perhaps, the cavity of the nostrils themselves, are all concerned in modifying the impulse given to the breath as it issues from the larynx, and producing the various components and vowels, according to the different capacities and shapes of their internal cavity.

In speaking or singing, the glottis, it has been generally supposed, performs the part of a reed. The membranes of which it is composed being kept at a greater or less state of tension by the muscles with which it is provided, and its opening expanded or contracted according to the degree of gravity or acuteness of the sound to be uttered. But the tone thus originally produced by the glottis is sustained and reinforced by the column of air in the larynx, throat, and mouth, whose dimensions and figure are susceptible of great variation by the action of the innumerable muscles which give motion to this complicated and intricate part of our frame. Thus in a general way we may conceive how the voice is produced and modified; but when we would penetrate further into particulars, the difficulties presented by the organs of the voice are even greater than those which beset the investigation of those of bearing.

One material one has been lately much elucidated by the experimental researches of M. Savart. How, we may naturally ask, can tones of such gravity as we hear produced by the human voice, be excited in so short a column of air as that contained in the throat of a man? The vibrating column here hardly exceeds a few inches in length, yet the notes produced by a bass singer are those which would require a pipe of several feet in length sounded in the usual manner. That it is not a mere relaxation of the membrane of the glottis is evident; the dropping of the lower jaw, and the effort made in every possible way to increase the dimensions and diminish the tension of the throat and fauces generally, in singing the lower notes of the scale, sufficiently prove that the note of the glottis is reinforced in this case, as in that of acuter Sounds, by the resonance of the cavity in which it sounds.

From M. Savart's experiments it appears that in short pipes, and cavities whose other dimensions bear a considerable ratio to their length, the tone yielded is rendered much graver when the pipe or cavity is constructed of a flexible material capable of being agitated and set in vibration by the air, than when made of more rigid materials. He constructed a cubic box-pipe with paper stretched on slight square frames of wood, joined together at the edges, and made it speak by an embouchure at the edge. He then observed, that so long as the paper was tightly stretched the Sound yielded by the cube was nearly as acute as it would have been had the whole been rigid, but that when its tension was diminished by exposing it to moist vapour, or even by wetting it, the Sound descended in the scale by an interval proportioned to the degree of moisture the paper had imbibed. It was thus lowered ever two whole octaves, when it grew so feeble as to be no longer audible; but, repeating the experiment in the still of night, it could yet be heard, and no limit indeed then seemed set to the descent of the Sound; and even when no longer audible the vibration of the paper sides could still be made sensible by sand strewned on them, which arranged itself in nodal lines, for the most part elliptic or circular.

The relaxation then, or increase of tension of the soft parts which form the cavity of the mouth and larynx, is no doubt a principal cause of the graduation of its tones. Whoever will sing open-mouthed before a looking-glass will not fail to be struck with the extraordinary contraction of the uvula (a small pendulous substance which seems to hang down from the roof of the mouth) which takes place in the higher notes. It shrinks up almost into a point, and every surrounding part seems to partake its tension.

We have observed that the glottis has been most generally regarded as performing the functions of a reed, especially since the free reed (ame che libre) invented by Kratzenstein, and revived by Grenié, (probably without knowledge of Kratzenstein's prior invention; vide Willis, Phil. Trans. Camb. vol. iii.) has been brought into general notice. This idea is strongly advocated among others by Biot. But M. Savart professes himself dissatisfied with such an explanation of its use. He remarks, and seemingly with justice, that the essential principle of a reed, the periodic opening and closing of the orifice through which the stream of air passes, is wanting in the glottis. Were the glottis a reed, the edges of the vocal ligaments which form the slit through which the air passes would require to be almost in contact, and should be alternately forced asunder by the effort of the air, and brought together by their tension. But on the contrary he found that the larynx of the dead subject, when left in its natural state, and gently blown into through the trachea, yielded Sounds approaching to those of the voice, although the opening left between the borders of the glottis was as much as one-sixth, or even one-fourth of an inch, and more than half an inch long.

The instrument to which M. Savart attributes the greatest analogy to the larynx, is a species of whistle, common enough as a children's toy or even as a sportsman's call, in the form of a hollow cylinder about three-fourths of an inch in diameter, closed at both ends by flat, circular plates, having holes in their centres. The form is not of
march importance, it may be made hemispherical, &c. Being held between the teeth and lips, the air is blown through it, and Sounds are produced which vary in pitch with the force of the blast. If the air be conducted to it through a portmi vent, and cautiously graduated, all the Sounds within the compass of a double octave may readily be obtained from it; and if great precautions are taken in the management of the wind, tones even yet graver may be educed, so as to admit, in fact, no limit in this direction.

When we come to investigate the nature of articulate Sounds, and of speech, the difficulties are much greater. Conrad Amman, in his work on the Voice, first attempted to explain the manner in which the vowels and consonants are formed. With regard to the vowels, he regards them as mere modifications of the continued tone produced by the larynx, depending on the configurations of the mouth. Thus to pronounce A (the broad A in Ah!) the tongue must be laid flat in the lower jaw, and the mouth opened wide, and lips turned outwards. Any musical or continued tone produced in the throat will then have the character of the vowel A. If the tongue be gradually elevated so as to bring its middle nearer the palate, and at the same time thrust forwards, its extremity approaching the upper teeth, the Sound will deviate from the broad A into a (hate,) e (peep.) These Sounds therefore (the a in hate, and the e in peep) he calls dental vowels. On the other hand, if, the tongue remaining as before, the lips be thrust out and drawn together, preserving as great an interior cavity of the fauces as possible, we shall have the Sounds of the vowels in all, hope, poor, wood. These he calls labial vowels, &c. These distinctions are to a certain extent correct and reasonable, but they give us no insight into the question, What it is which constitutes the essential distinction between vowel and vowel, and on what part of the mechanism of the voice do Sounds depend?

Pursuing this idea, Mr. Willis has lately entered more extensively into the subject, and, in a Paper recently printed in the XXIst volume of the Journal de Physique, p. 358. His principle consisted in the adaptation of a reed in all essential respects similar to Grenié's, where the tongue passes to and fro through the slit without contact, to a set of pipes of peculiar forms, some of them very odd ones, and for whose shapes no other reason could be given than their success on trial. This, however, was a great step. It showed the vowel quality of a Sound to be something distinct from mere pitch, and susceptible of being produced at pleasure by mechanical artifice.

This may be the place to remark the extreme imperfection of our written language in its representation of vowels and consonants. We have six letters which we call vowels, each of which, however, represents a variety of Sounds quite distinct from each other, and while each encroaches on the functions of the rest, a great many very good simple vowels are represented by binary or even ternary combinations. On the other hand, some single vowel letters represent true diphthongs, (as the long sound of i in alike, and that of u in rebuke,) consisting of two distinct simple vowels pronounced in rapid succession, while, again, most of what we call diphthongs are simple vowels, as bleak, thief, loud, &c. This will render an enumeration of our English elementary Sounds, as they really exist in our language, no matter how written, not irrelevant. We have therefore assembled in the following synoptic table sufficient examples of each to render evident their nature, accompanied with occasional instances of the corresponding Sounds in other languages. The syllables which contain the Sounds intended to be instanced are printed in italics where words of more than one syllable are instanced.

True Diphthongs.

1. Life; The Sounds No. 5 and No. 12, slurred as rapidly as possible, produce our English i, which is a real diphthong.
2. Brow; Plough; Laufen, (Germ.) The vowel Sound No. 5 quickly followed by No. 1.
3. Oil; Klusen, (Germ.) No. 4 succeeded by No. 13.
4. Rebuke; Yew; You; No. 18 succeeded by No. 1.
5. Yoke; No. 13 succeeded by No. 3.
6. Young; Yearn; Hear; Here; No. 13 succeeded by No. 2 more or less rapidly.

v.--- through it, and Sounds are produced which vary in pitch with the force of the blast. If the air be conducted to it through a portmi vent, and cautiously graduated, all the Sounds within the compass of a double octave may readily be obtained from it; and if great precautions are taken in the management of the wind, tones even yet graver may be educed, so as to admit, in fact, no limit in this direction.

When we come to investigate the nature of articulate Sounds, and of speech, the difficulties are much greater. Conrad Amman, in his work on the Voice, first attempted to explain the manner in which the vowels and consonants are formed. With regard to the vowels, he regards them as mere modifications of the continued tone produced by the larynx, depending on the configurations of the mouth. Thus to pronounce A (the broad A in Ah!) the tongue must be laid flat in the lower jaw, and the mouth opened wide, and lips turned outwards. Any musical or continued tone produced in the throat will then have the character of the vowel A. If the tongue be gradually elevated so as to bring its middle nearer the palate, and at the same time thrust forwards, its extremity approaching the upper teeth, the Sound will deviate from the broad A into a (hate,) e (peep.) These Sounds therefore (the a in hate, and the e in peep) he calls dental vowels. On the other hand, if, the tongue remaining as before, the lips be thrust out and drawn together, preserving as great an interior cavity of the fauces as possible, we shall have the Sounds of the vowels in all, hope, poor, wood. These he calls labial vowels, &c. These distinctions are to a certain extent correct and reasonable, but they give us no insight into the question, What it is which constitutes the essential distinction between vowel and vowel, and on what part of the mechanism of the voice do Sounds depend?

In 1779, the Imperial Academy of Peterburgh proposed as one of their prize questions, an inquiry into the nature of the vowel sounds A E I O U, and the construction of an instrument capable of artificially imitating them. The prize was awarded to M. Kratzenstein, whose curious Memoir on the subject the reader may find in the XXIst volume of the Journal de Physique, p. 358. His principle consisted in the adaptation of a reed in all essential respects similar to Grenié's, where the tongue passes to and fro through the slit without contact, to a set of pipes of peculiar forms, some of them very odd ones, and for whose shapes no other reason could be given than their success on trial. This, however, was a great step. It showed the vowel quality of a Sound to be something distinct from mere pitch, and susceptible of being produced at pleasure by mechanical artifice.

Pursuing this idea, Mr. Willis has lately entered more extensively into the subject, and, in a Paper recently printed in the XXIst volume of the Transactions of the Cambridge Philosophical Society, has succeeded in educating all the vowel Sounds by a mere combination of a reed on Kratzenstein's construction with a cylindrical pipe of variable length, and investigating the laws of their production.

This may be the place to remark the extreme imperfection of our written language in its representation of vowels and consonants. We have six letters which we call vowels, each of which, however, represents a variety of Sounds quite distinct from each other, and while each encroaches on the functions of the rest, a great many very good simple vowels are represented by binary or even ternary combinations. On the other hand, some single vowel letters represent true diphthongs, (as the long sound of i in alike, and that of u in rebuke,) consisting of two distinct simple vowels pronounced in rapid succession, while, again, most of what we call diphthongs are simple vowels, as bleak, thief, loud, &c. This will render an enumeration of our English elementary Sounds, as they really exist in our language, no matter how written, not irrelevant. We have therefore assembled in the following synoptic table sufficient examples of each to render evident their nature, accompanied with occasional instances of the corresponding Sounds in other languages. The syllables which contain the Sounds intended to be instanced are printed in italics where words of more than one syllable are instanced.

True Diphthongs.

1. Life; The Sounds No. 5 and No. 12, slurred as rapidly as possible, produce our English i, which is a real diphthong.
2. Brow; Plough; Laufen, (Germ.) The vowel Sound No. 5 quickly followed by No. 1.
3. Oil; Klusen, (Germ.) No. 4 succeeded by No. 13.
4. Rebuke; Yew; You; No. 18 succeeded by No. 1.
5. Yoke; No. 13 succeeded by No. 3.
6. Young; Yearn; Hear; Here; No. 13 succeeded by No. 2 more or less rapidly.
The consonants present equal confusion. They may be generally arranged in three classes: sharp Sounds, flat ones, and indifferent or neutral. The former two having a constant relationship or parallelism to each other, thus:

**Sharp Consonants.** S. sell, cell; t. (as we will here denote it) shame, sure, schirm, (Germ.); θ. thing; F fright, enough, phantom; K. king, coin, quiver; T. talk; P. Papa.

**Flat Consonants.** Z. zenith; cæment; Ç. pleasure, jardín, (French); ː the ː in the words the, that, thou; V. eile; G. good; D. duke; B. babe.

**Neutral Consonants.** L. lily; M. mamma; N. Nanny; v. hang; to which we may add the nasal N in gnw, Aïtna, Dnieper, which, however, is not properly an English Sound. R. rattle; H. hard.

**Compound Consonants.** C. or T. church, cicerone, (Ital.) and its corresponding flat sound J. or D ʃ, jest, gender; X. extreme, Xerxes; æ. esraperate, exalt, Xerxes; &c. &c.

We have here a scale of 13 simple vowels and 21 simple consonants, 33 in all, which are the fewest letters with which it is possible to write English. But on the other hand, with the addition of two or three more vowels, and as many consonants, making about 40 characters in all, every known language might probably be effectually reduced to writing, so as to preserve an exact correspondence between the writing and pronunciation; which would be one of the most valuable acquisitions not only to philologists but to mankind, facilitating the intercourse between nations, and laying the foundation of the first step towards a universal language, one of the great desiderata at which mankind ought to aim by common consent.

This enumeration will serve to show what are the difficulties which any one must contend with in constructing, what has been often attempted, a talking engine. Still the partial success obtained by Kratzenstein, and about the same time by Kempelen, who has given a very curious account of his experiments in Mécanisme de la Parole, ought to encourage further trials.

To return, however, to Mr. Willis's curious and novel researches. He relates that, having provided an apparatus consisting of a wind-chest, or reservoir, connected with a pair of double bellows, and opening into a port-cant, having a free reed, on Kratzenstein's, or Grenié's construction, at its termination, his first object was to verify Kempelen's account of the vowels. He therefore adapted his reed to the bottom of a funnel-shaped circular cavity, open at top, as in fig. 172, which represents a section of the apparatus, and on making the reed speak, and placing his hand in various positions pointed out by Kempelen within the funnel, he obtained the vowels A (No. 5.), E (No. 10.), I (No. 13.), O (No. 8.), U (No. 1.) very distinctly. On using, however, a shallower cavity these positions became unnecessary, and the hand might, he found, be replaced by a flat board slide over the mouth of the cavity; and by using a very shallow funnel, as represented in fig. 178, he succeeded in obtaining the whole series in the order U (No. 1.), O (No. 8.), A (No. 5.), E (No. 10.), I (No. 13.)

Being thus led away from Kempelen's experiment, he proceeded to try the effect of adapting to the reed cylindrical tubes, whose length could be varied at pleasure by sliding joints. This was easily accomplished by fixing the reed with its port-vent into the end of a pretty long horizontal pipe coming off from the wind-chest, over which on its outside a tube, open at both ends, was made to slide on leather wrapped round it in the manner of a piston, and capable of being lengthened, by the attachment of pieces of similar tube of its own length, to any extent. He thus describes the results so obtained. Let a b c d represent the length of the outer, or sounding pipe, projecting beyond the reed, and take a b, b c, c d, &c. equal to the length of a stopped pipe in union with the reed employed, that is equal to half the length of the sonorous wave of the reed. If, now, the pipe be drawn out gradually, the tone of the reed, retaining its pitch, first puts on in succession the vowel qualities I E A O U. As the length approaches to a c the same series makes its appearance in an inverted order, as represented in the diagram, then on passing the length a c in direct order again, and so on in cycles, each cycle being merely a repetition of the foregoing, but the vowels becoming less and less distinct in each successive cycle, and the distance of any given vowel from its respective central points a, c, &c. being the same in all the cycles.

If another reed be adapted to the same pipes having a different fundamental Sound or sonorous wave, the same phenomena will be produced, only that the central points of the new cycles will now be at a distance from each other equal to the sonorous wave of the new reed, but the distances of the general vowel points from the centres of the respective cycles will be the same as before; so that, generally, if the reed wave a c = 2 a, and the length of the pipe which produces the first high vowel, from a, be equal to u, the same vowel will be constantly reproduced by a pipe whose length b = 2 n a ± v, n being any whole number.

When the pitch of the reed is high, so that the length a c of its wave is less than twice the distance a U corresponding to any vowel, all the vowels beyond that distance become impossible. If, for instance a c be less than 2 a U, but greater than 2 a O, the series will never extend so far as U, but on lengthening the pipe indefinitely the succession of vowels I E A O A E I will be repeated. If, in like manner, still higher notes be taken for the reed, more vowels will be cut off. This, Mr. Willis remarks, is exactly the case with the human voice: female singers being unable to pronounce U and O on the higher notes of their voices. For example, the proper length for a pipe to produce O is that which corresponds to the note C" two octaves above the middle C of a piano-forte, and beyond this note in singing it will be found impossible to pronounce a distinct O.

Cylinders of the same length, or more generally cavities of any figure resounding the same note, give the same vowel when applied to one and the same reed.

The following table is given by Mr. Willis as expressing the distances from the central points of the cycles at which the several vowels are produced in inches.
SOUND.

On this Table Mr. Willis observes that he does not despair of its completion and extension by future experiments, eventually furnishing Philologists with a correct measure for the shades of difference in the pronunciation of the vowels by different nations. One source of fallacious decision, however, it must be remarked, will subsist in its application, in the effect of contrast, on which much of the difference between vowels depends. Its influence indeed may be traced in the above Table itself. Thus Mr. Willis, assisted, no doubt, by the contrast arising from rapid and frequent transition, has been able to discriminate between the vowel Sounds yielded by pipes of the lengths 3.05 and 3.8, though the Sounds in the exemplifying words Paw and Nought, which he has chosen, are so closely allied that we confess our own inability to detect any shade of difference, for which reason we have designated them by the same number.

Mr. Willis terminates this highly interesting Paper with some curious experiments and remarks on the mutual influence of a reed and a pipe with which it is connected, as also of the port-vent, which conducts the air to it. If a reed be made to sound in a pipe of variable length (l), the Sound yielded by it will remain constant till the length (l) (beginning we will suppose from o becomes nearly equal to $\alpha$, or one quarter the length of the original Sound). The wave of the reed; here it begins to flatten, and as l is still increased, continues to do so till the length somewhat exceeds $\frac{3}{4} \alpha$, when it suddenly jumps back to a note a quarter of a tone sharper than the original Sound of the reed, to which it, however, soon again descends, and continues stationary till the length $l$ becomes nearly equal to $2a + \frac{3}{4} \alpha$, when the flattening again commences, and continues till $l$ exceeds $2a + \frac{3}{4} \alpha$, and so on periodically, but less decidedly. The total amount of flattening is usually a whole tone. A jerk of the bellows, or a too hasty lengthening of the pipe, will make the pitch spring back much sooner than it would do with cautious management, may, with proper dexterity it may be made to yield, just about the point of junction, a double note, composed of one flatter and one sharper than the reed would yield alone. Mr. Willis seems to think that in this case, however, the two Sounds are only quickly alternated so as to seem to go on at once. Examining the pipe in a glass pipe with a magnifier, he found their excursions diminished when the note was flattened or sharpened; but when the double Sound was educed, they were no longer well defined, but the tongue of the reed seemed thrown into strange convulsions. This recalls the experiment of Biot and Hamel described in Art 199.

Beng thus brought back to the subject of reeds and forced vibrations, we must not omit to recommend to our reader's attention the curious and elaborate dissertation of MM. Weber and Floss, entitled Leges oscillationis oriunda si duo corpora diversd celeritate oscillantia ita conjungantur ut oscilIare non possint nisi simul et syn-chronic exemplo illustrata Tuborum Linguatorum. A detailed comparison of their results with those of Mr. Willis, which the necessity of bringing this Essay to a close forbids us to enter into, would be very interesting. MM. Weber and Floss agree with him in the periodical recurrence of the note of the reed at equal intervals, and in its flattening up to a certain point, &c.; while in other points there is diversity of result enough to make a careful revision of the whole subject well worth while; though, perhaps, it is not more than may be accounted for by the different constructions of their reeds; in the one set of experiments the oscillations of the tongue of the reed having been executed parallel, in the other at right angles to the axis of the cylinder. It is somewhat curious, that they seem to have entirely overlooked the vowel quality of the Sounds educed, perhaps from not having employed sliding tubes, and thus missing the effect of contrast.

We had proposed to have devoted a section to M. Savart's recent elegant application of his delicate methods of detecting and exploring sonorous vibrations to the determination of the law of elasticity in different directions with respect to the axes of crystallized bodies; but it would lead us too far, and we must be content to refer our readers to the XLIIId volume of the Annales de Chimie for information. The field is a wide one, and it will, we doubt not, be long before it is fully explored.

* Let the reader pronounce slowly, and distinctly, the words Paw, Gnaw, Naughty, Nought, for his own satisfaction.
Neither shall we devote a separate section to the description and explanation of acoustic phenomena which occur in Nature. Many such, indeed, have been sufficiently noticed already. In Art. 23 we have explained satisfactorily the origin of thunder, and we shall here only remark that the subterraneous thunder which accompanies earthquakes may (at least in some cases) be ascribed to a general cause not very dissimilar, the successive arrival at the ear of undulations propagated at the same instant from nearer and remoter points, or if from the same points, arriving by different routes, through strata of different elasticities.

The concise and unblunted propagation of Sound through water, remarked by Messrs. Colladon and Sturm, is curiously exemplified by the shock of an earthquake felt and heard at sea. The sensation is always described as that of striking on a rock; the Sound as that of grating on a gravelly bottom; none of the hard, rough Sounds of the first impulse being at all softened or rounded by the distance.

There is, however, one natural phenomenon so very surprising, and to us, we confess, so utterly inexplicable, though resting on the authority of ear-witnesses of such credit that it is impossible to disbelieve the facts, that we cannot forbear inserting a short description of it, with which we shall conclude.

There is a place about three leagues to the North of Tor, in the neighbourhood of Mount Sinai in Arabia Petraea, called El Nakous, (Nakous is the name of a sonorous metal plate used in the Greek convents in the East instead of a bell) from musical Sounds of a very singular and surprising character heard there. It has been visited by very few Europeans, two of whom, however, Mr. Seetzen and Mr. Gray of Oxford, have published accounts of it, the former in the Monatliche Correspondenz, (Oct. 1812;) the latter in Dr. Brewster's Edinburgh Philosophical Journal, where also Mr. Seetzen's account of it will be found translated, which is as follows:

"After a quarter of an hour's walking, (from Wody El Nachel?) we reached the foot of a majestic rock of hard sandstone. The mountain was quite bare, and composed entirely of it. I found inscribed on it several Greek and Arabic names, and also some Gothic characters, which showed that the place had been visited for centuries. At noon we reached the part of the mountain called Nakous. There, at the foot of the ridge, we beheld an isolated peaked rock. Upon two sides this mountain presented two surfaces, so inclined, that the white and slightly adhering sand which covers it scarcely supports itself, and slides down with the smallest motion, or when the burning rays of the sun complete the destruction of its feeble cohesion. These two sandy declivities are about 150 feet high. They unite behind the insulated rock, and forming an acute angle, they are covered like the adjacent surfaces with steep rocks, which are mostly composed of a white and friable free-stone.

The first Sound was heard an hour and a quarter after noon. We climbed with great difficulty as far as the sandy declivity, a height of 70 or 80 feet, and stopped under the rocks where the pilgrims are in the habit of placing themselves to listen. In climbing, I heard the Sound from beneath my knees, and this made me think that the sliding of the sand was the cause, not the effect, of the sonorous motion. At three o'clock the Sound was heard louder, and it lasted six minutes, when, having ceased for ten minutes, it began again. It appeared to me to have the greatest analogy to the humming-top; it rose and fell like the Sound of the Æolian harp. To ascertain the truth of my discovery, I climbed with the utmost difficulty to the highest rocks, and I slid down as fast as I could, and endeavoured, with the help of my hands and feet, to set the sand in motion. This produced an effect so great, and the sand in rolling under me made so loud a noise, that the earth seemed to tremble, and I certainly should have been afraid, had I been ignorant of the cause.

"But how can the motion of the sand produce so striking an effect, and which is, I believe, produced nowhere else? Does the rolling layer of sand act like a fiddle-bow, which, on being rubbed upon a plate of glass, raises and distributes into determinate figures the dust with which the plate is covered? Does the adherent and fixed layer of sand perform the part of the plate of glass, and the neighbouring rocks that of the sounding body? Philosophers must decide this."

We give here M. Seetzen's account in preference to Mr. Gray's as being the earliest, and in his own words, preserving even his own conjectures (not the most plausible) on its cause, and we shall be glad if the visits of future travellers to the spot shall throw further light on this very strange phenomenon.

Slough, Feb. 3, 1830.

S O U N D.

Sound. 

Mode of its production, 352—357.

Voices, noises heard in their eruptions explained, 40.

Voices, enumeration of, 360. Willis, Kratzenstein, and Kempelen's researches on, 369, et seq.

For human organ-pipe, 206.

Willis, conveyance of sounds along, 36.

Walker, determination of velocity of sound by, 6.

Waves, in still water how propagated, 42. What, 44. In a field of corn, 45. Their velocity distinguished from that of their molecules, 46. Their breadth, 47. Various species of, 48. Sorous

YOUNG, Dr., his experiments and discoveries, passim. His experiment on the sound of a tuning-fork, 117. Its explanation, 332.
