1. **Electro-Magnetism** is that science which has for its object the investigation of the relation which subsists between Magnetism and Electricity. The discovery of such a relation is of very recent date, and the science itself can only be considered as in the earliest state of infancy.

§ I. **Brief outline of the history of the science.**

It was for many years suspected that there existed a strong analogy, if not a complete identity, between the electric and magnetic fluids, and various attempts were made to establish such relation on satisfactory principles. It was known, for instance, that lightning destroyed and reversed the polarity of magnetised needles, and that it produced a magnetic power in pieces of steel which had not before any such action. Now lightning and electricity have been long known to be identical; consequently, electricity ought to produce similar effects to lightning on magnetic and simple steel bars; but the attempts which were made to discover a satisfactory proof of this action, by means of the electric apparatus, were not attended with success; at least all that was effected in this way amounted only to communicating the magnetic property to steel bars, but without the experimenter being able to predict in what directions the poles would lie, and therefore was little more than might be produced by a blow, by twisting, and various other means. It was indeed stated that the magnetism was more fully developed when the shock was passed through the needle transversely, than when it passed lengthwise; but still no definite conclusions could be drawn from the experiments.

Philosophers having thus failed of tracing the analogy between the electric and magnetic fluids, by means of the electrical apparatus, had next recourse to the galvanic battery, which was known to possess electrical properties. Of these experiments, those of Ritter are the only ones of any importance. He stated that he had succeeded, by placing a louis d'or in contact with the extremities of a galvanic circuit, in giving to it a positive and negative electric pole, which remained after it had been in contact with other metals; he also magnetised a gold needle by means of the galvanic battery, and seems to have had some obscure ideas of electric terrestrial poles at right angles to the magnetic poles. These experiments, however, were never much regarded, and the relation between the two fluids seemed still to remain doubtful.

Soon after the time that Ritter made his experiments, Professor Oersted, of Copenhagen, published a work, (1807) in which the subject was again resumed, and the hypothesis brought forward, which ultimately conducted him to a successful result. After describing some analogies between magnetism and electricity, he arrives at this conclusion, viz. that, "In galvanism the force is more latent than in electricity, and still more so in magnetism than in galvanism; it is necessary therefore, to try whether electricity, in its latent state, will not affect the magnetic needle." It is extraordinary, after this idea had once been formed, that means were not taken by the author to submit it to the test of experiment, or if he did submit it, that he had not discovered at the time, the relation he was in search of; yet such was the case, for, from this time to 1820, we hear no further on the subject; but, in the course of the latter year, Mr. Oersted's attention seems to have been again called to the subject: he placed a magnetic needle within the influence of a wire, connecting the extremities of a voltaic battery; and which was now, for the first time, observed to deviate in different directions, and in different degrees, according to the relative situation of the wire and needle. Subsequent experiments proved, that the wire, of whatever metal it was composed, became, during the time the battery was in action, magnetic, and that it affected a magnetic needle through glass, and every other non-conducting body; but that it had no action whatever on a needle, similarly suspended, that was not magnetic.

This discovery opened a new field for philosophical
inquiry: notices of Mr. Oersted's experiments were transmitted to Paris, London, and to the several German universities, and, immediately, the most distinguished philosophers of Europe were engaged in the pursuit of this novel and interesting science. In France, the experiments were repeated and extended by MM. Biot, Arago, and Ampère; in Germany, by Professors Rive, Seebeck, Moll, and others, whose names will occur in the following pages; and in England, by Sir Humphry Davy, Professor Cumming, Mr. Faraday, and Mr. Barlow; the three former of whom had for their object to trace the relation between the two sciences of electricity and magnetism, and that of the latter, to reduce the laws of action to the principles of mathematics.

2. In the first instance, it was conceived that the greater the power of the battery, or the machine by which the electricity was excited, the greater would be the effects produced on the magnetised needle; and, accordingly, scarcely any attempted experiments, who had not at command a powerful galvanic apparatus. After some time, however, it appears that great tension of the electric fluid was not only unnecessary, but injurious to the effect produced; and that the most active power was found to proceed from single plates of considerable surface; and even single plates of very small dimensions were found more efficient than larger plates in high combination. In fact, the exhibition of the electro-magnetic effect on the needle, was soon reduced to such a state, that Professor Cumming constructed, on this principle, a galvanometer, which exhibits the existence of electricity, when in so low a state as to be inappreciable with the gold-leaf electrometer, and other delicate instruments proposed for this purpose; and thus a power, which had remained hidden for so many years, and which, after it had been discovered, was so difficult to exhibit, is all at once, as it were, become one of the most delicate tests of the existence, and measurer of the quantity of electricity in bodies under experiment.

3. Up to this period the attention of philosophers had been directed to the examination of the amount of the disturbance which the magnetic needle experienced on the approach of the galvanic wire; to the means of exciting magnetism in steel bars; to the representation of magnets by the galvanic wire under different forms; to the action of galvanic wires on each other; and, consequently to the nature of the force by which these effects were produced. Professor Oersted, who had made the discovery, and who was wholly indebted for his success to the preconceived theory he had entertained of the nature of electric action, conceived the force to proceed from what he denominated the 'conflict of the electricities,' proceeding from the opposite extremities of the battery. Mr. Ampère, on the other hand, attributed to peculiarities of action, to the electric current passing along the wire, and assumed, that magnets owed their peculiar properties to currents of electricity perpetually circulating about their axis. Professor Cumming and Mr. Barlow, without attempting to explain the mechanical means by which this mysterious power is brought into action, and, independent of each other, deduced that all the phenomena which a magnetic needle exhibits in the vicinity of a galvanic wire, might be explained, by assuming that every particle in the wire acts on those in the needle according to a tangential direction, and that every known fact might be illustrated by this hypothesis. The latter went still further, he demonstrated by experiments, which we shall detail, that if this tangential power was conceived to vary inversely as the square of the distance of the particles in the wire and needle from each other, that not only all the facts alluded to might be illustrated, but that they might be computed, and that the results agreed numerically with experiment.

4. Prior to this, however, Mr. Faraday, of the Royal Institution, had made a most interesting discovery; namely, that the nature of the force was such, that if a galvanic wire be freely suspended over the pole of a magnet, and the fluid passed through the wire, the latter will commence a rapid rotation about the magnet; and, on the contrary, the wire being fixed, and the magnet free, the latter will revolve about the former. This curious fact pointed out most distinctly, that the force, whatever it might be, was totally different from any that had yet come under the contemplation of philosophers, for no known natural force was competent to the production of a motion of rotation. The results of these curious experiments having been transmitted by the author to M. Ampère, he, in his turn, succeeded in causing the magnet to revolve about its own axis; and lastly, Mr. Barlow completed the set of rotatory experiments, by causing the wire also to revolve on its axis.

5. In this state of the science, every fact seemed to have been exhausted; the laws of disturbance and of rotation had been reduced to mathematical laws, and the effect of every new combination might not only be predicted as to direction, but computed as to quantity. At this time, however, some new facts were discovered by Professor Seebeck, of Berlin, not in respect to any new laws of action, but to a different process for exciting the electro-magnetic power, which was by the application of heat to the union of two dissimilar metals; this again opened a new field for investigation, and much that has been elicited on this head, is due to Professor Cumming, whose labours have been as conspicuous as the resources of his genius appear to be inexhaustible. He has examined, by means of the delicate instrument to which we have alluded, the numerical ratio, between the electrical powers of the different metals in contact, and has furnished some valuable tables of this description, to which we shall have to refer as we proceed. This has been described by the term Thermo-Electric-Magnetism, the preceding being termed Hydro-Electric-Magnetism, to distinguish the means by which the powers are excited in the two cases.

6. Another discovery still remains to be noticed in this novel and prolific branch of natural philosophy: it is well understood that two different metals were necessary for exciting the electro-magnetic action in the conducting wire, whether the excitation was produced by acids or by caloric; but Professor Moll, of Utrecht, has shown by some recent experiments, that this is not the case, for that one metal with acids will exhibit all the leading phenomena to which we have above referred.

7. The above is a very concise view of the present state of electro-magnetism; we shall now proceed to examine more particularly the discoveries of the different philosophers to whom we have referred, and to
§ II. Detail of electro-magnetic experiments, according to the order in which they have been made by the different authors.

1. Experiments of Professor Oersted.

8. The first experiments, in reference to date, as well as in the natural order of development, were those of the above distinguished philosopher; and which he published in the several journals of the continent, and in England, in nearly the following terms.

The galvanic machine being charged, and its poles connected by a wire of any metal, (which may be called the conductor, or uniting wire,) the following effects on a magnetized needle were produced.

Let the straight part of the wire be placed horizontally above the magnetic needle properly suspended, and parallel to it; the uniting wire, if necessary, being bent so as to assume a proper position for the experiment. Things being in this state, the needle will be moved, and the end of it next the negative side of the battery will go westward, (see fig. 1.) If the distance of the uniting wire does not exceed three quarters of an inch from the needle, the declination of the needle makes an angle of about 45°, and if the distance be increased, the angle diminishes proportionally. The declination likewise varies with the power of the battery.

The uniting wire may change its place, either towards the east or west, provided it continues parallel to the needle, without any other change of the effect than in respect to its quantity; consequently the effect cannot be ascribed to attraction; for the same pole of the magnetic needle which approaches the uniting wire, while placed on its east side, ought to recede from it when on the west side; if these declinations depended on attraction and repulsion. The uniting conductor may consist of several wires or metallic ribbons connected together, and the nature of the metal does not alter the effect, but merely the quantity.

Wires of platinum, gold, silver, brass, iron, ribbons of lead and tin, a mass of mercury, were employed with equal success. The conductor does not lose its effect though interrupted by water, unless the interruption amounts to several inches in length.

The effect of the uniting wire passes to the needle through glass, metals, wood, water, resin, stone ware, stones, for it is not taken away by interposing plates of glass, metal, or wood; even glass, metal, and wood, interposed at once, do not destroy, and indeed scarcely diminish the effect. The disc of the electrophorus, plates of porphyry, a stone-ware vessel, even filled with water, were interposed with the same result. The author found, indeed, the effects unchanged when the needle was included in a brass box filled with water; and this, it should be observed, is the first instance in which electricity was known to transmit its effects through non-conducting substances; and from which we may infer that it is not actually the electric fluid that is transmitted, but some power that is excited by its presence. If the uniting wire be placed in a horizontal plane under the magnetic needle, all the effects are the same as when it is above the needle, only they are in opposite directions; for the pole of the magnetic needle next the negative end of the battery then declines to the east, (fig. 2.)

That these facts may be more easily retained, we may use this formula, viz. the pole, above which the negative electricity enters, is turned to the west; under which, to the east.

If the uniting wire be so turned in a horizontal plane, as to form a gradually increasing angle with the magnetic meridian, the declination of the needle increases, if the motion of the wire be towards the place of the disturbed needle; but it diminishes if the wire moves further from that place. When the uniting wire is situated in the same horizontal plane as that in which the needle moves, and parallel to it, no declination is produced either to the east or to the west; but an inclination takes place, so that the pole, next which the negative electricity enters the wire, is depressed, when the wire is situated on the west side, and elevated when situated on the east side, (fig. 3.)

If the uniting wire be placed perpendicular to the plane of the magnetic meridian, whether above or below it, the needle remains at rest, unless it be very near the pole; in that case the pole is elevated when the entrance is from the west side of the wire, and depressed when from the east side, (fig. 4.)—Note. It Fig. 4. should be observed, that more recent experiments have shown that, with sufficient power, the needle is inverted in this position of the wire.

When the uniting wire is placed perpendicularly opposite to the pole of the magnetic needle, and the upper extremity of the wire receives the negative electricity, the pole is moved towards the east; but when the wire is opposite to a point between the pole and the middle of the needle, the pole is moved towards the west; but when the upper end of the wire receives positive electricity, the phenomena are reversed.

If the uniting wire be bent so as to form two legs parallel to each other, it repels or attracts the magnetic poles according to the different conditions of the case. Suppose, for example, the wire placed opposite to either pole of the needle, so that the plane of the parallel legs is perpendicular to the magnetic meridian, and let the eastern leg be united with the negative end, the western leg with the positive end of the battery; in that case, the nearest pole will be repelled either to the east or west, according to the position of the plane of the leg; but the eastern leg being united with the positive, and the western with the negative side of the battery, the nearest pole will be attracted. When the plane of the legs is placed perpendicularly to the place between the pole and the middle of the needle, the same effects recur, but reversed.

A brass needle, suspended like a magnetic needle,
ELECTRO-MAGNETISM.

is not moved by the effect of the uniting wire. Needles of glass and of gum lac, remain likewise quiescent.

Such were the first discoveries of this interesting and popular science.

Subsequent experiments by Oersted.

9. Mr. Oersted did not, however, stop here; he pursued the experiments he had so happily begun, and discovered, independent of what was going forward in Paris, that the magnetism excited by electric action, resembled that of the magnet itself, so far as it directed the magnetic meridian; or, in other words, that such a combination was, as the needle itself, under the direction and influence of the terrestrial magnetism; a discovery, however, in which he had been anticipated by Ampère.

To Professor Oersted we also owe the important discovery, that electro-magnetic effects do not depend upon the intensity of the electricity, but solely on its quantity. He found that a plate of zinc, six inches square, immersed into a copper vessel containing the dilute acid, produced a considerable magnetic effect; but when the plate had 100 square inches surface, it acted upon the needle with such force, that the effects upon it were visible at the distance of three feet; and when forty such troughs were employed, the effect was found to be rather diminished than increased.

In making these experiments, the difference in the direction of the currents, between a simple combination of two plates, and that of a compound battery, presented itself, and is thus explained by the author: "Let fig. 5, represent a galvanic arc, composed of one piece of zinc z, a piece of copper c, a metallic wire a b, and a fluid conductor l. The zinc always communicates a portion of its positive electricity to the water, as the copper does of its negative electricity, which would produce an accumulation of negative electricity in the upper part of the zinc, and of positive electricity in the upper part of the copper, if the communication by a b did not reestablish the equilibrium, by presenting a free passage to the negative electricity from g to c, and of the positive electricity from c to g; the wire a b, therefore, receives the negative electricity of the zinc, and the positive electricity of the copper; whereas a wire which forms a communication between the two poles of a battery, receives positive electricity from the pole of the zinc, and negative from that of the copper.

If we attend to this distinction, says Mr. Oersted, we may, with a single galvanic arc, arranged as I have described, repeat all the experiments which I had before made with a compound galvanic apparatus. One great advantage of this plan is, that we may form the arc sufficiently light to be suspended by a small metallic wire, so as to revolve round the axis of the wire prolonged; and in this way we may examine the action of a magnet on the galvanic arc.

For this purpose I employed the arrangement, in fig. 6, which is a perpendicular section of it in the direction of its breadth, c c c c being a trough of copper, three inches high, four inches long, and half an inch wide, z z a plate of zinc, kept in its place by two pieces of cork l l; c f f f f f f, a brass wire about a quarter of a line in diameter; a b, a brass wire as small as possible, but capable of sustaining the apparatus; c c, a linen thread for attaching the wire to the apparatus, or trough which contains the non-conducting fluid. The uniting wire of this apparatus will attract the north pole of the needle when it is placed on the left side of the plane e f f f f, regarded in the direction f z. On the same side, the south pole will be repelled; on the other side of this plane, the north pole will be repelled and the south pole attracted. In effecting this, we must not place the needle above f f, nor below f z, or f c. If, instead of presenting a small movable needle to the uniting wire, we present to one of the extremities f f, one of the poles of a strong magnet, the attraction or repulsion (indicated by the needle) will cause the galvanic apparatus to revolve round the prolonged axis of the wire a b.

If we substitute, in place of the conducting wire, a large ribbon of copper of the same breadth as the plate of zinc, a feebler effect only is produced. The effect is, on the other hand, increased by making the conductor very short.

Fig. 7, represents the perpendicular section of this arrangement, in the direction of the breadth of the trough; and fig. 8, is a perspective view of it, in which fig. 8. a b c d e f represents the conducting plate, and c z f the plate of zinc. Here the north pole of the needle will be attracted towards the plane of a b c, and the south pole will be repelled from the same plane; e d f will have contrary effects. In this apparatus the extremities act like the poles of the needle, but it is only the faces of the extremities, and not the intermediate parts that have this analogy.

A moveable galvanic apparatus may also be made of two plates, one of copper, and one of zinc, twisted into spirals, and suspended in the conducting fluid. This apparatus is more moveable, but greater precautions are necessary to avoid deception, when experiments are made with it.

At this time Professor Oersted had not been able to exhibit the terrestrial action upon his electro-magnetic arc, but he did afterwards succeed, although not before he had been anticipated in the discovery by Ampère, as above stated.

10. We may state generally the following as the discoveries of these three distinguished philosophers. First, M. Arago discovered the magnetic power of the conducting wire upon steel filings, and the possibility of magnetising steel bars by means of the electric current.

M. Biot, by some delicate experiments made upon Biot's experiment, a very long and fine conducting vertical wire, proved, by observing the oscillations of a needle in its vicinity, that the following laws were observable in its action; viz. From the point where the particle resides, conceive a perpendicular line to be drawn to the axis of the wire. The force which acts on this particle is perpendicular to this line and to the axis of the wire, and its intensity is in the inverse ratio of the simple distance. The nature of the action is the same as that of a magnetic needle, which is placed tangentially to the contour of the wire, so that a particle of austral, and a particle of boreal magnetism would be drawn in opposite directions, although always in the same right line determined by the preceding construction.

It will be seen in a subsequent article, where we have given an account of Mr. Barlow's experiments
on the mathematical laws of electro-magnetism, that the general expression for the action of a vertical wire, is

\[ \int \frac{dx}{\sqrt{x^2 + a^2}} = \frac{1}{a} \arctan \frac{x}{a} ; \]

and which, when \( x = l \), becomes

\[ \frac{2}{a} \arctan \frac{l}{a} ; \]

and which last, of course, when \( l \) is infinite, or very long, reduces to \( \frac{2}{a} \times \arctan \frac{a}{90} \).

That is, the force ought to diminish according to the inverse law of the simple distance, although the action between particle and particle varies inversely as the square of the distance.

11. The discoveries of M. Ampere were very considerable, both in number and importance: to this philosopher we are indebted for the idea of the spiral wire for magnetising needles, and for exhibiting electro-magnetic effects in a manner so as to resemble those of a common electric battery; he was also the first to show the action of the earth, or of the terrestrial magnetism, upon electro-magnetic combinations; and particularly for the discovery of the mutual action of two galvanic wires on each other, while in connection with the poles of the battery. This discovery he afterwards made the foundation of his theory of electro-magnetism, on which he endeavours to show that magnets themselves owe their properties only to the electric currents which are perpetually circulating in planes perpendicular to their axes. The discoveries of Mr. Faraday, respecting the rotation of the conducting wire and magnet about each other, led him afterwards to modify his hypothesis, and to attribute the effects to currents made about each particle, but still in the same plane, and according to the same manner. From these experiments of M. Ampere, he shows that when two parallel currents of electricity are passing in the same direction, they attract each other, and when in opposite directions they repel.

In a subsequent part of this treatise we shall exhibit these as a part of the general course of electro-magnetic experiments; and it is therefore unnecessary to enter upon them at length in this place; but still a connected view of what was effected in this science in Paris, within the first few months of its being known, will be both interesting and instructive, and we avail ourselves in giving the following detail from an excellent article published in the Annals of Philosophy, which, although anonymous, is evidently from the pen of one who has taken great pains to inform himself of every particular.

12. At a meeting of the Royal Academy on September 18, 1820, M. Ampere described an experiment, proving that the voltaic pile itself acted in the same manner as the wire, connecting its two poles, and produced an instrument which, at the same time that it proved this action, was shown to be of great use in experiments on currents of electricity. This was merely a magnetic needle, but, from the uses to which it was applied, was called a galvanometer.

When placed near a pile, or trough, in action, having its pole connected either by a wire, or by introducing them into one cell, it immediately moved; becoming obedient to the battery in the same manner as to the connecting wire, and the motions were such as if the battery were simply a continuation, or part, of the wire. In consequence of this action, the needle becomes an instrument competent to indicate that state of an active voltaic pile, and the wire connecting it, which is supposed to be occasioned by currents of electricity, and in which only, magnetism has yet been discovered.

On Sept. 25, M. Ampere announced the new fact of the attraction and repulsion of two wires connecting the poles of a battery; and showed that the magnetic needle, which had previously been used to prove the magnetic attractions and repulsions of the wire, could be replaced by another connecting wire like the first. This discovery seemed to free the phenomena of magnetism from any peculiar power resident in the magnet, and to prove its production by electricity alone. When by Oersted’s discovery it had been shown that a wire connecting the poles of a voltaic battery would act on a magnet, attracting and repelling it, just as another magnet would do, it was fair to assume that the wire possessed the powers of the magnet it supplied; and when the second magnet was replaced by another connecting wire, as in Ampere’s experiment, and the powers and actions still remained as before, it was clearly to consider these powers and actions as magnetic; so that it became evident that magnetism could be exerted independently of magnets, as they are usually called, and of any of the means of excitation usually employed, but wholly by electricity, and in any good electrically conducting medium. The phenomena with two conductors situated between the poles of the battery are as follows: When they are parallel to each other, and the same ends of them are similarly related to the battery; i.e. when the supposed currents, existing in them, are in the same direction, then they attract each other; but if the opposite ends be connected with the battery, so that the currents conceived to exist in them are in opposite directions, they repel each other. If, also, the one being fixed, the other moveable, and the currents be sent, or the connections be made in opposite directions, then the moveable one will turn round until they are in the same direction. The contrast between these attractions and repulsions, and those usually called electrical, are very striking. These take place only when the circuit is complete; those only when it is incomplete. The attractions take place between the similar ends of the wires, and repulsions between the dissimilar ends; but the electrical attractions take place between dissimilar ends, and the repulsion between similar ends. These take place in vacuo, but those do not. When the magnetic attraction brings the two wires together, they remain in contact; but when electrical attraction brings two bodies together, they separate after the contact.

These experiments are varied in several ways by M. Ampere; and the apparatus with which they were made, appears, from the plates and descriptions published, to be very delicate, ingenious, and effectual. The general results drawn up by M. Ampere himself from them are; 1st, that two electrical currents attract when they move parallel to each other, and in the same direction; and repel when they are parallel to each other in a contrary direction; 2ndly, that when the metallic wires traversed by these currents
ELECTRO-MAGNETISM.

M. Ampère's experiments.

13. On Sept. 25, M. Arago stated to the Royal Academy of Sciences, that he had ascertained the attraction of iron filings by the connecting wire of the battery, exactly as by a magnet. This fact proved not only that the wire had the power of acting on bodies already magnetised, but that it was itself capable of developing magnetism in iron, that did not previously possess this power. When the wire in connection with the poles of the battery was dipped into a heap of filings, it became covered with it, increasing its diameter to the size of a goose quill; the instant the communication was broken at either pole, the filings dropped off; and the instant it was re-established, they were reattracted. This attraction took place with wires of brass, silver, platina, &c. and was so strong as to act on the filings when the wire was brought near them without actual contact. It was shown not to belong to any permanent magnetism in the wire or filings, by the inactivity of both when the connection was not made with the battery; and it was proved not to be electrical attraction, by the connecting wire having no power over filings of copper, or brass, or over sawdust. When soft iron was used, the magnetism given was only momentary; but on repeating the experiment with some modification, M. Arago succeeded completely in magnetising a sewing needle permanently.

14. The theory which M. Ampère had formed to account for the magnetic phenomena of magnets by electrical powers only, assumed that magnets were only masses of matter, around the axis of which electrical currents were moving in closed curves. This theory led him, when informed by M. Arago of his experiments, to expect a much greater effect if the connecting wire were put into the form of a spiral, and the piece to be magnetised were placed in its axis. According to the theory, in a needle or magnet, pointing to the north, the currents were in the upper part from east to west. In consequence of these exceptions, MM. Ampère and Arago made experiments with spirals, or helices, and the results are mentioned in M. Arago's paper, on the Communication of Magnetism to Iron Filings, published in the Annales de Chimie, xx. 93; so that probably the experiments date from Sept. 25, though there is no date to the paper.

On twisting a wire round a rod, it may be made to pass either in one direction or the other, giving rise to two distinct but symmetrical helices, which have been named by botanists dextorsum and sinistrorsum. The dextorsum, or, as we may call it, the right helix, proceeds from the right hand downwards towards the left above the axis; the tendrils of many plants exhibit instances of it, and it is almost exclusively used in the arts; the sinistrorsum, or left helix, proceeds from the left hand downwards towards the right above the axis.

Having made some of these helices, one was connected by its extremities with the poles of a voltaic battery, and then a needle wrapped in paper placed within it; after remaining there a few minutes, it was taken out, and found to be strongly magnetised; and the effect of a helix above that of a straight connecting wire was found to be very great.

Then with regard to the position of the poles in the magnetised needle, it was found that whenever a right helix was used, that end of the needle towards the negative end of the battery pointed to the north, and that towards the positive end towards the south; but that with a left helix, that end of the needle towards the positive, pointed north; and the other end south.

In order to establish this point, the connecting wire was sometimes formed into one helix, sometimes into two or three, which was readily done by twisting it round a glass tube, or rod, first in one direction, then another; and when needles (previously enclosed in glass tubes) were placed in these helices, the magnetic poles they received were always in accordance with the statement just given. In one case, also, where the connecting wire had been formed into three consecutive helices, the middle one being of course different to the other two, a single piece of steel wire sufficiently long to pass through all three of them being enclosed in a glass tube, was placed within them. On being again removed, and examined, it was found to have six poles; first, a north pole, a little further on a south pole, then another south pole, a north pole, another north pole, and at the further end a south pole.

In the same paper, M. Arago also states, that when the connecting wire was perfectly straight, a needle placed beneath and parallel to it was not at all magnetised. He also states, that it sometimes happened, though not frequently, that the copper wire connecting the poles of the battery retained its magnetism for a few instants after the connection had been broken; and also that M. Boisgeraud had observed the same fact with a platinum wire. These wires, it is said, would sometimes take up iron filings, or even a needle, when separated from the battery; but the power soon disappeared, and could not be reproduced at pleasure.

15. On Oct. 9, M. Boisgeraud read a paper to the M. Boisgeraud Royal Academy of Sciences, containing the detail of numerous experiments, most of which, however, are variations of Oersted's first experiments. He remarked that connecting wires, or arcs, placed anywhere in the battery, would effect the needle—a result that follows as a consequence from Oersted and Ampère's experiments. He noticed the difference of intensity in the effects produced when electrical conductors were employed to complete the circuit—a difference which Oersted himself had pointed out in the case of water. M. Boisgeraud, however, proposes to ascertain the conducting power of different substances by placing them in one of the arcs, cells, or divisions, of the battery, and bringing the magnetic needle, or Ampère's galvanometer, towards another arc, viz. to the wire, or other connecting body used to complete the circuit in the battery. With regard to the positions, which M. Boisgeraud notices of the needle and wire, they are all confirmatory of Oersted's statement.

16. On Oct. 9, M. Ampère read another Memoir on the phenomena of the voltaic pile, and on the method he intended to pursue in calculating, the action of two rectilineal electrical currents. At this sitting also, he showed the mutual action of two
ELECTRO-MAGNETISM.

Ampère discovered the terrestrial action of electric currents; i.e. of two straight portions of the connecting wires; for it appears that the phenomena of attraction, repulsion, &c. were first observed with spiral wires. These actions, however, are exactly similar; and the view already given of them, as it relates to straight wires, is consequently more simple than the description of the effects with spiral wires; i.e. considering it as a matter of experiment only, and not of theory.

In consequence of the view which M. Ampère took of the nature of magnetism as depending simply upon currents of electricity, it became an important object with him to ascertain the action of the earth upon such currents, excited by the voltaic battery; for, from this theory, he expected that it would be equally efficient in directing these currents as in directing those supposed to exist in the magnetic needle. After some trials, he succeeded in overcoming the obstacles he found, in forming sufficiently delicate suspension, contact, &c. and constructed an apparatus, in which a part of the wire, connecting the two poles of a battery, was rendered so light, and mobile, as to move immediately the connection was completed with the pole, and took a direction which, with regard to the earth, was almost constant, and in accordance with M. Ampère’s theory. An account of these experiments, with the apparatus used in them, was read to the Royal Academy on Oct. 30. The first consisted of a wire bent so as to form almost a complete circle, of about sixteen inches in diameter; the two extremities were made to approach, and were placed one just beneath the other; and being attached to two steel points, were connected by them with two little basins of platina containing mercury, fixed so as to receive them: one of the points only touched the bottom of the cup it was placed in; so that the friction was scarcely sensible, and the mercury secured a good contact. The cups were connected with other wires that passed to the voltaic battery; so that it was easy to make this moveable circle connect either one way or the other between the poles; and being enclosed in a glass case, any movement it might receive was readily observable, without danger of its resulting from any other cause than the electric action.

When the extremities of this apparatus were connected with the poles of a battery, the circle immediately moved, and, after some oscillations, placed itself in a plane perpendicular to the magnetic meridian of the earth; and on every repetition of the experiment, the same effect took place. The direction in which it moved depended upon the way in which the connection had been made with the battery; and if it be assumed that there is a current passing through the wire from the positive to the negative end, the curve so arranged itself, that that current always passed downwards on the eastern side, and upwards on the western. This circle moved round a perpendicular, and, therefore, only represented the direction of the magnetic needle; in order to represent the dip, a wire was formed into a parallelogram, and being fixed to a glass axis, was suspended by fine points, and connected as before, so as to move round a horizontal axis; then this axis being placed perpendicular to the magnetic meridian, and the wires being connected with the poles of a battery, the parallelogram immediately moved towards a position in the plane perpendicular to the dipping needle; when the communication was broken, it returned towards its first position; and when renewed, it resumed the second, evidently indicating the magnetic influence of the earth over it. In consequence of the difficulty of placing the centre of gravity in the centre of suspension, and keeping it there, this conductor did not take its position exactly in a plane perpendicular to the dipping needle, but approached towards it, till in equilibrium between the magnetic and the gravitating powers of the earth. These instruments are more particularly described in our general course of experiments.

On Oct. 30, MM. Biot and Savart read a Memoir to the Academy of Sciences, the object of which was to determine the law by which a connecting wire acted on magnetised bodies; the general object of which has been already stated at the beginning of this section.

17. Having succeeded in magnetising iron and steel Arago by the wire discharging the voltaic apparatus, M. magnets Arago was led to expect the same effect from common needles with electricity; and on trial found the results to be the same. He announces this fact verbally to the Royal machine.

18. In consequence of M. Ampère’s theory, which attributed the powers of magnets to electrical currents, and also of the views taken of the manner in which it was supposed the currents of electricity in the connecting wire, induced currents in the steel bars placed near them, as in M. Arago’s experiments, it was earnestly hoped and expected that such an arrangement might be made of magnets, wires, &c. as to produce the decomposition of water, or some other electrical effects; for, as electricity produced magnetism, it was considered that magnetism might produce electricity. Many arrangements were made of magnets together, and of wires about and round magnets; and at first it was stated that electrical effects, such as the decomposition of water, attractions, &c. had been produced; but on Nov. 6, M. Fresnel, who had been very earnest in his endeavours to obtain these effects, admitted to the Royal Academy, that the appearances were not such as to authorize the conclusion, that any certain effect had been obtained.

19. At the same sitting, also (Nov. 6) M. Ampère Magnet noticed an effect produced by the connecting wire imitated by a spiral wire. This may be easily understood by considering that the direction of the magnetic power is always perpendicular to the conducting wire. When, therefore, the conducting wire is parallel to the axis of the helix, the power is perpendicular to that axis; when the wire forms a circle round the axis, in a plane perpendicular to it, the power is in the direction of the axis; but when, as in the helix, it passes round the axis in a direction intermediate between parallelism and perpendicularity, the direction of the power is of course inclined accordingly. In this case the power may be considered as composed of two portions; one perpendicular to the axis, the other parallel to it. As M. Ampère considered magnets to be assemblages of currents perpendicular to their axis, he wished, in his imitation
of them, to do away with that effect due to the extension of the wire in the direction of the axis of the helix, and succeeded in this attempt by making the wire at one end return through the helix, so as not to touch it in any part; for in this position, its magnetic effects being contrary to those belonging to the length of the helix, and also near to them, they neutralise, or hide each other. An imitation of a magnet was now made by forming a helix, and making the wire at the two extremities return through the centre of the helix half-way, and then pass out upwards and downwards, so as to form a perpendicular axis on which the whole might move. The extremities of a battery being connected with these two ends of the wire, the helix became magnetic, and was attracted and repelled by a magnet, precisely as a real magnet would have been.

**Miscellaneous experiments.**

20. On Nov. 13, M. Lehot stated to the Academy of Sciences, that, notwithstanding the results obtained by M. Fresnel, he was still convinced of the decomposing power given to iron wires by magnets; and quotes experiments he had made six years before, by connecting iron wires to the poles of a magnet, and then immersing their ends in water. The south pole caused oxidation, the north pole preserved its wire bright; again in tincture of litmus, the south pole reddened the tincture, the north pole did not. There does not, however, seem any reason to consider these experiments as decisive; and M. Lehot himself does not attach more importance to them than to those made twenty years ago by Ritter, and on the uncertainty of which M. Fresnel had sufficiently remarked.

On Nov. 13, also, M. Ampere read a note on the electro-chemical effects of a spiral wire, subjected to the action of the earth alone. The wire formed a helix round a paper cylinder, the axis of which was placed parallel to the dip and direction of the needle, the extremities were placed in a solution of common salt. In seven days gas appeared on both ends, but most on that answering to the negative end of the battery; the bubbles were displaced, but fresh ones appeared, the end remaining bright, while the other end became oxidized, and gave no more gas. On the whole, however, the experiments seemed uncertain, especially after what M. Fresnel had said; and M. Ampere himself stated, that he still doubted as to the existence of the action.

**3. Experiments by Sir H. Davy.—First series.**

21. Sir Humphry Davy was amongst the first philosophers who repeated Mr. Oersted’s experiments, and was thus led to the discovery of several curious facts, some of which, however, were, during the same time, fallen upon by others. These results were communicated to the Royal Society, through a letter addressed to Dr. Wollaston, dated November 16, 1820; but the experiments detailed in it were principally made in the preceding month. The following is very little more than a bare enumeration of the facts which it contains, namely:

That the wire in connection affected the needle as Mr. Oersted described; the effect was immediately attributed to the wire itself becoming a magnet; and this was instantly proved by bringing it near iron filings, which were attracted, and remained attached to it as long as the communication continued. This is, in fact, the same experiment as that made by M. Arago, but it was made by the two philosophers independent of each other; and as no detail of M. Arago’s experiments has, as yet, been published, the accurate description of Sir H. Davy’s will be found highly interesting. This effect took place in any part of the wire, and any where in the battery. Steel needles placed on the connecting wire became magnetic; those parallel to the wire acted like the wire itself; those across it had, each, two poles; such as were placed under the wire, the positive end of the battery being east, had north poles on the south of the wire, and south poles to the north; those needles above were in the opposite direction; and this was constantly the case, whatever the inclination of the needle to the wire might be. This position, it will be observed, is precisely that which has been referred to in the account of Mr. Oersted’s experiments. On breaking the connection, the steel needles across retained their magnetism, while those parallel to the wire lost it at the moment. Wires of platinum, silver, &c. in the same situation, were not rendered magnetic, except, by accident, they formed part of the circuit. Whatever the position of the battery, or wire, the effect was the same. Contact was found not necessary; instantaneous effect was produced by mere juxtaposition, though thick glass intervened; filings arranged themselves in right lines across the wire on a glass plate, held over it at a quarter of an inch distance. The effect was proportional to the quantity of electricity passing through a given space, without any relation to the metal transmitting it. Increasing the size of the plates, proportionally increased the magnetic effects of the connecting wires. The wire connecting a battery of sixty pair of plates, did not take up half so many filings as when the battery was arranged so as to form thirty pair of plates twice the size. The magnetic power of the wires rose with its heat.

Considering that a great quantity of electricity was necessary to produce sensible magnetism, Sir H. Davy concluded, that a current from the common machine would have no effect, whilst a discharge would; and this was found to be true; the poles of the needle magnetised, being situated exactly as before. In these experiments a battery of seventeen square feet, highly charged, being discharged through a silver wire, one-twentieth of an inch in diameter, rendered bars of steel of two inches long, from one-tenth to one-twentieth thick, so magnetic, as to lift up pieces of steel wire, and needles; and the effect was communicated to needles, at a distance of five inches from the wire, even when water, or thick plates of glass, or metal intervened.

By these kinds of experiments it was found, that a tube of sulphuric acid, one-fourth of an inch in diameter, did not conduct electricity enough to render steel magnetic; that an explosion through air, made the needle, placed transversely to it, magnetic; though not so strongly as a wire would have done; that steel bars in the circuit, or parallel to it, did not become magnets; that two bars placed together across the wire, passing through the common centre of gravity, showed no magnetism after the discharge, before they were separated, but exhibited poles on separation.

One conclusion drawn by the author from these experiments is, that magnetism is produced whenever concentrated electricity is passed through space.
On arranging numerous wires in circles, and in other directions around and about the discharging wire, it was found after the discharge, that all were magnetic, and the poles exactly as before expressed; so that the north pole of one needle was towards the south pole of the next, and in a constant relation to the course of the discharge.

The connecting wire being divided in one part into three, four, or more, by small wires, and a voltaic battery discharged through them, they were all found magnetic at once, and took up different cylinders of filings; when the opposite side of two of these were brought together, the filings attracted each other. From this, it was expected, that when the similar sides were brought together, the filings on them would repel each other. This was tried by two batteries arranged parallel, but in opposite directions. The filings on these connecting wires repelled each other; and connecting wires of platinum, and fine steel wire without filings, exhibited similar phenomena of attraction and repulsion. These experiments, it will be perceived, are similar to those made by M. Ampere, on the attraction and repulsion of two connecting wires, or, as he calls them, two electrical currents, and prove the same thing. On placing straight pieces of platinum, silver, and copper wire, on two knife-edges of platinum connected with the opposite poles of a battery, they were found to be attracted and repelled in directions according to what has been said. Gold leaf made in the same way to form the connexion, was found to be moved by a magnet.

22. At the conclusion of the paper, of which the second above is an abridgement, Sir H. Davy mentions some other experiments he had in view, and which he afterwards performed and made the subject of another memoir. It would be useless to attempt any condensation of these results into less space than they occupy; we believe, therefore, that we can only do justice to the author, by giving the particulars as they are stated in the article itself, which is as follows:

"In my letter to Dr. Wollaston, on the new facts discovered by Mr. Oersted, which the Society has done me the honour to publish, I mentioned that I was not able to render a bar of steel magnetic, by transmitting the electrical discharge across it, through a tube filled with sulphuric acid; and I likewise mentioned, that the electrical discharge passed across a piece of steel through air, rendered it less magnetic than when passed through a metallic wire; and I attribute the first circumstance to the sulphuric acid being too bad a conductor to transmit a sufficient quantity of electricity for the effect; and the second, to the electricity passing through air in a more diffused state than through metals.

"To gain some distinct knowledge on the relation of the different conductors to the magnetism produced by electricity, I instituted a series of experiments, which led to very decisive results, and confirmed my first views.

"I found that the magnetic phenomena were precisely the same, whether the electricity was small in quantity, and passing through good conductors of considerable magnitude; or, whether the conductors were so imperfect as to convey only a small quantity of electricity; and in both cases they were neither attractive of each other, nor of iron filings, and not affected by the magnet; and the only proof of their being magnetic, was their occasioning a certain small deviation of the magnetised needle.

"Thus a large piece of charcoal placed in the circuit of a very powerful battery, being a very bad conductor compared with the metals, would not affect the compass needle at all, unless it had a very large contact with the metallic part of the circuit; and if a small wire was made to touch it in the circuit, only in a few points, that wire did not gain the power of attracting iron filings; though when it was made to touch a surface of platinum foil coiled round the end of the charcoal, a slight effect of this kind was produced. And in a similar manner fused hydrate of potassa, one of the best of the imperfect conductors, could never be made to exert any attractive force on iron filings, nor could the smallest filaments of cotton moistened by solution of hydrate of potassa placed in the circuit, be made to move by the magnet; nor did steel needles, floating on cork on an electrised solution of this kind, placed in the voltaic circuit, gain any polarity; and the only proof of the magnetic powers of electricity passing through such a fluid, was afforded by its effect upon the magnetised needle, when the metallic surfaces, plunged in the fluid, were of considerable extent; that the mobility of the parts of fluids did not interfere with their magnetic powers, as developed by electricity, was proved by electrifying mercury and Newton's metal fused in small tubes. These tubes, placed in a proper voltaic circuit, attracted iron filings, and gave magnetic powers to needles; nor did any agitation of the mercury or metal within, either in consequence of mechanical motion or heat, alter or suspend their polarity.

"Mr. Pepys having had the goodness to charge the great battery of the London Institution, consisting of 2000 double plates of zinc and copper, with a mixture of 1168 parts of water, 108 parts of nitrous acid, and twenty-five parts of sulphuric acid; the poles were connected by charcoal, so as to make an arc, or column of electrical light, varying in length from one to four inches, according to the state of rarefaction of the atmosphere in which it was produced; and a powerful magnet being presented to this arc or column, having its pole at a very acute angle to it, the arc or column was attracted or repelled with a rotatory motion, or made to revolve, by placing the pole in different positions, according to the same law as the electrified cylinder of platinum described in my last paper, being repelled when the negative pole was on the right hand by the north pole of the magnet, and attracted by the south pole, and vice versa.

"It was proved by several experiments, that the..."
motion depended entirely upon the magnetism, and not upon the electrical inductive power of the magnet, for masses of soft iron, or of other metals, produced no effect.

"The electrical arc or column of flame was more easily affected by the magnet, and its motion was more rapid when it passed through dense than through rarefied air; and in this case, the conducting medium, or chain of aeriform particles, was much shorter. I tried to gain similar results with currents of common electricity sent through flame, and in vacuo; they were always affected by the magnet; but it was not possible to obtain so decided a result as with voltaic electricity, because the magnet itself became electrical by induction, and that whether it was insulated, or connected with the ground.

25. "Metals, it is well known, readily transmit large quantities of electricity; and the obvious limit to the quantity which they are capable of transmitting, seems to be their fusibility or volatilization, by the heat which electricity produces in its passage through bodies.

Now I had found in several experiments, that the intensity of this heat was connected with the nature of the medium by which the body was surrounded; thus a wire of platinum, which was readily fused by transmitting the charge from a voltaic battery in the exhausted receiver of an air-pump, acquired in air a much lower degree of temperature.

"Reasoning on this circumstance, it occurred to me, that, by placing wires in a medium much denser than air, such as ether, alcohol, oils, or water, I might enable them to transmit a much higher charge of electricity than they could convey without being destroyed in air; and thus not only gain some new results as to the magnetic states of such wire, but likewise perhaps determine the actual limits to the powers of different bodies to conduct electricity, and the relations of these powers.

"A wire of platinum of $\frac{1}{4}$ inch diameter and three inches in length, was fused in air, by being made to transmit the electricity of two batteries of ten zinc plates of four inches, with double copper, strongly charged: a similar wire was placed in sulphuric ether, and the charge transmitted through it. It became sure enough to give out a spark of fire, but no other change took place; and in this situation it bore the discharge from twelve batteries of the same kind, exhibiting the same phenomena. When only about an inch of it was heated by this high power in ether, it made the ether boil, and became white hot under the globules of vapour, and then rapidly decomposed the ether, but it did not fuse. When oil or water was substituted for the ether, the length of the wire remaining the same, it was partially covered with small globules of gas, but did not become red-hot.

On trying the magnetic powers of this wire in water, they were found to be very great, and the quantity of iron filings that it attracted, was such as to form a cylinder round it, of nearly the tenth of an inch in diameter. To ascertain whether short lengths of fine wire, prevented from fusing by being kept cool, transmitted the whole electricity of powerful voltaic batteries, I made a second independent circuit from the ends of the battery with silver wires in water; so that the chemical decomposition of the water indicated a residuum of electricity in the battery, operating in this way, I found that an inch of wire of platinum of $\frac{1}{4}$ inch diameter, kept cool by water, left a great residual charge of electricity in a combination of twelve batteries, of the same kind as those above mentioned, and after making several trials, I found that it was barely adequate to discharge six batteries.

26. "Having determined that there was a limit to the quantity of electricity which wires were capable of transmitting, it became easy to institute experiments on the different conducting powers of different metallic substances, and on the relation of this power to the temperature, mass, surface, or length, of the conducting body, and to the conditions of electro-magnetic action.

"These experiments were made as nearly as possible under the same circumstances, the same connecting copper wire being used in all cases, their diameter being more than one-tenth of an inch, and the contact being always preserved perfect, and parts of the same solution of acid and water were employed in the different batteries, and the same silver wire and broken circuit with water were employed in different trials; and when no globules of gas were observed upon the negative silver wire of the second circuit, it was concluded that the metallic conducting chain, or the primary circuit, was adequate to the discharge of the combination. To describe more minutely all the precaution observed, would be tedious to those persons who are accustomed to experiments with the voltaic apparatus, and unintelligible to others; and, after all, in researches of this nature, it is impossible to gain more than approximations to true results; for the gas disengaged upon the plates, the different distances of the connecting plates, and the slight difference of time in making the connections, all interfere with their perfect accuracy.

"The most remarkable general result that I obtained by these researches, and which I shall mention first, as it influences all the others was, that the conducting power of metallic bodies varied with the temperature, and was lower in some inverse ratio as the temperature was higher.

"Thus a wire of platinum of $\frac{1}{4}$ inch, and three inches in length, when kept cool by oil, discharged the electricity of two batteries, or of double plates; but when exposed to the air, and especially when exposed to the air, and especially when exposed to the fumes of hydrochloric acid, the same effect was produced; and the conducting power of the wire was reduced to about a third of its former value.

"Whether the heat was occasioned by electricity, or applied to it by some other source, the effect was the same. Thus a wire of platinum, of such length and diameter as to discharge a combination without being considerably heated, when the flame of a spirit lamp was applied to it so as to make a part of it red-hot, lost its power of discharging the whole electricity of the battery, as was shown by the disengagement of abundance of gas in the secondary circuit; which disengagement ceased as soon as the source of heat was withdrawn.

"There are several modes of exhibiting this fact, so as to produce effects, which, till they are witnessed, must almost appear impossible. Thus, let a fine wire of platinum, of four or five inches in length, be placed in a voltaic circuit, so that the electricity passing through it, may heat the whole of it to redness; and let the flame of a spirit lamp be applied to any part of it, so as to heat that part to whiteness, the rest of the wire will instantly become cooled below..."
the point of visible ignition. For the converse of the experiment, let a piece of ice, or a stream of cold air, be applied to a part of the wire, the other part will immediately become much hotter, and from a red, will rise to a white heat. The quantity of electricity that can pass through that part of the wire submitted to the changes of temperature, is so much smaller when it is hot than when it is cold, that the absolute temperature of the whole wire is diminished by heating a part of it.

In comparing the conducting powers of different metals, I found much greater differences than I had expected. Thus, six inches of silver wire of \( \text{\(\gamma_{\text{\(\theta\)}}\)} \), discharged the whole of the electricity of sixty-five pair of plates of zinc and double copper, made active by a mixture of about one part of nitric acid of commerce, and fifteen parts of water. Six inches of copper wire of the same diameter, discharged the electricity of fifty-six pair of the same combination; six inches of tin of the same diameter, carried off that of twelve only; the same quantity of wire of platinum, that of eleven; and of iron, that of nine. Six inches of wire of lead of \( \text{\(\gamma_{\text{\(\theta\)}}\)} \), seemed equal in their conducting powers to the same length of copper wire of \( \text{\(\gamma_{\text{\(\theta\)}}\)} \). All the wires were kept as cool as possible, by immersion in a basin of water. I made a number of experiments of the same kind, but the results were never precisely alike, though they sometimes approached very near each other. When the batteries were highly charged, so that the intensity of the electricity was higher, the differences were less between the best and worst conductors, and they were greater when the charge was extremely feeble. Thus, with a fresh charge of about one part of nitric acid, and nine parts of water, wires of \( \text{\(\gamma_{\text{\(\theta\)}}\)} \) of silver, and platinum five inches long, discharged, respectively, the electricity of thirty-seven double plates.

Finding, that when different portions of the same wire plunged in a non-conducting fluid were connected with different parts of the same battery equally charged, their conducting powers appeared in the inverse ratio of their lengths; six inches of the absolute wire of platinum of \( \text{\(\gamma_{\text{\(\theta\)}}\)} \) discharged the electricity of ten double plates, three inches discharged that of twenty, one inch and a half that of forty, and one inch that of sixty; it occurred to me, that the conducting powers of the different metals might be more easily compared in this way, as it would be possible to make the contacts in less time than when the batteries were changed, and, consequently, with less variation in the charge.

Operating in this way, I ascertained, that in discharging the electricity of sixty pair of plates, one inch of platinum was equal to almost six inches of silver, to five inches and a half of copper, to four of gold, to \( 3 \frac{3}{5} \) of lead, to about \( \text{\(\gamma_{\text{\(\theta\)}}\)} \) of palladium, and \( \frac{2}{3} \) of iron, all the metals being in a cooling fluid medium.

I found, as might have been expected, that the conducting power of a wire for electricity, in batteries of the size, and numbers of plates just described, was nearly directly as the mass; thus, when a certain length of wire of platinum discharged one battery, the same length of wire, of six times the weight, discharged six batteries; and the effect was exactly the same, provided the wires were kept cool, whether the mass was the same, the same wire, or composed of six of the smaller wires in contact with each other. This result alone showed, that surface had no relation to the conducting power, at least, for electricity of this kind, and it was more distinctly proved by a direct experiment; equal lengths and equal weights of wire of platinum, one round, and one flattened by being passed transversely through rollers, so as to have six or seven times the surface, were compared; as to conducting powers, the flattened wire was the best conductor in air, from its greater cooling powers, but in water no difference could be perceived between them.

27. These experiments, relative to the conducting power of wires, under different circumstances, are highly important, not only in reference to the construction of electro-magnetic apparatus, as will be seen as we proceed, but they are also calculated to throw great light upon the first principles of electricity and galvanism; and they are followed in the same paper by several others, on the conducting power of fluid menstrua, but these not being immediately applicable to the subject at present under investigation, we shall pass over, and only give further, the concluding section of this valuable memoir, which is stated by the author as follows:

28. "The magnetism produced by electricity, though with the same conductors it increases with the heat, as I mentioned in my last paper; yet with different conductors, I find it follows a very different law. Thus, when a chain is made of different conducting wires, and they are placed in the same circuit, all exhibit equal magnetic powers, and take up equal quantities of iron filings, so that the magnetism seems directly as the quantity of electricity which they transmit. And when in a highly powerful voltaic battery, wires of the same diameters and lengths, but of which the best conducting is incapable of wholly discharging the battery, are made separately and successively to form the circuit, they take up different quantities of iron filings, in some direct proportion to their conducting powers.

"Thus, in one experiment, two inches of wire of \( \text{\(\gamma_{\text{\(\theta\)}}\)} \) of an inch being used, silver took up thirty-two grains, copper twenty-four, platinum eleven, and iron eight and one-fifth."

5. Experiments by Mr. Faraday.

29. At the time, when Mr. Faraday commenced his experiments on this interesting science, in the summer of 1821, nothing had been discovered relative to the magnetic action of the conducting wire, but its directive quality, its power of communicating magnetism, and the action of electrical conductors on each other, as depending on their magnetic, and not on their electrical state. These facts, it is true, are very important, and within the short space that such a power had been known to exist, were highly honourable to the zeal and talents of the philosophers by whom the subject had been pursued. But the experiments we are now about to detail, form an entirely new and distinct feature in the science, and deserve particular notice. Mr. Faraday's object, when he commenced these experiments, was the repetition of those of Mr. Oersted; and having the advantages of a powerful apparatus, he was enabled to mark the various changes that took place in the direction of the needle, under different positions of the conducting wire, with great accuracy and precision; and he therefore soon observed, that the position of the needle, with respect to the wire, greatly modified the effects produced. He
Electro-Magnetism.

Eleetro-Magnetism. ascertained, for example, that the apparent attraction of the needle on the one pole, and its consequent repulsion on the other, did not occur under all circumstances; but that accordingly as the wire was placed nearer to, or removed farther from, the pivot of the needle, attraction or repulsion was produced on the same side of the wire; that is, says the author, "If the wire be made to approach perpendicularly towards one pole of the needle, that pole will pass off, on one side, in that direction which the attraction and repulsion at the extreme point of the pole would give; but if the wire be continually made to approach the centre of motion, by either the one or the other side of the needle, the tendency to move in the former direction diminishes; it then becomes null, and the needle is quite indifferent to the wire; and, ultimately, the motion is reversed, and the needle powerfully endeavours to pass the opposite way."

From these facts Mr. Faraday conceived the happy idea, that, but for the impossibility of such motion, with the magnet suspended in the usual way, the pole of it would revolve about the wire, and conversely, the wire about the magnet; at least, that they would each have such tendency, if sufficient mobility could be given to them, but still preserving sufficient contact for the transmission of the fluid. Moreover, as the same effects, but in opposite directions, took place with the opposite poles, the author concluded, that each pole had its peculiar power of action on the wire, and not as any part of the needle, or as connected with the opposite pole. The attractions and repulsions hitherto noticed, he considered merely as exhibitions of the tendency to revolution in different parts of the circle. We shall not attempt to follow Mr. Faraday in this place, through all the various difficulties he had to contend with, in carrying this very ingenious and original idea into execution. It will be sufficient here to state that he succeeded, and was thus the first philosopher that ever produced a rotatory motion, independent of mechanical principles, that is, from a natural force, of which, till this time, no one ever imagined the existence. In our chapter, in which is given a course of electro-magnetic experiments, according to their natural order of dependence on each other, and not in that of the date of their discovery, we shall only give Mr. Faraday's experiments in their complete form, but at present we shall content ourselves with describing one of his most simple apparatus, merely for the purpose of illustrating what is stated above.

30. This machine is represented in fig. 9; its construction and action being as follow: place a portion of mercury in a tube closed below with a cork, and fix a small magnet so that one pole shall project above the surface of the mercury; take a piece of clean copper wire about two inches in length, amalgamate the two ends, form a loop at one end, and at the end of another piece of wire form another loop, by which hang the first piece, thus affording free motion, and at the same time sufficient contact: fix this over the magnet, so that the end of the moveable piece shall just dip into the mercury; then connect the mercury with one pole of a voltaic combination, which is readily done through the magnet, and the wire with the other, and the moveable part will immediately revolve round the magnetic pole, and continue to do so as long as the contact remains. On bringing the magnetic pole from the centre of motion to the side of the wire, there is neither attraction nor repulsion, but the wire has a tendency to pass off in a circle, still leaving the pole for its centre, and that either on the one side, or on the other, according to circumstances. If the magnet be taken out and reversed, we have still the same kind of motion, but it takes place in an opposite direction; that is, if it were to the right in the first instance, it will now be to the left, the contact with the poles of the battery remaining the same. And if these be reversed, so also will be the motion. Mr. Faraday recommends, that instead of a magnet, as above described, a piece of iron be applied, and a strong magnet used exteriorly, to induce either pole in the iron.

In some future trials a different apparatus was constructed, which exhibited this rotation upon a larger and better scale, and also the rotation round the wire, the latter being fixed, and the former free; but as these will be described in the following general course, this notice of the results will be sufficient for the present.

31. We have already mentioned the experiments of Mr. Faraday, M. Ampere, by which the effect of the terrestrial magnetism was shown, by giving direction to a galvanic wire; Mr. Faraday was therefore induced to try whether this also was not sufficient to give a rotation to a freely suspended wire of the same kind: at the time when he published his first experiments his attempts had not been successful, but he ultimately obtained the motion and rotation sought. Having assumed the line of the dip as the direction or resultant of all the magnetic forces in any given place, and judging from other experiments, the results expected were, that a connecting wire would always move laterally, and in a plane at right angles to the dip; this required the wire to be perpendicular to the dip; but still if removed from the perpendicular a little way, it was expected that it would still move, although with a diminished force. To obtain this result experimentally, a horizontal piece of wire was suspended from the ceiling by a silk thread; its ends dipped into mercury in two basins, and these were connected with the poles of the battery; the wire immediately moved laterally, and that in every azimuth, the direction of motion being such, that when the wire was east and west, the east end to the zinc, and the west to the copper plate, (a single pair being used,) the motion was towards the north; when the connections were reversed the motion was towards the south. When the wire hung north and south, the north end to the zinc and the south to the copper, the motion was towards the west, when the connections were reversed towards the east, and the intermediate positions gave intermediate directions of motion.

An apparatus was afterwards made use of, which showed these results in a more distinct and satisfactory manner, somewhat resembling that above described for producing rotation in the wire about the magnet; the wire being suspended, so as to make with the vertical a greater angle than the dipping needle with the same; and here, the moment the contact was made, Mr. Faraday had the satisfaction to see the rotation commence precisely in the same manner as it would have done about the south pole of an artificial magnet.

These were the more important of Mr. Faraday's
ELECTRO-MAGNETISM.

Magnetism discoveries, but a number of other highly ingenious experiments were made by him at the same time, and are published in the same paper, (No. 23, Journal of the Royal Institution,) and in a note in the following number. Some of them shall have occasion to describe in the following general course, and for the rest we must refer the reader to the paper in question.

6. Experiments of a miscellaneous nature due to several German philosophers and others.

32. So many persons were engaged in the pursuit of this new and interesting science, after the first announcement of the discovery by Professor Oersted, that it is nearly impossible to observe the proper order of discovery in point of date, we shall therefore, in this place, mention several miscellaneous experiments made about this time by different authors; but as most of these will occur in the general course, a very short notice of each will be sufficient.

33. M. le Chev. Yelin discovered, independent of what had been done in Paris, the effect of enclosing a needle within a spiral wire, both by the discharge of the electric apparatus by sparks, and by galvanism. These results were published in the Allgemeine Zeitung, December 2, 1820.

34. Mr. Bockman made experiments on spirals of different diameters; increasing the diameter from the smallest size to thirteen inches, no perceptible diminution of effect was observed; but it was much impaired when the diameter was thirty-four inches, and scarcely any power remained, when it was increased to eighty-four inches.

35. M. Von Buch, of Utrecht, corrected an error in Mr. Oersted's first paper. Mr. Oersted says, that if the uniting wire be placed perpendicularly to the plane of the magnetic meridian, whether above or below it, the needle remains at rest, unless it be very near the pole; in that case the pole is elevated if the entrance be from the west side of the wire, and depressed when from the east. M. Von Buch points out, that this state of rest does not continue in two of these four positions of the wire. When the connecting wire is below the centre of the needle, and the positive current is from east to west, the needle remains unmoved: when the current is from west to east, it performs half a revolution; on the contrary, the connecting wire being above the current from east to west, makes the needle turn half way round, while that from west to east leaves the needle unmoved. The author concludes, that this peculiarity escaped Mr. Oersted, in consequence of the little power in his first apparatus. This was, no doubt, the case, for nothing is now better established than this fact of the inversion of the needle in the cases alluded to, when the power of the wire exceeds that of the terrestrial directive force.

M. Von Buch also appears to have ascertained the effect of common electricity, in producing magnetism, without a previous knowledge of what had been done by others, and succeeded in producing the effect by a much smaller power than had before been employed for the purpose. He found that a strong discharge was not necessary, nor even a Leyden phial; but fixing a helix between the prime conductor of a machine and another insulated conductor, placing a steel needle in it, and then drawing sparks from the latter conductor, the needle became magnetic. One single turn of a machine, with two discs, eighteen inches in diameter, was sufficient to make the needle evidently magnetic.

36. M. de la Rive, in the Bib. Univ. (March 1821,) describes a very pretty little apparatus for exhibiting some of the leading facts connected with this science. It consists simply of two thin strips, one of copper and another of zinc, connected by a wire soldered to each, the wire itself being wound into a spiral, and the whole attached to a cork, and immersed in dilute acetic acid; by this simple machine, many curious and important facts may be satisfactorily exhibited, but as it will be described more at length in the general course, this notice will here be sufficient.

37. M. Moll, of Utrecht, in three letters to the M. Moll editor of the Journal de Physique, the first dated March 23, the others without date, gives an account of some experiments made to ascertain the relative power of a battery consisting of many plates, and one of two large plates only. The large apparatus consisted of a narrow trough of copper, containing a plate of zinc, presenting near four square feet of surface: the smaller apparatus was one consisting of plates, four inches square, put together in Dr. Wollaston's manner, with the copper round the zinc. With the large apparatus, M. Moll remarked, that the magnetic power was very great, when the connecting wire was of considerable thickness, (two-tenths of an inch,) but when a platinia wire, much smaller, was used, (one-twentieth of an inch,) the power diminished considerably. With a copper cylinder, however, about an inch in diameter, the power was diminished: no chemical action could be obtained by this apparatus, on making the connection with saline solution, or tincture of litmus, though the magnetic effects were very powerful. In making the comparison between this apparatus, and that with smaller plates and cells, thirty-six pair of the latter were taken; so that an equal surface was used in both instruments. These being put into action by the same acid, and the connecting wires being similar, that of the two plates made the needle deviate from 60° to 70° from the magnetic meridian; while that of the small plate battery made it deviate only 12°. The decomposing power of the small plate battery was very considerable, and M. Moll draws the conclusion, that the apparatus with cells produces chemical effects, while its magnetic action is very little; while the single plates have scarcely any chemical effect, though their magnetic power be very great.

M. Moll also remarks, that the positive and negative state of his single plates is in opposition to the states of a battery of many plates, inasmuch as the zinc pole is negative, and the copper pole positive. He found the position of the magnetic needle near his wire the reverse of what it was near the wire of a battery of many plates; for when the wire extended from the zinc pole, north, to the copper pole, south, a needle placed beneath turned towards the west instead of the east, and above, in the contrary direction. The cause of this difference will be readily seen, when it is remembered that M. Moll was using the wire that connected the zinc and copper plates of the same pair, and not of different pairs; so that, in fact, his connecting wire was in the inverse direction of those used to connect between the poles of a battery with four or more plates. This fact, as we have seen, (art. 9,) was noticed also by Oersted.

38. It remains now only to notice a few of the new
ELECTRO-MAGNETISM.

Experiments which followed, and were dependent on those of Mr. Faraday. We have seen that this gentleman succeeded in making a galvanic wire rotate about a magnet, and then a magnet about the wire, and lastly a wire about the pole of the terrestrial magnetism, in any place. Pursuing the ideas thus developed, M. Ampere succeeded in causing a magnet to revolve on its own axis, by passing the galvanic current through it; Mr. Barlow produced a similar rotation in the galvanic wire, and some other rotations of rather a curious nature, which will be described as we proceed; and lastly M. Ampere proposed a very small and compact combination, which exhibited the rotatory property of the wire without the aid of any other galvanic apparatus than the machine itself. This also is described in the general course.

7. Experiments by Professor Cumming.—First series.

39. Professor Cumming’s experiments embraced all those which had been previously published, at the time when he commenced, but we shall only mention those which brought to light some fact not before known. The apparatus he employed was a single pair of zinc and copper plates, having two feet and a half surface, with conducting wires of copper; in the first instance, of one-fifteenth of an inch in diameter, but which he afterwards varied, in order to examine the effects due to different dimensions of the conducting arc. These we shall speak of as we proceed; at present it will be better to follow the order in which the experiments are reported. The first object of the author was, to ascertain the actual direction of the force by which the needle was disturbed; for this purpose the conducting wire was bent into a circle, and two delicate needles were used, one horizontal and one vertical, or suspended like a dipping needle; and in this way Professor Cumming discovered what has since been observed by other philosophers, and had, indeed, been previously observed, that the tendency of the electro-magnetic force is to place the needle transversely to the wire, a position which it actually took up, when the needle was neutralized so as to destroy or counteract the natural directive power of the earth upon it.

While carrying on these experiments the author found, that when the needle was placed within a conducting circle, the effects were much greater than when a single wire was employed, and this suggested to him the idea of constructing an apparatus for examining small galvanic effects, which he calls a galvanometer: it consists in placing a needle within a circular or square conducting wire, of two or more coils, and by neutralizing the terrestrial direction when necessary, we shall describe this, or a similar instrument, as we proceed; it is only spoken of here in order to mark the time of the invention, April 1821, as a foreign claimant of later date has recently appeared in some of the Foreign and English journals.

Professor Cumming observes, after mentioning the effect produced by so small an apparatus, "it may seem singular, that in Professor Oersted’s earlier experiments, the effects were barely apparent, owing, as he imagined, to the feeble power of his battery; the reason of this he afterwards discovered to be, that the magnetic effect was dependent, not on the intensity, but the quantity of galvanism evolved; but he does not seem to be aware of the extent to which this observation may be applied. My first experiments were made with a battery of 290 double six-inch plates, possessing very powerful effects, both electrical and chemical, yet its influence on the needle was scarcely perceptible. One of these plates taken separately caused a deviation of nearly 80°. It is evident then, that though the circuit be complete, much of the magnetic influence is destroyed by the same circumstances which generates the electrical effects. This can be no other than the tension produced in consequence of the obstruction presented to the free passage of the galvanism, by the fluid interposed between each pair of plates; magnetism, therefore, cannot be properly considered as the effect of voltaic electricity, but of galvanism in its original form."

40. Professor Cumming next proceeded to examine on the effects of different lengths of conducting wire.

41. "In using the magnetic needle as a measure of galvanic effects, we may either observe the deviation at a standard distance of the connecting wire from the needle, or assume a standard angle and measure the distance. The latter method seems to have the advantage, as enabling us to use a smaller, and therefore a more delicate needle, with this additional convenience, that the scale is increased in proportion as the length of the needle is diminished. I therefore constructed an instrument, having a connecting wire fixed upon a moveable slide, divided into inches and tenths, to which a vernier might be added if necessary. My first object was to ascertain the divisions on the scale, corresponding to variations in the angle of deviation; for this purpose the moveable wire was placed at different distances from the needle, increasing in arithmetical progression, and the corresponding deviations were observed. As the effects decreased very rapidly during the galvanic actions, the experiments were made as quickly as possible, proceeding from a distance of half an inch to ten inches and a half, and again returning to the first distance. On taking the mean of several trials made in this manner, I found that the tangent of the deviation varies inversely as the distance of the connecting wire from the magnetic needle." We have already explained that the deviation varying according to this law, when the wire is of considerable length, answers to the law of the inverse square of the distance between particle and particle.

42. "It is well known, that in a galvanic arrangement intensity is given by the number, and quantity by the magnitude of the plates; but I am not aware that any notice has been taken of the effects produced by varying their distances from each other. On placing
ELECTRO-MAGNETISM.

43. All the experiments that had been made on the subject of electro-magnetism, from the first discovery of that power by Mr. Oersted, seemed to indicate a strong affinity, although not a complete identity, between the simply magnetic and the electro-magnetic forces; or, if the identity be admitted, still a certain difference must be conceived to have place in the modes of action.

In a work entitled *An Essay on Magnetic Attractions,* &c., the author had attempted to reduce the laws of induced magnetism to mathematical principles, and to render the results susceptible of numerical computation. Mr. Barlow, in the neighbourhood of iron and the position of the mass of iron and its position, with respect to the compass, being given; and he was now desirous to establish, on similar principles, the law of electro-magnetism; but it was some time before he was able to construct an apparatus convenient for the purpose. Having, however, at length effected this necessary preliminary to his satisfaction, he proceeded to make the course of experiments, and to undertake the investigations which form the subject of the present section.

Having repeated, very carefully, all the experiments of Mr. Oersted, MM. Ampere, and Arago; of Sir H. Davy and Mr. Faraday, with some others, suggested by the results thus obtained; and having attentively considered all the peculiarities of action thus developed, he was led to consider that all the apparently anomalous effects produced on a magnetised needle by the action of a galvanic wire, might be explained by the admission of one simple principle; viz. that every particle of the galvanic fluid in the conducting wire acts on every particle of the magnetic fluid in a magnetised needle, with a force varying inversely as the square of the distance; but that the action of the particles of the fluid in the wire, is neither to attract nor to repel either poles of a magnetic particle, but a tangential force which has a tendency to place the poles of either fluid at right angles to those of the other; whereby a magnetic particle, supposing it under the influence of the wire only, would always place itself at right angles to the line let fall from the perpendicular to the wire, and to the direction of the wire itself at that point.

The author made no attempt to illustrate the mechanical principles by which such an action might be produced; he only undertook to show, that if such a force be admitted, all the results obtained from the reciprocal action of a galvanic wire and a magnetised needle may not only be explained but computed, and that the results agree numerically with experiments.

44. The galvanic machine which he employed, is constructed after the principle of Dr. Hare's colorimeter, differing from his only in the mechanical contrivance for lowering and raising it out of the fluid: it consists of twenty zinc, and twenty copper plates, each ten inches square; but it possesses a power far beyond what is requisite for making every experiment connected with this branch of philosophy.

This machine is represented in fig. 10, p. I. a, b, c, Machine d, e, &c. is a pretty strong frame of wood, intended to carry the forty plates which are arranged as follows:

- on a stout strip of copper, at the back of the cross bar k l, are soldered, by their middles, ten zinc plates, and to another similar strip of copper are soldered, in like manner, ten copper plates; which are held in their respective places by nuts screwed on the ends of screw pins attached to the strips of copper, and passing through the cross bar, as seen in the figure; the two strips of copper having an opening of half an inch nearly between them. The other twenty plates, ten copper and ten zinc, are soldered in the same way to one copper strip the whole length of the frame, and screw-bolted to the corresponding cross bar of the frame on the opposite side, the ten copper first, and then the ten zinc; they are then arranged, so that there is one copper and one zinc, alternately, throughout the series; the plan of this combination is shown more particularly in (fig. 10, a) s, p, are the two poles, Fig. 10, a, which consists of hollow tubes of copper, soldered to the copper and zinc plates, which are the inside ones of the front row.

Into these tubes are inserted the ends of the conducting wire, when any experiments are to be made, the latter just fitting the tubes, so as to give a great freedom of motion, and yet such as to preserve a good contact.

A B C D E is a strong wooden box lined with copper, its purpose being to contain the acid into which the plates are immersed for experiment; it is two feet in length, sixteen inches in breadth, and nineteen inches deep. F G H I is a frame attached to the side of the box, having a cross-piece at top supporting a winch and iron axis, to which, in the middle, is attached a piece of catgut, which, passing over pulleys or rollers at the end, descends and receives into nooses, at the ends, the extremities of an iron bar which passes through the copper handles H H, and through two long slips cut in the upright pieces, from the top to the bottom. The axle is furnished with a racket wheel and catch behind. By this contrivance the experimenter may lower the plates into the fluid, and raise them again at pleasure: an object of importance, because the machine loses its power, if kept long immersed. It moreover possesses the advantage of enabling the experimenter to immerse the...
plated, more or less, at his pleasure, the catch-wheel preventing its running down. The table in front, may be let down or fixed up like the leaf of a table: when up, it serves as a support for the apparatus on which the experiments are to be made. The other part of the apparatus, peculiar to the experiments, is shown in fig. 11, A B, is an upright stand, placed near the poles of the battery; a b, c d, are two staples of stout copper wire, driven into the upright, the two ends at b and c passing quite through, as shown at C and Z; and on which two wires are fastened by spiral turns, and with which the communication is made with the poles of the battery; e f g h, are two copper wires of the same dimension as the staples, each four feet long, having their ends flattened and drilled so as just to enable them to slide freely upon the wires a b, c d, and the vertical wire f h, also four feet in length, which passes through a hole in the top of the table F G H I, and so tight as to render it perfectly fixed. On the plane of the table, which is two feet square, the circle N E S W is described about the centre o, and divided into the points of the compass and smaller divisions; N S, is an index or box ruler, through which the wire f h passes, so that the former may be turned freely about the latter, and set to any proposed azimuth. On this ruler is placed the small compass c', by means of which the deviation at any time may be taken; c" is another compass placed on the top of the support L c", and is intended to remain fixed in its place, in order to serve as a standard for estimating and comparing the power of the battery at different times.

45. For the principal experiments this apparatus is placed so that the plane of the rectangle of wires is perpendicular to the magnetic meridian; because in this position, the horizontal wires being east and west, they have no effect in deflecting the needle from its direction, (at least there is only one exception to this, which will be noticed hereafter,) and consequently, all the effect produced upon the needle during the rotation of the index in the circle N E S W, is due to the vertical wire only, except so far as the horizontal wires may increase or diminish the directive power of the needle. This, however, in the cases to which we shall refer is very inconsiderable.

But in order that we may know precisely what part of the change of deviation between one situation of the compass and another is actually due to that change of position, recourse must be had to the standard compass, which always remaining fixed in its position, may be used as a constant indicator of the strength of the battery.

The vessel which contains the dilute acid, into which the plates were immersed, holds nearly twenty gallons; and the experiments were begun with little more than twelve gallons; moreover the plates were not, in the first instance, let down to their lowest point. The intensity, shown by the standard compass after the connection had been made some minutes, was noted; and by breaking off and making the contact anew, this same intensity occurred again, the power being always strongest when the contact is first made; then, when the standard compass returned, to its former bearing, the observation with the other compass was taken; the contact broken and renewed, and so on as long as the battery retained sufficient power. When this failed, the plates were lowered a little more, the power thus increased, and the observation resumed, till at length the plates being wholly down, and the power too weak, recourse was had to a supply of more dilute acid; by which means a tolerably steady action was kept up, longer than was necessary for any series of experiments of this kind.

Having thus explained the means employed, and the precautions adopted, to ensure accuracy, we shall proceed now to explain the principles of computation, and to compare the numerical results thus obtained, with those derived from experiments.

46. According to the hypothesis, (art. 43,) if we conceive the wire, in the first instance, to be vertical, and the compass placed to the north or south of it, and opposite its middle point, the centre of action will lie in the horizontal plane, and at right angles to the natural horizontal direction of the needle. The latter, therefore, (which, for simplicity sake, we shall at present consider as indefinitely short, with regard to the distance,) will, at either of those points, be acted upon by two rectangular forces; viz. the galvanic force in an east and west direction, and which we may denote by \( f \), and the natural magnetic or directive force \( m \); consequently, according to the principle of forces, the resultant will be expressed by \( \sqrt{f^2 + m^2} \) and the angle which it makes with the natural direction of the needle, being called \( \Delta \), we shall have

\[
\tan \Delta = \frac{f}{m}
\]

(1)

Hence the magnetic force being constant, the tangent of the needle's deviation at the north or south will be a correct measure of the galvanic power.

We have thus a principle, by means of which we may verify a part, at least, of our theory by experiments.

For example; since, by the supposition, every particle of the galvanic vertical wire acts inversely as the square of its distance from a given point, we ought to find a determined relation between the tangent of deviation and the length of the wire; or the length of the wire remaining constant, between the tangent of deviation and the distance, provided always that the intensity of the battery remain constant.

The apparatus explained furnishes the means of making both these comparisons. For the sliding horizontal rods will enable the experimenter to shorten the vertical conducting part of the wire; and in the second case, it is only necessary to slide up the compass to different distances, which may be done so quickly that it will not be necessary even to have recourse to the standard compass.

It is fortunate also that the calculation here alluded to, is of the simplest kind. For denoting the length of the wire by \( 2l \), and the distance of the compass by \( d \); assuming also \( x \) as any variable length, the corresponding elementary action at this distance will be \( \frac{x}{d^2 + x^2} \), and the sum of these actions will be

\[
\int_{0}^{d} \frac{x}{d^2 + x^2} \, dx = \frac{1}{d} \arctan \frac{x}{d}
\]

which vanishes when \( x \) vanishes; and which therefore when \( x = l \), and the two lengths are included, becomes

\[
\frac{2}{d} \arctan \frac{1}{d}
\]
consequently if we denote the deviation, as we have done above by \( \Delta \) we ought to find this force vary inversely as \( \tan \Delta \) or

\[
\cot \Delta \left( \frac{1}{d} \arctan \frac{l}{d} \right) = \text{a constant quantity.}
\]

The following are a few out of numerous experiments of this kind which the author made and which were all found equally satisfactory.

**Experiments to determine the magnetic deviation caused by a galvanic vertical wire at different distances.**

* That is, the mean of two observations at each station of the compass; the contact being changed. The same is to be understood of the deviation with the standard compass.

When it is considered that these observations were made on a compass needle only one inch in length, and that the divisions extended only to quarter points, it is impossible to expect a closer approximation. The needle and card, however, being delicately suspended, and the latter very distinctly divided, the observations might be depended upon to the nearest degree; for by means of a strong magnifying power the observer could always bisect and trisect the quarter points without any very sensible error.

* The standard compass cannot be used in these experiments, because the wire by which it is deflected is necessarily shortened with that on which the observations are made.

These results (except the last) although not so uniform as the above will be found, notwithstanding as nearly so as we have any reason to expect, particularly as the standard compass could not be employed.

Mr. Barlow, however, is inclined to attribute the discrepancy between the observed deviation and the computed, as the vertical wire shortens, to the approach of the horizontal wire, which has a tendency to increase or decrease the directive power of the needle, according to the pole with which the wire is connected, (as will be seen as we proceed,) and thereby rendering the action of the vertical wire more or less effective, according to the circumstances of the connection. (See art. 51.)

47. Having thus far verified his hypothesis by experiment, he next proceeds to the consideration of the deviation in different azimuths.

**Let \( Z \) (fig. 12.) represent the horizontal section of Fig. 12.**

a vertical wire proceeding from the zinc end of the battery downwards, \( o \) a particle of the magnetic fluid in different whose natural direction is in \( n s \), join \( Z o \), and draw \( r t \) perpendicular to \( Z o \); then, according to the hypothesis, the direction of the force excited by the wire \( Zs \), will be in the line \( r t \). Now the intensity of this force to turn the particle about \( o \) will vary as \( \sin \; t \; o \; n \), or as \( \cos \; Z \; Z \; o \), and its intensity in the line \( n s \), will vary as \( \sin \; S \; Z \; o \) which latter force will be additive to the directive power of the terrestrial magnetism. Let the latter force on the horizontal needle be called \( m \), and the galvanic force in \( r t = f \), also the angle \( S \; Z \; o = \phi \), \( S \) being the south point of the horizon.

Then the particle \( o \) will be urged by the two rectangular forces,

\[
m + f \sin \phi \text{ in the direction } n s \]

\[
f \cos \phi \text{ in the direction perpendicular to } n s \]

consequently, denoting the angle of the resultant, or the deviation of the particle from the line \( n s \) by \( \delta \), we shall have from the known principle of forces

\[
\tan \delta = \frac{f \cos \phi}{m + f \sin \phi}
\]

Let \( \Delta \) denote the deviation of the needle at the south point; then, from what has been already demonstrated (equation 1)

\[
f = m \tan \Delta
\]

which being substituted for \( f \) in the above equation, reduces it immediately to

\[
\tan \delta = \frac{\cos \phi}{\cot \Delta + \sin \phi}
\]

From which equation (the deviation \( \Delta \) being supposed known) the deviation \( \delta \) at every other azimuth may be computed.

48. This formula is as comprehensive as it is simple, and indicates by the changes of the signs in \( \sin \phi \) and \( \cos \phi \), a variety of cases, the whole of which with the author most satisfactorily confirmed by experiments. These may be stated as follows:

First, cot \( \Delta \) may be greater, equal to, or less than unity, accordingly as the observed deviation at the south is less, equal to, or greater than four points, or 45°. This consideration leads to three distinct cases.

**Case I. when cot \( \Delta \) > 1.**

Here the denominator of the formula is necessarily positive throughout the circle. In the first quadrant of which, \( \sin \phi \) and \( \cos \phi \) being both positive, \( \tan \delta \) is also positive, and the deviation is all one way.

2. When \( \phi = 90^\circ \), \( \cos \phi = 0 \); and \( \tan \delta = 0 \); there is therefore no deviation at the east point.

3. In the second quadrant, \( \cos \phi \) is negative, as is
Magnetism triary way, but it is the same in quantity in all equi-
distant situations north or south of the east.

4. At the north point, \( \sin \varphi = 0, \cos \varphi = -1 \)
and we have
\[
\tan \delta = -\tan \Delta
\]
the deviation is therefore the same as at the south,
but in an opposite direction.

5. In the third quadrant, \( \cos \varphi \) is still negative, as
in the second, but \( \sin \varphi \) is also negative, and therefore
the deviation, although of the same kind in direction
as in the second quadrant, is greater in its amount,
the denominator being less.

6. At the west, the \( \cos \varphi \) vanishes, \( \tan \delta \) becomes
zero, and the needle again resumes its natural direc-
tion that is, the needle will stand east and west.

7. In the fourth quadrant, \( \cos \varphi \) again becomes
positive, the deviation changes in its quality, but is
the same in quantity as in the third quadrant.

**Case II. when \( \cot \Delta = 1 \).**

8. Here the results are precisely the same in the
four quadrants with respect to direction, as in those
above explained; except that at the west point, where
\( \sin \varphi \) and \( \cot \Delta \) being each equal to zero,
and with contrary signs, the denominator vanishes with
the numerator, and the needle is indifferent to any
direction.

**Case III. when \( \cot \Delta \leq 1 \).**

9. Here in the first two quadrants the deviation
has the same character as in the preceding cases.
But in the third quadrant, the denominator of the
fraction vanishes before the needle reaches the west
point, \( \tan \delta \) becomes infinite, and the deviation is 90°;
that is, the needle will stand east and west.

10. For the remainder of this quadrant, \( \tan \delta \) is
plus, and the character of the deviation changes, till
at the west point the needle is found inverted.

11. From this point \( \cos \varphi \) becomes positive, but
the denominator being negative, \( \tan \delta \) is negative,
and remains so till it becomes infinitely negative,
as on the other side of the west, and the deviation
is 270°.

12. Lastly, from this point to the south, the de-
nominator is positive, and \( \tan \delta \) has the same sign as
at first, and at the south point resumes its original
development, provided the intensity of the battery has
been preserved constant.

To illustrate this last case by an example, let us
suppose that the deviation at the south point is
greater than 45°, as for instance 50°, then since \( \cot 50° = 0.83990 \),
and sin (150° + 57° 2') = -0.83914;
the denominator will vanish when the compass is
placed 57° from the north towards the west; the
\( \tan \delta \) is therefore infinite, or the needle will at this
place stand east and west.

Proceeding on towards the west, the deviation will
increase more and more till, at the west point itself,
the needle will be found inverted. At 57° from the
south, or 32° from the west towards the south, the
denominator again vanishes, and the needle stands
west and east; from which position the deviation
decreases till it becomes 50° again at the south point
as at first.

Hence it appears that in passing the index which
**Carries the compass from the position west 33° N. to
west 33° S., that is through 66° only, the needle
ought to make a complete semi-revolution on its
pivot; whereas if we pass the index the other way,
viz. through the north, east and south, we must
move it through 92° to produce the same motion
in the needle. A single trial will show how cor-
rectly this theoretical deduction accords with ex-
periment.

In the above case the needle makes a complete
reversion on its pivot while it is carried round the
wire; but this will not happen if the deviation at
the south be less than 45°. Let us, for example,
suppose it to be 40°; then cot 40° = 1.9175, and
\( \sin \varphi \) is never greater than + 1, or less than - 1;
consequently the denominator will not become zero.
In this case the deviation will be the greatest when

\[
\cos \varphi \over \cot \varphi + \sin \varphi
\]
is a maximum,
which happens when \( \sin \varphi = -\tan 40° \), viz. at 33°
from the west towards the north and south; but in
passing the index through this arc, the north point
of the needle will not, as in the former instance, pass
through the south, but will fall back towards the
north, passing through it as the index passes through
the west. Here again the theory is most satisfactorily
confirmed by observation.

It is proper, however, to caution the reader that to
ensure success in these experiments, it is necessary
to have a short needle, and to work at as great a
distance from the wire as the power of the battery will
allow of; because the above deductions have been
made by supposing the length of the needle incon-
siderable in comparison with the distance and length
of the wire.

The following is one series of numerical results
derived from the preceding formula, with the cor-
responding observations.

**Experiments on the deviation of the needle caused by Table of
a vertical galvanic wire at different azimuths, the deviations
at the south point being 16° 30', and the standard
compass showing always 25°.**

E L E C T R O - M A G N E T I S M.

49. Although the aberrations in these results are greater than could be admitted in experiments which allowed of more accurate means of observation, yet they are such as may be adduced as a confirmation of the hypothesis that has been advanced.

It may be proper here to observe, that the sign of plus or minus prefixed to the angle of deviation, is wholly arbitrary. We have called it plus when the deviation is easterly, and minus when it is westerly.

This sign however being thus fixed, it is necessary to give an indication of the course of the needle as it is affected by the galvanic wire, which at present has only been stated in general terms; viz. that it has a tendency to arrange itself at right angles to the line joining the nearest point of the wire and its axis.

To conceive this effect more particularly, the author directs that the reader should consider himself as a part of the galvanic circuit, or coinciding in position with it, having his head towards the zinc end of the battery, and his face to the needle; then the effect will be too carry the north end of the needle placed before him always to his left hand, when the apparatus consists as in this case of a simple combination of two plates; it is the reverse with a compound battery.

This is in all cases sufficient to remember, because it necessarily implies that the south end is carried to the right, and that if the wire proceed from the other extremity of the battery, the observer's direction will be reversed, as will also the motion of the needle, and the signs of the angles of deviation.

50. We have at present shown no other application of the standard compass than that of its indicating an uniformity of power in the battery at the time of registering the observation; it may, however, be equally useful in other cases. For example, let us suppose it to be placed (as in the experiments reported above) to the north of the wire, and let its deviation at any given intensity of the battery be $D$, while that of the other compass at the north or south is $A$; and let its deviation with a different intensity be $D'$, and the corresponding deviation with the other compass be $A'$; then it is obvious from what has been stated, that

$$\tan D : \tan A :: \tan D' : \tan A'$$

consequently, if the power of the battery between any two observations is such as to alter the deviation of the standard compass from $D$ to $D'$, that of the principal compass will be found from the equation

$$\tan \Delta' = \frac{\tan D \tan D'}{\tan D}.$$

We have therefore only to introduce this value of $\tan \Delta$ into our general equation,

$$\tan \delta = \cot \Delta' + \sin \phi'$$

which will thus become

$$\tan \delta = \frac{\cos \phi}{\tan D}$$

$$\frac{\tan \Delta \tan D'}{\tan \Delta + \sin \phi}$$

a formula which is applicable to all degrees of intensity.

51. Let us now examine the circumstances attending the deviations caused by a horizontal wire placed in the magnetic meridian.

In this case conceive $SENW$ (fig. 13) to represent a vertical circle in the plane of the section of the wire, and corresponding with its middle point, of a horizontal $\Sigma$ and $W$ being its east and west points. Let $o$ be a zonal magnetic particle or a horizontal needle, the direction of which is perpendicular to the plane $SENW$ examined.

Let the force in the line $r$ be denoted by $f$ as before, and call the angle $SZo = \phi'$. Resolve $f$ into the two rectangle forces, $f \sin \phi'$, $f \cos \phi'$; the former of which being perpendicular to the horizon will only affect the inclination of the needle; but the other force, $f \cos \phi'$, being horizontal, and in an east and west plane, will be wholly effective in producing its deviation.

Let $\Delta$ be the deviation at $S$, which will be the same whether the wire be horizontal or vertical, because in both cases the tangential force is horizontal and perpendicular to the needle.

Consequently, as in the former case,

$$f = m \tan \Delta$$

and our two forces become

$$m \tan \Delta \cos \phi', \text{ in the horizontal plane,}$$

$$m \tan \Delta \sin \phi', \text{ in the vertical plane;}$$

the former, as we have seen, is the only one which affects the bearing of the needle, and is therefore the only one we have to examine.

From this we obtain,

$$\tan \delta = \frac{m \tan \Delta \cos \phi'}{m} = m \tan \Delta \cos \phi';$$

and hence we learn, that as the compass is carried round the wire in a vertical circle, the tangent of the deviation of the needle will vary as the cosine of the angle $SZo$.

This cosine being zero at the east point, the tangent $\delta$ vanishes and the needle stands in its natural direction, but will be inclined downwards by the force

$$\tan \Delta \sin \phi';$$

Beyond the east point the cosine $\phi'$ becomes negative, the sign of $\tan \delta$ changes, and consequently the deviation is now the contrary way. At $N$, $\cos \phi = -1$, and $\tan \delta = -\tan \Delta$, we have therefore here the same deviation as at first, but in an opposite direction.

In the next or third quadrant, the cosine $\phi'$ is still negative, and the deviation is the same both in quantity and direction as in the second quadrant. At the west point $\cos \phi'$ again vanishes, and the needle returns to its proper direction. In the fourth quadrant $\cos \phi'$ is positive, and the deviation is the same both in quantity and direction as in the first quadrant. There is not therefore in this case the same kind of anomalous deviation which takes place in the vertical wire.

The other force $\tan \Delta \sin \phi$, which affects the needle's inclination, is greater at the east and west points; it is nothing in the zenith and nadir, and in all intermediate positions it varies as the sine $\phi$. All these deductions are perfectly consistent with the general character of the observations of Mr. Oersted, and other experimenters.

* By the east point is meant that point in the circle which is to the east of the wire, and in the same horizontal plane with it.
It was at first asserted by Mr. Oersted that a horizontal wire arranged east and west had no power on the needle, except to disturb its inclination. But it ought obviously, according to the above theory, to produce the same anomalous action as the vertical wire in the case where $\cot \Delta$ is equal to or less than unity; because then the galvanic force being equal to, or exceeding the terrestrial directive force, it ought, when the two are opposite, to reverse the direction of the needle; and this will be found to be the case by suspending the latter above the upper, or below the lower horizontal wire, when the former is connected with the zinc end of the battery, and the reverse with the opposite connection; it was, doubtless, the weakness of Mr. Oersted's machine that prevented him from noticing this action in the first instance. It is this effect to weaken or reverse the direction of the needle that we have alluded to in art. 46.

52. We might now proceed to a variety of other investigations for different directions of the wire, or even generally for every possible direction, and for a needle freely suspended and susceptible of motion in all directions; but as it would be difficult to submit the results to the test of numerical experiments, it would be useless to proceed with the investigation, as our results are necessarily only approximative; because we have throughout supposed the needle indefinitely short in comparison with the distance and length of the wire; but by this means the subject has been rendered perfectly intelligible to every one; whereas had we taken the actual case of the reciprocal action of every particle of the fluid in the wire upon every particle in the needle, and had been able to complete the investigation, it could only have been understood by a few mathematicians; at the same time the minute corrections thus introduced would not have been appreciable in the comparison of the results with experiments; these latter being necessarily both liable to small irregularities and difficult to observe.

It may also be observed, that we have hitherto supposed only one species of action in the galvanic wire; but it is highly probable that it is compound, and that while the north end of the needle is carried in one direction, by the action we have supposed, the south end is carried in an opposite direction; not merely as a consequence of the first force, but by a distinct power. This will not, however, in any respect affect our investigation; because both forces lead to similar results.

We have seen a precisely analogous instance in our investigation of the laws of induced magnetism, where it appears that we obtain exactly the same results, whether the magnetic fluid is considered as simple, and acting equally on each extremity of the needle, or as compound, and acting reciprocally on both; and it was only for the sake of certain analogies, (explained in our section on Terrestrial Magnetism,) which the author was desirous of preserving, that he was induced to adopt the latter hypothesis. Similar reasons may also render it necessary, in this case, to admit the existence of a compound action in the galvanic wire; but which, as we have already stated, will in no respect affect the preceding investigations.

53. These experiments furnish one striking fact, which must not be lost sight of, in forming a theory of electro-magnetism; they prove, incontestably, that to whatever mechanical principle the electro-magnetic action may be referred, the result of that action is a tangential force, which, between particle and particle, varies inversely as the square of the distance, and if nothing more is ever known of this principle, we shall be, perhaps, as well informed on this, as we are on most other physical subjects. What more do we know of the nature of gravitation, or universal attraction, or of simple electric and magnetic forces? In these, and in various other physical subjects, we are content to find the mathematical laws, without making useless inquiries concerning first causes; and it is highly probable, that after all that has been or may be written on the present subject, we shall be obliged to stop at the same point, and to leave the first cause as a matter too subtle for our comprehensions. At all events, we know that two currents of electricity in motion, impress by their mutual action a force differing very essentially from those commonly considered as electric, and which affects the magnetic needle according to the laws which have been stated in the leading articles of this section.

§ III. Thermo Electric-Magnetism.

1. Professor Seeback's experiments.

54. The advances that had now been made, seemed to have nearly exhausted the subject, and to have elicited all the principle facts connected with the science of electro-magnetism; it had been demonstrated by what had been already done, that magnetism was produced whenever a current of electricity was made to pass through any conducting body, and some of the conditions and laws relative to the magnitude, length, temperature, &c., had been investigated by Sir H. Davy and Professor Cumming; the mathematical laws of this action had been satisfactorily developed by Mr. Barlow; Mr. Oersted and M. Ampere, had each laid down a theory, which, whether either of them were fully competent or not, to meet all the facts, served to generalize the greater number of them, and to reduce the action of magnets, and that of galvanic currents, to one general principle. But a new field was now opened to philosophical investigation, by the discoveries of Professor Seeback. This philosopher, a Member of the Academy of Berlin, discovered that an electric circuit may be established in metals, without the interposition of any liquid. The electric current is here established by merely disturbing the
ELECTRO-MAGNETISM.

Experiments by Baron Van Zuylen, Dr. Van Beek, and Professor G. Moll.

55. Professor Moll begins by observing, that "It was stated some time ago, by Professor Seeback, in one of the French and German scientific journals, that antimony, brought into proper contact with another metal, and unequally heated, would cause the magnetic needle to deviate from its meridian. With a view to ascertain this fact, and to investigate whether this property was restricted to antimony, or extended to other metals, the following experiments were made:

1. "A parallelopiped of antimony was procured, about fifteen inches long, and one inch square. This bar was prepared by treating crude antimony with sulphate of potash and tartrate of potash. A slip of copper was attached to both ends of the antimony, and bent, as fig. 14 indicates. It was kept in close contact with the antimony, by means of copper rings. This bar was laid in the direction of the magnetic meridian. A needle was placed on the antimony, as shown in the figure, and the ends N and S of the bar were successively heated by a spirit lamp. When the heat was thus applied to the south end S, the magnetic needle immediately and strongly deviated to the east. The extent of this deviation depends on the length, mobility, and strength of the needle. We have seen it as much as 60°. When the heat spreads more uniformly through the metal the deviation decreases, and the needle gradually returns to the magnetic meridian."

3. "The apparatus was then placed as in the first experiment, and both ends heated by a spirit lamp. No deviation was observed; on removing the lamp under the south end, the deviation was to the west; and on removing the lamp under the north end, that under the south remaining, the deviation was easterly.

4. "Two bars of antimony were used, and the needle placed between them, as shown in fig. 17. If both the ends N and N' were heated, the needle placed in c did not deviate. If the ends N and S' were heated, the needle deviated to the west. If S and N' were heated, the deviation was to the east.

5. "In this experiment, both ends of the bar of antimony were connected, not by copper but by zinc, as in fig. 14. The bent slip of zinc was fastened to the antimony by rings of the former metal. In order to make the experiment succeed, the oxide must be carefully removed from the place where both metals are in contact. If the end of the bar of antimony turned to the north, is heated, the deviation of the needle is westward, but much less than when the conjunctive slip is copper. By these experiments, Professor Seeback's statement is, we presume, fully confirmed.

6. "It then became necessary to inquire, whether antimony alone would act in this manner on the needle, or whether any other two metals, joined in the same manner, would produce similar effects. After some trials, the following apparatus was adopted. A thin slip of red copper of one-fourth of an inch in width, and a similar one of zinc, were bent, as in fig. 17, C.D., being about eight inches in length. The ends of the two metals were rivetted together at A and B, and the whole placed in the magnetic meridian, and a needle in E. A spirit lamp was applied to the end B, turned to the north, and the needle deviated 10° to the west. If the whole was suffered to cool again to the temperature of the atmosphere, and the lamp was applied at A, the needle would deviate to the east.

7. "The apparatus being inverted, so as to have the zinc above, and the copper under the needle, then on heating the part B, turned to the north, the deviation was 10° to the east.

8. "The experiment was repeated with silver and zinc, instead of copper and zinc, as in fig. 17. The apparatus being thus situated, the deviation was to the east, if heat was applied to the end turned to the north; and to the west, if applied to the end turned to the south.

9. "It was thus evident, that the property mentioned by Professor Seeback, is not restricted to antimony, but that other metals, properly disposed, will produce the same effect."

Professor Moll goes on in his letter to describe some other experiments, but in which acids, instead of heat, were applied to produce the electrical current; these therefore belong rather to the hydro-electric magnetism, than to the thermo electric; but as several of the experiments have reference to the results obtained by heat, and as several others differ from the usual hydro electric experiments in this, that only one metal is employed, while it had always been hitherto supposed that two metals were necessary, we are disposed to continue the series in this place, although
the remainder of the experiments may not be properly classed under the head of Thermo Elecricks.

3. Continuation of Professor Moll's experiments, in which the electro-magnetic action is excited, by means of an acid, and one metal only.

56. In continuation of his series from Experiment 9, above reported, the Professor states that General Van Zuylen here suggested a different way of applying the heat, and causing the deviation of the needle, in order to render the effects more striking.

Slips of copper and zinc were disposed as in fig. 18. Wheels about its axis, turning first through the west. With this view, a trial was first made with a metal, the point of the needle turned 70° to the east. Soon after, this deviation decreased, and became as strongly westerly, and another in D, were so arranged as to have their directions in the same plane. Sulphuric acid was then added, the needle immediately deviated to the east, while, by using sulphuric acid and water, it is to the west; when the end turned to the south is dipped in the fluid, the chemical action between the acid and the metals, independently of the heat evolved, having such a powerful influence on the results of the experiments, it was deemed necessary to inquire whether one metal, with an acid to act upon it, would produce the deviation. With this view, a trial was first made with a metal and an acid, not strongly acting on each other.

10. A slip of copper, perhaps sixteen or eighteen inches long, was then bent, as in fig. 19, and the ends coiled up, and brought as close into contact as possible; the whole being, as usual, disposed in the magnetic meridian, the needle being inside the copper, and the coil to the south. If sulphuric acid is added to the water in the cup, there is no deviation of the needle perceptible. But then, if a bar of zinc be immersed in the fluid, and made to touch the copper, the needle deviates 10° or 12° eastward.

11. If, instead of sulphuric acid, nitric acid be employed, a deviation of the needle to the west is observable, as soon as the acid is added to the water.

12. The bent slip was now made of zinc, in the same manner as it was made of copper in fig. 19, as in the former experiment. The coil being turned to the south, and sulphuric acid poured into the cup, the effect was very strong. The needle, placed as in fig. 19, first deviated to the east, but soon after turned to the west. In that situation it remained for some minutes, and then gradually returned to the magnetic meridian. If a new quantity of acid be added to the fluid, a subsequent deviation is produced, the needle first turning eastward, and afterwards westward. Whilst this deviation took place a bar of copper was introduced into the fluid, and made to touch the zinc. The needle began irregularly to vacillate, and actually was made to turn round several times on its axis.

13. The same experiment was repeated, but the ends of the zinc were made so as not to touch each other, as in fig. 20. As soon as the acid is added, there is a slight deviation to the east, to which succeeds a stronger one to the west. A bar of zinc is now introduced in the fluid, and successively made to touch the ends A and B. When this zinc touches the end A, the deviation increases to the east, but if it touched the end B, the deviation increases to the west. Both ends being joined by the zinc, the deviation is to the west.

Instead of a bar of zinc, another of copper is introduced, and successively made to touch the ends of the zinc. If it touches the end A, the deviation is to the west; if it touches the end B, the deviation is to the east; if both ends are joined by the copper, the needle wheels about its axis, turning first through the west.

14. The apparatus was then so far altered, as to connect both ends of the zinc by a bar of copper. This disposition was as follows: the needle A and B were united by a bar of copper C, extending between them, as shown by dotted lines. This part of the apparatus, as in the preceding, was turned to the south, and dipped in water. A thermometer proved the temperature of this water about 56°. When sulphuric acid was added, the needle immediately deviated strongly to the east; and as the temperature augmented to 92°, the deviation became strongly westerly.

15. Instead of zinc, iron was now made use of, and a hoop of three or four feet long, two inches wide, and one-tenth of an inch thick, was bent, as shown in fig. 21. The plane of this bent hoop was placed in the magnetic meridian, and two needles, one in C, and another in D, were so arranged as to have their directions in the same plane. Sulphuric acid was then poured on the water in the cup, and, instantaneously, the point of the needle turned 70° to the east. Soon after, this deviation decreased, and became as strongly westerly, and remained so for several minutes. It then slowly returned to the magnetic meridian: when returned in this situation, nitric acid was added to the sulphuric acid water already in the cup; by these means the deviation became 90° to the east, and remained so for a considerable time. Then a lump of zinc was thrown in the acids, and the easterly deviation changed to a westerly. After this a piece of copper was introduced, which made the needle turn on its axis. While the needle placed in C was thus deviating, the other in D followed in a contrary direction. Thus, if the needle C deviated to the east, the needle D deviated to the west. In general, the deviations of the exterior needle D were about one half of those of the interior one C. If, for example, C would deviate 90° to the east, the deviation of D was 45° to the east.

4. Experiments of Professor Cumming.—Second series.

57. It has been stated, that Professor Seeback, of Professor Berlin, first discovered that electricity or electro-magnetism might be developed by heat, but that we experiments were not in possession of his actual experiments. This seems also to have been the case with Professor Cumming, who appears to have had nothing to guide him in the long series of ingenious and important experiments we are about to detail, but the following very slight notification. "Take a bar of antimony, about eight inches long and half an inch thick, connect its extremities by twisting a piece of brass wire round them, so as to form a loop, each end of the bar having several coils of the wire. If one of the extremities be heated a short time by a spirit lamp, electro-magnetic phenomena may be exhibited in every part of it."

This, as we have said, was all the hint furnished,
relative to this new species of electro-magnetism, and to which we are indebted for the several important facts developed by the author, in his memoir, published in the Transactions of the Cambridge Philosophical Society for 1823.

58. The first object was to ascertain whether the coils, described as being made about each end of the bar, were actually necessary, as in some other electro-magnetic experiments we have described, or whether contact only was necessary. It was soon determined that the mode of attaching the wire to the bar was immaterial, provided only that a good contact was obtained. Instead of the coils, therefore, the wire was attached to the bar, by riveting, soldering, or by casting the bar on the wire, as was found most convenient.

59. The next inquiry was, is the effect described due only to antimony, or is it common to other metals? This query was answered by showing, that not only all the metals, including fluid mercury, but likewise plumbago and charcoal, and some, at least, of the metallic sulphures, possess the property of exhibiting electro-magnetism by heat, differing, however, both in quantity and quality. But before the reader can properly comprehend the nature of the experiments, from which the author drew his results, it will be necessary to describe the instrument which has been already mentioned in art. 39, i.e. the galvanometer, or galvanascope, for rendering obvious very small electric forces. This is represented in fig. 23.

A K are tubes filled with mercury, to be connected with the galvanic plates.

A B C D E, &c. a wire placed in a spiral form round the compass needle n s.

a b c, d e f, brass wires inserted in the galvanascope, and carrying the sliding wires b g, and e h, i k, l m, the neutralizing magnets attached to the wires b g, and e h; the purpose of which is to diminish or destroy the terrestrial directive power on the needle.

o p, q r, a brass wire inserted in the galvanascope at o, carrying a small magnet, moveable round q r, and employed for the nicer adjustments of the needle.

The galvanascope is placed east and west; the compass needle is then brought nearly into the plane of the spiral by the large magnets i k, l m, and the adjustment is completed by the small magnet t s.

This being understood, the wires on which the experiments are to be made, are inserted in the tubes A B, and the effect is immediately shown, and may be measured by the deviation of the needle.

60. A different form of this instrument has been lately described in the Philosophical Magazine for December, 1823, by an ingenious artist, James Marsh. It is as follows:

A B, C D, (fig. 24) are two wooden supports or pillars, through which pass brass wires, having each at its extremity a small brass cup, to the other extremity of each is attached, by good contact, the square helix cage shown in the figure; on the top of the prop E is a fine point, carrying a very light and delicate compass needle, with a card below; F G is a stand for holding the bar of bismuth, antimony, or other metal; R S, and n m, n' m', are wires of a different metal, soldered or bound round at the ends R and S. The set-screw at s, is for adjusting to any height. The brass cups being now rubbed with a little nitrate of mercury, and pure mercury being poured into them, the contact is made or broken at pleasure, by placing the wires in, or throwing them out of the cups; and the effect thus produced is shown in the most sensible manner by the needle within the cage, which, in very delicate cases, may be neutralized by the small magnets n s, n' s in the foot below, when the instrument is placed east and west, or by inserting them in holes, for the purpose, in the props A B, C D, as seen at p and q, when it is in the meridian. Then by applying the lamp at R, then at S, changing the bars and wires, and the size of the latter, &c., all the variety of experiments connected with this inquiry, may be readily performed.

61. Having thus explained the means adopted to continue the experiments into effect, we shall proceed to describe them more at length. It was stated, that all the different metals possessed the property in question; but in different degrees, and with opposite characters. If, for instance, a bar of bismuth, at each end, be heated at one extremity, on placing the wires in the mercurial cups of the galvanascope, the heated end produces a deviation of the compass needle, in the same direction as the wire from the silver disc in the common galvanic circuit; with antimony it is the reverse. These metals may therefore so far be considered as positive and negative to each other. On examining the other metals with copper wires, Professor Cumming found, that they might be distinguished into two classes, the heated end of the one, and the cooler end of the other, exhibiting the silver or positive electricity; but there were some singular modifications when other wires were employed which engaged much of the author's attention, and will, we have no doubt, excite great interest in the minds of other experimenters in this novel and instructive branch of philosophy. In detailing these modifications it will be best to use the author's own words.

62. "If the bar be of copper, the deviation becomes negative, or positive, accordingly as the wires are platina or silver; or if the extremities be considered as positive and negative with the one, they are negative and positive with the other. The same effect was produced with a bar of zinc, and zine or copper wires, and with silver, platina, and palladium, as the wires were silver or platina. In these instances it seems remarkable, not only that the bar appeared to change its electrical station with different wires, but that electricity, or rather electro-magnetism, should be exhibited when the bar and wire were of the same metal. In the first case, it might be supposed, that the electricity was excited by the contact of dissimilar metals, (that is, dissimilar as to their galvanic relation,) as, in the galvanic circuit, copper is positive to zine, but negative to silver. But this hypothesis is applicable to cases of the second description. If the effect depended on the contact of dissimilar metals, it would be greatest between those which are opposed in the galvanic circuit, and would cease when the bar and wire were of the same substance.

"On making the trial with a bar of zine and silver wires, the deviation was not greater than that by the same bar and wires of zine. Again, platina and silver are both positive with reference to copper, yet the deviations were opposite; and silver and copper bars acted strongly with silver and copper wires respectively. As in these instances, to prevent ambi-
I cannot but conclude, that the hypothesis of

Pig. 25. Magnetism bars. Electro-guity, the wires were not soldered, but riveted to the be heated at one extremity, and presented to the ductors of electricty, electro-magnetism may be having its ends connected by copper wire, A a'b B, produced, whether the temperature be elevated or de pressed. On placing one end of a bar of bismuth in a freezing mixture, or even by allowing a few drops of ether to evaporate from its surface, there was produced a considerable deviation on the needle of the galvanoscope; that extremity which remained at the temperature of the room, acting as the heated end of the bar in the other instances.

64. "If these experiments be referred to the hypothesis, which accounts for electrical excitation by the oxidation of the metals, they seem equally adverse to it. Not to repeat the instances of its production, where the heated bar and the wires were of the same metal, and in consequence similarly, if at all, oxidated; it can scarcely be imagined, that an elevation of temperature of not more than two or three degrees, should cause a difference of oxidation; and it is to be remarked, that the effect is produced, whether the temperature be elevated or depressed. In placing one end of a bar of bismuth in a freezing mixture, or even by allowing a few drops of ether to evaporate from its surface, there was produced a considerable deviation on the needle of the galvanoscope; that extremity which remained at the temperature of the room, acting as the heated end of the bar in the other instances.

Having ascertained that in all the perfect conductors of electricity, electro-magnetism may be excited by the unequal distribution of heat, my next endeavour was to determine the direction in which this peculiar influence is exerted, and the mode of its propagation. If a bar of antimony, A B (fig. 25,) having its ends connected by copper wire, A a' b B, be heated at one extremity, and presented to the compass, the deviation, in every part both of the bar and the wire, is of the same nature, and therefore the current of electricity (if there be such a current) is throughout in the same direction. The effect is similar, whatever metal be employed; but, as will be seen by reference to the first of the following tables, the direction of the current in some is opposite to that in others. If two bars of the same or of similar metals (that is similar, as to their development of electro-magnetism by heat) equal in power, be connected at their heated extremities; or, which is the same thing, if a single bar be heated at the middle no effect is produced, the equal and opposite currents counteracting each other: if under the same circumstances, the metals are dissimilar, the effect is that arising from the joint action of their aspiring currents. In some respects this arrangement is analogous to that of the galvanic circuit; heat in one case acting the part of an acid in the other; but there is one material difference between them. In the first, the metallic circuit is complete, and the current is, as has been already observed, in the same direction throughout every part of it. In the second, the circuit is interrupted, and the current through the acid is opposite to that through the wire, (fig. 26, 27.)

65. "If the bar of antimony A B above-mentioned be broken unevenly into two parts, a b, cd, (fig. 28,) and these be connected by a copper wire, on heating one part and cooling the other regularly throughout, no effect is produced, but if at b, the deviation is positive, the extremity a becoming the cooler end, and the part c d merely conducting the electricity; but as the bar cools, a b, and e the extremity of the other part, gradually acquiring the same temperature, and consequently the bars act negatively as at first. It appears then, that when the bar was entire, the heat was not merely conducted from one extremity to the other, but by some means modified in its progress; and that, for the production of this species of electricity, there is required the juxtaposition of two particles of the same metal at different temperatures. If, therefore, a cylindrical bar, unequally heated, be supposed to be divided into an indefinite number of circular laminae, each will act, as a layer of hot particles upon the laminae on one side, and of cold upon the other, and the total effect of the bar will arise from the aggregate action of these laminae.

"By soldering wires to a long rod of bismuth, (fig. 29,) the parts of which were alternately hot and cold, it was found that the action of the whole exceeded that of any two portions taken separately, and as the only condition appears to be, that there should exist a difference of temperature between two adjoining particles, it may be inferred, that if it were possible to increase these divisions sine limite, each bar would act as an assemblage of an indefinite number of small plates; as the common magnet may be conceived to be composed (if the expression may be allowed) of an indefinite number of atomic magnets."

66. The highly ingenious idea advanced above, Method of relative to the juxtaposition of two particles of the same metal at different temperatures, being an essen tial, if not the only condition requisite for the production of this species of electricity, led the author subsequently to a result by no means inferior in importance to any of the new and interesting facts that have been yet developed in this new branch of physics. "It occurred to me," says Professor Cumming, in an Appendix to his Memoirs, "that as the juxtaposition of two particles of the same metal, at different temperatures, was the sole condition requisite for eliciting electro-magnetism, it might be exhibited by the minutest metallic specimens. Portions of bismuth and antimony, each weighing one grain, were therefore placed on a silver disc, connected with the galvanoscope. On touching the upper surface of each separately with one end of a heated silver wire, the other extremity of which was placed in the other cup of the galvanoscope, the needle deviated through 90° positive, and negative respectively." By this method the author was enabled to examine the compound ore of iridium and osmium, of which...
ELECTRO-MAGNETISM.

The largest specimen did not exceed 1/4 ths of a grain, and to verify in a few minutes results for which the laborious process of casting bars of different metals had been previously requisite.

The following are the tabulated results obtained by Professor Cumming, exhibiting the thermo electric relation of different substances.

Note.—The specimen of silver was afterwards found to be not pure; the proper place for this metal is immediately above zinc. (See Annals of Philosophy, N. S. No. 35.)

The above table will be found highly useful in forming any experimental thermo electric combination.

Vol. IV.
69. In some subsequent experiments, Professor Cumming detected a very curious anomaly when iron wire was employed, and the heat produced by a spirit lamp; namely, that the deviation, in some cases, gradually attained a maximum, then returned through zero, and at a red heat assumed an opposite direction; an effect by no means the less interesting, that from the experiments detailed in sec. vi. of our treatise of Magnets, is shown that the magnetic power of simple iron changes its character when the metal attains this degree of temperature.

The results alluded to above, are contained in the following table:

Similar effects were not observed when iron was used with platinum or lead; and it was not noticed in any case, if iron were not one of the metals employed; but some other anomalies, not much less interesting, were noticed, as follows; viz. that when the heat was produced by dipping wires not previously connected in boiling mercury, the deviation in the first instance was found to depend upon which of the two wires was first immersed. Thus,

- Copper with gold: copper last, negative, then slightly positive.
- Silver: copper last, negative, then gold last, positive.
- Zinc: copper last, negative, then zinc last, positive, then negative.
- Brass: copper last, negative slightly, then positive, then brass last, positive.
- Plumbago: plumbago last, positive, then negative.

Similar results were obtained with zinc, iron, plumbago, gold, and brass, and other combinations.

These peculiarities, and the other interesting facts, which have been noticed above, seem to offer some of the best criterions hitherto known for tracing to its source the principle of this curious science. A number of other important facts relative to these inquiries, may be seen in the Memoir from which the above abstract has been made, published in the Transactions of the Cambridge Philosophical Society for 1823.

70. At present we have only very slightly alluded to the theoretical principles of this science, it will, however, be proper now to give some particulars relative to the theories that have been advanced, for explaining and generalizing the numerous facts elicited by the several experimenters whose names have been recorded.

In this part of the subject Professor Oersted, to whom the science itself owes its birth, stands first in the order of date; the theory, in his mind, having preceded and led the way to the discovery. It appears that, so far back as the year 1806, or 1807, when this philosopher began to examine into the nature of electricity, he conceived the idea that the propagation of electricity consisted (to use his own words) in a continual destruction and renewal of equilibrium, and thus possessed great activity, which could only be explained by considering it as an uniform current: he then regarded the transmission of electricity as an electric conflict, and his researches into the nature of heat, produced by electrical discharges, led him to the conclusion that the two opposite electrical forces, which pervade a body heated by their effects, are so blended as to escape all observation, without, however, having acquired perfect equilibrium; so that it was probable they might still exhibit great activity, although under a form of action differing entirely from that which may be properly termed electrical. It must be acknowledged, that it is difficult from the above statement to comprehend the views of the author, and we are by no means certain that we properly understand them; but he, at all events, was led, by some considerations of this kind, to suspect, as light and heat were both developed in an electrical discharge, that probably so also was magnetism; and in another place the author says, "it must then be determined whether electricity in its most latent state, has any action on the magnet as such." It is singular that, after entertaining such an idea, its truth should have remained so long a mere matter of speculation, and that it should not till the month of July, 1820, have been satisfactorily exhibited by experiment. This being, however, at length effected, some more distinct views of the mode of action developed themselves to the author, and which are stated by him as follows: "When opposite electrical powers meet under circumstances which offer resistance, they are subjected to a new form of action, and in this state they act upon the magnetic needle in such a manner, that positive electricity repels the south, and attracts the north pole of the compass; and negative electricity repels the north, and attracts the south pole of the compass; but the direction followed by the electrical powers is not in this state a right line, but a spiral one turning from the left hand to the right." As far as we can comprehend Mr. Oersted's ideas as above expressed, it is, that when the opposite electricities meet in their progress through the conducting wire, the positive electricity is turned out of its natural rectilinear course, and is made to perform a spiral motion along the wire in one direction, while the negative electricity, in like manner, performs a similar spiral motion in an opposite course, and that in this state the action exerted by these currents is no longer electrical but magnetic.

The author does not state, but we conceive that he means, that the spires of this spiral are indefinitely near to each other, and, therefore, that the magnetic action is thus exhibited, either exactly, or very nearly, in a tangential direction to the conducting wire. Indeed, as the spiral motion in this form differs very little from a circular current about the wire, the author assumes the circular motion in all his subsequent illustrations. We may, therefore, it is presumed, state, in concise terms, that Mr.
Oersted's idea of electro-magnetic action is, that the conflict of the two electromagnetics produces in these fluids a new mode of action, which is exhibited by its action on the magnetic needle in circular currents at right angles to the direction of the conducting wire. By means of this principle the author illustrates not only the action of a galvanic wire on the magnet, but the action of one galvanic wire on another; the discovery of which fact is due to M. Ampere.

Ampere's theory.

71. Let us now give some idea of what we conceive to be M. Ampere's theory of these actions. This philosopher seems to deny, in toto, the existence of magnetic fluids, or forces, otherwise than as they arise from certain electrical actions.

In his repetition of Mr. Oersted's experiments, he discovered that two conducting wires of the same, or of different galvanic batteries, acted on each according to certain principles; viz. that when the wires were parallel to each other, and the currents in each passing in the same direction, they were mutually attracted; and when the currents were passing in opposite directions, they were mutually repelled. And with this fact he ventured upon the bold assumption, that what we have hitherto been accustomed to consider as magnetic fluids, or forces, in a natural or artificial magnet, consist merely of electric currents always revolving about every particle of such a body in planes perpendicular to its axis, so that the attraction or repulsion that takes place between the opposite poles of two magnets, is merely the attraction of these electric currents; and in the same way the direction, which a magnetic needle assumes when under the influence of a galvanic wire, proceeds from the attraction between the wire and the parallel currents in the magnet when these correspond in direction, or from the repulsion between them when the currents are in opposite directions. And, in like manner, the direction which a needle assumes from the terrestrial action, is not, as has been hitherto assumed, due to magnetic poles in particular situations in the earth, but to the attraction of electric currents circulating about the earth in circles nearly parallel to the equator.

73. This theory serves to generalize a great number of facts; viz. first, the action of electrical currents on each other, as they are exhibited by freely suspended conducting wires; secondly, the action exhibited between a galvanic wire and a magnet; thirdly, the action of magnets on each other; and, fourthly, the principles of terrestrial magnetic action; and therefore, whether it be or be not a true exhibition of the actual mode of action, it possesses great advantages as an hypothesis, by its generalizing so many facts, and is highly creditable to the genius and talents of the author. That it is not actually a correct exhibition of the modus operandi, appears probable, because, in the first place, we can see no reason why a current of electricity in motion should possess a power which it does not exhibit when at rest; considering it as M. Ampere does, purely as an electrical property, and not as a power impressed upon it in consequence of the opposition or conflict of two electivities on each other. In this respect we think that Mr. Oersted's ideas approach perhaps nearer to the truth. It is, moreover, an immense demand upon the reader to require him to admit an infinite number of infinitely small electric currents perpetually circulating within the solid mass of a magnet or steel bar.

instance, much easier to imagine that the conflict of the electrical fluids in the conducting wires, should give rise to magnetic currents in planes perpendicular to the axis of the wire, and that these should act upon the magnetic particles in a bar of steel, whose direction is parallel to the axis of the bar, than to suppose the electric transmission to be made in right lines, and that these currents in this state act upon the corresponding supposititious circular currents in the magnet; and either hypothesis, if we are not much mistaken, will lead to the same results, at least as far as they serve to illustrate the electro-magnetic action. It is, for instance, obvious, that whether we consider currents of magnetism perpendicular to the axis of the wire attracting the lines of magnetic particles whose directions are parallel to the axis of the magnet, or whether we conceive currents of electricity revolving in planes perpendicular to the axis of a magnet, attracting the line of electric particles parallel to the axis of the wire, the result in both cases will be the same; namely, to place the axis of the electric and magnetic particles at right angles to each other, and to the line which may be conceived to join them, which is precisely the principle that we have seen, (art. 49.) Mr. Barlow has laid down in order to deduce from it the mathematical laws of electro-magnetism.

73. To see the agreement of the two hypotheses a little more distinctly, let the reader conceive a galvanic wire to be everywhere encompassed by magnetic currents perpendicular to its direction at any point, and imagine these attracting the magnetic particles in a magnet arranged, according to the common hypothesis, parallel to the axis of the magnet; then it is obvious, if a magnetic particle thus situated were free, it would arrange itself parallel to the magnetic currents in the wire, and therefore place itself at right angles to the direction of the wire and to the line joining the magnetic particle, and the general centre of action of this wire, that is, the magnetic and electrical particles would be placed at right angles to each other.

Let us now, with M. Ampere, suppose the direction of the electricity to correspond with that of the wire and the magnetic particles, (which we will suppose, for the present, still existing in the magnet,) to be surrounded by electrical equators perpendicular to their axis, and let us conceive the current in the wire to attract or repel these electric equators, then, again, it is obvious that the action between the wire and the equators of any magnetic particle will be to bring these parallel to each other, and consequently to place the particles exactly as in Mr. Oersted's hypothesis. It is true that M. Ampere admits of no magnetic particles, but attributes every magnetic phenomena to these equators only; this, however, does not affect the case, as we have put it; the existence of the particle being merely admitted for the sake of the idea of direction.

So that whether we employ the hypothesis of Mr. Oersted, or that of M. Ampere, we still arrive at the same result which Mr. Barlow has made the foundation of his investigation of the mathematical laws of electro-magnetic action; viz. "That every particle of the galvanic or electric fluid in the conducting wire, acts on every particle of the electric fluid or a magnetised needle, with a force varying inversely as the square of the distance; but that the
action of the particles of the fluid in the wire is neither to attract nor repel either poles of a magnet, nor does it produce tangential force which has a tendency to place the poles of either fluid at right angles to those of the other."

And as our object in this place is not to reduce the principles of magnetism to those of electricity, but merely to illustrate the several electro-magnetic phenomena, and as the latter hypothesis is by far the most simple idea that can be formed of this action, we shall for the present, as the safest plan, not stop to inquire into the mechanical means by which such a power is brought into action, but simply conceive it to exist, and then to act. To explain the various facts and reciprocal actions which have been observed to take place between a galvanic wire and a magnet.

Before we commence, therefore, our course of experiments, it is desirable that the reader endeavors to make himself familiar with the idea of his coinciding in position with any part of the conducting wire, and then to retain in his mind this formula: that when his head is towards the positive pole of the battery, and his face to the magnet, the north pole of the latter, or of a single particle, will be urged to his left hand, and the south pole to his right hand; and the contrary with the contrary position.

This being properly comprehended, the explanation of the several phenomena exhibited in the following course of experiments, will be found exceedingly simple and satisfactory.

**Course of Electro-Magnetic experiments.**

**Experiment I.**

74. *To illustrate the nature of the tangential force assumed in the theory.*

The reader conceiving himself to be making experiments on the table, fig. 11, plate I., let w fig. 30, be supposed to represent a section of the wire proceeding from the zinc or positive end of the battery downwards to the copper; and let ns, ns, &c. represent a magnetic needle in various positions about the wire. Let the effect of the terrestrial power on the needle be neutralized, by opposing to the needle a strong magnet at a proper distance, whereby it retains its magnetic power, but possesses no direction. If now the wires be connected with the poles of the battery, the needle will, wherever it is posited, take up one of the directions shown in the figure; that is, it will place itself directly at right angles to the wire, and to the line joining the centres of the needle and wire, or in a tangential direction to the wire at the point where the latter line meets its circumference.

If the upper part of the wire, as we have supposed, be connected with the zinc end of the battery, then the needle will assume the direction shown in the figure; that is, such that a person conceiving himself coinciding with the wire, and his head upwards or towards the zinc, and looking towards the needle, will find the north end of the latter on his left hand, and the south on his right; but if, on the contrary, the upper part of the wire be connected with the copper end of the battery, then also the needle will assume a similar tangential direction; but the north end will now be carried to the right hand, and the south to the left; that is, the direction of the needle will be reversed.

In like manner, if instead of the needle turning on a pivot, as supposed above, we conceive it turning on a axis like a dipping needle, and bring it against the upper or lower wire of the rectangle, (fig. 11,) then, also, the same tangential position will be observed, and the same principle obtained with regard to direction, as in the other case, the reader still assuming his position as coinciding with that of the conducting wire.

In our hypothesis we assume this as a fundamental principle of action, and therefore make no attempt to reduce it to mechanical principles; but M. Ampere, by going one step farther back, illustrates or accounts for this phenomenon by assuming that every particle of the needle, taken in the direction of its length, is encompassed by an electric current revolving in planes perpendicular to the axis of the needle, and which currents are attracted by the current in the wire, and brought parallel to it, and which consequently tends to place the needle at right angles to the wire, as shown in the figure.

Another method of exhibiting this effect is shown in fig. 31, where AB represents a horizontal section of a wooden vessel having a hole in its bottom, which slips tightly over the vertical wire of the rectangle, (fig. 11,) so as to hold a quantity of water, and ns is a magnetic needle stuck through a bit of cork so as to keep it afloat; the wires being then connected with the battery, the needle will first arrange itself in the tangential direction ns, and then gently approach the wire coming in contact with it in its middle point. This approach M. Ampere would explain by the attraction between the electric current in the wire, and the currents in the needle perpendicular to its axis. According to our principle of illustration, the extremity s of the needle is urged in the direction ns, and the extremity s in the direction sr, each perpendicular to the radius sW, nW, and which, of course, will urge the needle towards the wire in the manner exhibited by the experiment.

Another interesting form of this experiment is as follows: Let Z abc d C, fig. 32, represent a galvanic method. A wire of the form there shown, and AB a vessel of water, ns is a magnet stuck through a piece of cork, having one of its poles, as for example, the south, as much below the surface of the water as possible, and the other just above it. Let this be set afloat in the basin, and make the contact with the battery, and immediately the magnet will be affected and advanced towards the opening between the two branches of the wire, having its motion accelerated as it gets nearer, and when directly between them it will be urged with still greater force from the wire on the other side, and be carried to a distance where the influence of the wire ceases.

There is no question, we believe, that M. Ampere's theory is fully competent to the explanation of this experiment, but it is not immediately obvious; whereas, according to the principles advanced above, we see that the wire being ascending on one side, and descending on the other, the action of both branches conspire to give to the pole n, the only one exposed to the action of the wire, a motion in the same direction, and that this action will be greatest when the pole is between the two branches. With the combination shown in the figure, the motion is to the left hand of a person standing in the wire cd; but by

**ELECTRO-MAGNETISM.**

changing the contact, or by inverting the magnet, the motion will be reversed.

If the needle be made to float horizontally on the surface, as in the last experiment, then it will not pass through the branches of the wire, but remain in a central position with its middle point exactly in the plane of the two legs, as ought obviously to be the case, both wires acting with opposite forces on the two poles.

**EXPERIMENT II.**

75. To magnetise steel bars with the galvanic battery.

To magnetise steel bars.

Take a piece of steel wire, as for example a sewing needle, and dip its ends first into steel or iron filings, in order to ascertain that it has no magnetism already in it, which will be the case if the particles of iron do not adhere to it; if they do, another needle must be tried, till we find one free from every species of magnetic action; this being done, connect the ends of the battery by the conducting wire C Z, and place the needle N S across it, (fig. 33,) and it will be found in a very short time to have acquired the magnetic property; for on immersing its extremities again in the filings they will be found to adhere to it, in the same manner as to a needle magnetised in the usual way.

This very interesting experiment is strictly conformable to our hypothesis; for, according to this, the action of the galvanic particles in the wire being tangential, will act upon the latent magnetic particles in the needle, in the direction of its length, and cause a displacement of them, precisely in the same manner as would be done by a magnet; and also, in that case, the cohesive power of the steel preventing the return of the fluids to their natural state, the needle will remain magnetic.

If the needle be made a part of the galvanic circuit, or if it be placed lengthwise of the wire, no perceptible permanent magnetic power will be developed, which is also consistent with the hypothesis; because in this case, the action of the wire will be transverse of the needle, which is the least favourable direction for the development of the magnetic power; the tendency of the action being to place the poles transversely instead of lengthwise.

In order to ascertain the polarity given to the needle in this experiment; let the needle and wire be placed as in the last experiment, (see foregoing figure,) that is, the needle being above the wire, and Z denoting the zinc end of the battery of two plates only, and it will be found that the extremity N will attract the south end of a compass needle, and the extremity S the north end; in short, that the north poles of the latent magnetic particles have been carried towards the left hand, and the south towards the right hand, agreeably to the principles indicated in art. 45.

Let now the needle be placed under the wire, instead of being placed over it, and in other respects the process described in the last example repeated, and it will be found that the polarity of the needle will be exactly the reverse of that in the last experiment, which ought to be the case according to the principle of the above article; because by this the north polarity is always carried to the left hand of the observer, who conceives himself to form the galvanic circuit, his head being towards the zinc end, and his face towards the magnet; for thus his position being now the reverse of what it was in the preceding experiment, the polarity ought to be the reverse also.

**EXPERIMENT III.**

76. To show the effect produced by a galvanic wire on steel or iron filings.

This experiment is performed by strewing a quantity of iron dust or filings on a table, and bringing on steel the connecting wire near to them, when the filings and iron will immediately be affected by the action of the wire, some few flying towards it and adhering to it as to a magnet; and if the wire be brought into actual contact with them, a very considerable quantity may be taken up by it, exactly the same as at the extremity of a bar magnet; but the moment the contact is broken the filings fall.

In order to produce the best effect in this experiment, the wire intended to be operated upon should be smaller than the conducting part of the circuit. This latter, in all cases, is the better for being stout, at least \( \frac{1}{4} \) of an inch in diameter; but in this, as in several other experiments, it is best to have the extremities of the wires terminated by a much smaller wire, wound round the former as a spiral, or by simple contact, for by this means the transmission being made through a smaller space, the intensity of action is proportionally increased.

This experiment, as we have already stated, is due to M. Arago, and it seems at first sight somewhat at variance with our hypothesis; because we have here an appearance of actual attraction between the iron and the wire, whereas we have supposed that there is no attraction between them. A little consideration will, however, show, that instead of contradicting, this fact will serve to confirm the hypothesis in question.

Let us, for example, conceive W (fig. 34) to denote the section of our conducting wire descending vertically from the zinc end of the battery; then, the first and direct action of this wire will be to excite magnetism in any small particle of iron n s, according to the direction indicated by the letters in the figure, and agreeably to what has been stated in Experiment II.

After which, the action of the wire will be to urge the point n in the line n w, perpendicular to n W, and the point s, in the line s w, perpendicular to s W, and, in consequence of the combined action of these forces, the particle n s ought necessarily to approach the wire in the same way as it would do by a direct attractive force. As we have already explained in Experiment I.

This experiment may be pleasingly varied by using an helix instead of a straight wire. The best form of which, in this case, is that where the wire lies all in one plane, as in fig. 35. This being connected by fig. 38, its two extremities with the poles of the battery, will take up an astonishing quantity of filings, which, by their reciprocal attraction towards each other, exhibit the most pleasing appearance.

**EXPERIMENT IV.**

77. To magnetise a needle by placing it in a spiral conducting wire.

Let Z C (fig. 36) represent a conducting wire bent into a spiral form, and let the needle n s be placed...
ELECTRO-MAGNETISM.

78. To imitate a bar magnet by a galvanic wire.

Let a piece of copper or brass wire be wound round any small cylinder, so as to give it a regular spiral form as in the last experiment; and when completed, remove the cylinder and pass each wire down from its respective end to the middle, and then let each be turned through without touching the wire, which may be readily done if the wire possesses sufficient stiffness. Let then, the ends Z and C be carried off to the poles of the battery, and the connection established. This done it will be found that one of the extremities of the spiral, as N, will be a decided and strong north pole, and the other extremity a south pole possessing all the properties of a common magnet, as far as regards its magnetic action on a needle; but it has certain peculiarities, which will be noticed as we proceed. It is unnecessary to add, that by changing the contact the poles will be inverted.

This experiment, which is due to M. Ampere, is highly favourable to his theory, which reduces all magnetic phenomena to currents of electricity; the effect produced, however, is equally consistent with our hypothesis; for at the extremities of the spiral we have the sum of all the effects of the tangential actions of the wire in one direction, while in any intermediate part of its length, the spiral on one side, and on the other are acting in opposite ways, and are completely neutralized in the centre. See fig. 38.

EXPERIMENT VI.

79. To examine the effect of a spiral conducting wire on a floating magnetised needle.

Let a wire be wound about a glass tube of about a half or three quarters of an inch diameter, and hang it within a basin of water, as shown in fig. 39, so that the surface of the water rises to about the axis of the bore; then having pierced a small piece of cork with a needle previously magnetised, so as just to preserve it from sinking when immersed in the basin, make the connection with the battery. The needle will instantly be agitated, and will soon arrange itself in front of the spiral in a direction parallel to its axis, and then suddenly dart into the interior of the tube with a force nearly sufficient to carry it to the other extremity; it then returns again towards the other end, and at length becomes stationary in the middle of the axis, arranging itself exactly parallel to it.

If the spirals have the direction shown in the figure, and Z communicates with the zinc side, the needle, if placed near the extremity of the tube A, will enter with its south end; if placed near the other extremity, it will enter with its north end; but if the direction of the spiral be changed, the needle will enter in both cases the reverse way, as it will also if the direction of the spires remain the same, but the contact be changed. This experiment will succeed equally well if the tube be placed upright in the water, the needle will then dive like a fish, and remain below till the contact is broken.

This entertaining and instructive experiment is due to Mr. Faraday; the explanation of it by our hypothesis is obvious, for the north pole of the particles of the needle being carried to the left of an observer conceiving himself coinciding with the direction of the wire, and with his head towards Z, all the effects ought to take place precisely as above stated. M. Ampere, as we have seen, had assimilated a spiral wire of this kind with an actual magnet, and Mr. Faraday instituted the above experiment to show that there was not that identity which had been assumed; for by suspending a hollow cylindrical magnet in the same way, the needle was always attracted to the nearest extremity of its edge, and indicated no tendency to enter the tube.

To this, however, M. Ampere has replied, that if we consider the electric currents, which give action to a magnet, to circulate about every particle, then it ought to follow that a needle cannot enter the bore of a hollow magnet; because even in this form we are still outside of the revolving currents, so that a magnet, according to M. Ampere, can only be strictly imitated, but by combining in one an infinite number
Terrestrial Magnetism. 

EXPERIMENT VII.

To exhibit the terrestrial directive quality of a galvanic wire.

It was not long after the first experiments of Mr. Oersted, that the question naturally suggested itself. "Has the galvanic wire a directive, as well as a general, magnetic power?" This question was soon answered in the affirmative by M. Ampere, who made use of the following ingenious construction:

Fig. 40. A B, fig. 40, represents a piece of wood fixed to any convenient support, through which pass the two wires G, E, and where they remain fixed. At their upper and lower extremities are soldered the small metal cups a, b, c, d. DHI K, &c. is a part of the conducting wire, bent into the form shown in the figure, having small steel points soldered upon it at c and d. These points are inserted into the cups c, d, the upper one only resting on the base of its cup, the other being merely brought into contact with d, by a little quicksilver placed in it for that purpose, by which means the rectangle has a great freedom of motion given to it, the only solid contact being on the point c. Mercury is also poured into the other cups for the sake of a more perfect and certain communication than that afforded by the mere juxtaposition of the wires.

The apparatus being thus prepared, the two wires proceeding from the copper and zinc sides of the battery, are inserted into the cups a, b, and thus the connection is established; first, by means of the wire G with the cup c, thence by means of the contact of the point with the cup and mercury, it is carried forward from c, through the rectangle, to the cup d, whence it proceeds to the cup a.

We have already seen that of this connecting wire, the part from c to d has a perfect freedom of motion upon the point at c, and will therefore obey any exciting force. This force, in the experiment in question, is the magnetic influence of the earth, and in consequence of which the rectangle, immediately the contact is made, places its plane perpendicularly to the plane of the magnetic meridian, and to which position it will always return after a few vibrations, if it be drawn out of it by the hand, or otherwise.

This arrangement of the moveable conductor is perfectly consistent with our hypothesis, as is obvious without any further illustration than what has been given in the several preceding experiments; the magnetic poles of the earth now acting as those of an artificial magnet.

Fig. 41. A differently formed wire, and a more simple mode of suspension, is shown in fig 41. Here a brass or copper wire A C, rests at its bent end A, in a cup containing a little mercury, and is very moveable in azimuth round this point. The other end passes through the centre of a circular piece of pasteboard, and then forms spiral turnings in the plane of this circular piece. The wire is attached by thread or silk to the pasteboard disc, and at the point B it turns and descends till its extremity reaches the quicksilver in the cup D. The communication being now made at A and D with the battery, the spiral will immediately arrange itself, as in the last case, in a plane perpendicular to the magnetic meridian. This experiment is originally due to M. Ampere, and is one of great importance, as connecting the terrestrial magnetic powers with galvanism.

A needle upon a different and still better construction, also due to M. Ampere, is shown in fig. 42. The directive quality of the galvanic wire has been since exhibited in a variety of ways, much more simple than that above described, of which we shall only state the following:

M. de la Rive's apparatus.—This consists of a small galvanic combination attached to a cork; the plate of zinc is nearly half an inch wide, and extends about one and a half or two inches below its cork, its upper end passing through the same; the slip of copper is of equal width to the zinc, but passes round it, being thus opposed to both its surfaces, as in Dr. Wollaston's construction; its upper end also appears through the cork. A piece of copper wire, covered with silk thread, is coiled five or six times, and tied together so as to form a ring about an inch in diameter, and the ends of the wire are connected, by solder, one with the zinc, and the other with the copper slip above the cork. See fig. 43.

When this small apparatus is placed in water, slightly acidulated with sulphuric or nitric acid, the ring becomes highly magnetic, and will arrange itself in a plane perpendicular to the magnetic meridian, or it will at least indicate a tendency to take up that position, but the escape of the bubbles, arising from the decomposition of the water, prevents it from preserving a fixed direction.

Its magnetic qualities, however, are more obviously shown by bringing to it a strong magnet, such, for instance, as a cylindrical one about three quarters of an inch in diameter, and eighteen inches in length. This being applied at the distance of several inches, the ring is immediately attracted or repelled, accordingly as one or the other of the poles of the magnet is presented, or accordingly as one or the other side of the wire is opposed to the latter. When the result of the application is attraction, the cork will advance towards the extremity of the magnet, and if the latter be held horizontally, and in a line with the centre of the former, this will continue to advance till the pole of the magnet is within the ring, and then proceed with considerable velocity till it reaches the middle of the magnet, where it remains perfectly stationary. If now the magnet be withdrawn, and changed end for end, and reintroduced into the ring, the latter will go off from the magnet, turn itself round when quite free from it, again advance and settle itself as before in the centre.

This very simple apparatus, which may be made at the expense of about a shilling, throws great light upon the nature of the electro-magnetic action, and shows most satisfactorily, that, notwithstanding the intimate relation between the electro-magnetic and simple magnetic powers, they are not identical; a similar difference being observable here, as in Experiment VI. All the above facts will be found perfectly consistent with the hypothesis that has been advanced; for it will be seen, when the wire and cork are in equilibrio, as above stated, that an observer, conceiving himself situated as in art. 43, will have the north end of the magnet to his left hand, and the
south to his right, at equal distances, and acting therefore with equal and opposite powers; consequently the wire itself ought to be in equilibrio, and when disturbed from it will have a tendency to regain it, and hence be subject to all the conditions of motions that have been described. This is, in fact, very similar to Experiment VI, the difference only consisting in this, that in the present case the wire is moveable and the magnet fixed, whereas in the former, the wire was fixed and the magnet free; the explanation is of course the same in both.

Another form of this apparatus is shown in fig. 44. Both the above apparatuses are much improved by fixing to the cork a light glass cylinder A B to contain the acid, instead of floating them in it; the apparatus may then be floated on common water, and all the facts exhibited as above described.

This appendage to the original construction is due to Mr. James Marsh, an ingenious artist at Woolwich. Mr. Marsh has constructed a portable electro-galvanic apparatus; which within the space of little more than a cubic foot, contains not only the necessary galvanic combination, but also all the instruments necessary for repeating nearly the whole of the experiments detailed in this section. For this curious construction the inventor received thirty guineas and the silver medal of the Society for the Encouragement of Arts and Manufactures.

83. Apparatus of Prof. Van den Boss.—Here CD, fig. 45, is a copper plate, E G a similar one of zinc, about an inch square, kept from touching each other by the interposition of some small piece of wood: both plates are attached and suspended to slender brass wires P and R. The wire P enters at P, in the hollow space formed by a case of very thin quills inserted into each other, about six or seven inches long. The end of the wire comes out of the quill at the extremity T and returns, being wound as a spiral about it to the other extremity V; it then again enters the quill and proceeds in a right line to R, where coming out it descends and is attached to the other plate. The whole is suspended in equilibrio to a piece of untwisted silk X. The plates are now dipped into dilute acid, and the whole is suspended at X, when immediately the magnetic quality of the wire becomes manifest; but, like the former instrument, it is not so sensible to the terrestrial as to the action of a strong artificial magnet, with which its extremities T and V may be attracted or repelled, according as the one or the other pole of the magnet is applied; and which ought necessarily to be the case agreeably to the explanation given in the preceding case.

Experiment VIII.

84. To examine the inclination of a freely suspended galvanic wire as affected by the terrestrial magnetism.

This is an experiment first performed by M. Ampere, in which he employs the apparatus exhibited in fig. 46, where the galvanic circuit is carried on from the extremity of the battery towards V, passes by V S, through the steel pivot k, placed on the metallic plate N, and thence through the rectangle A B C D ; whence, passing through the tube x y, which serves as an axis for the machine, it is carried by means of a second steel pivot to the extremity of the battery towards R. The moment the connection was made, M. Ampere found the moveable part of this conductor in a state of vibration, which after a short time subsided; when the plane of the rectangle was found to coincide with what has been denominated the magnetic equator of a needle,—that is, with a plane perpendicular to the direction of the dipping needle.

It will of course be understood, that the axis of the machine must in the first instance be placed very exactly at right angles to the magnetic meridian, that the whole requires to be very nicely balanced, and that a little mercury be placed on the plates M N to render the contact the more perfect.

The lozenge z w is made of very light wood, and being fixed on the axis serves to keep the rectangle in its proper form.

That the machine ought, according to our hypothesis, to assume this direction, is obvious from all that has been previously stated, and therefore requires no particular illustration.

Experiment IX.

85. To exhibit the action of the terrestrial magnetism upon a galvanic wire freely suspended.

Let A B G D, fig. 47, represent a rectangular piece of hard wood, having two grooves a b, c d, Terrestrial magnetic action on a freely suspended galvanic wire.

C p, Z q are wires fixed in the board and passing each into its respective groove, with cups for making the connection with the battery wire, at Z and C. O m is a long piece of silk proceeding from the ceiling, or some other convenient place, and to which is tied the wire k m n, bent as in the figure, the points k and n being slightly immersed in the quicksilver. If now the connection be made at Z and C, with the zinc and copper sides of the battery, the moveable part k m n of the galvanic circuit, which has a great freedom of motion, will be projected towards the extremity A B of the board; and if the contact be changed, by making the zinc connection at C and the copper at Z, the wire will be driven towards the other extremity. As no magnet is introduced in this experiment, we have a right to attribute the motion to the effect of the terrestrial magnetism, the direction of it corresponding precisely with what we ought to expect from such action. For the terrestrial magnetism of our latitude being of the same kind as that exhibited by the southern pole of a magnet, the moveable wire ought to pass from right to left in the first case, and from left to right in the second, to an observer situated as described in art. 43; viz., as forming a part of the galvanic circuit, and with his head towards the zinc end of the battery; that is to say, with the first contact the wire ought to be projected towards A B, and with the second towards D G.

To prove that the motion proceeds from this cause, let the south pole of a strong magnet be brought under the board between Z and C, and make the contact again; and the same motion will take place, but in a much stronger degree, the wire being now thrown very forcibly out of the mercury.

The effect therefore being precisely of the same character, but much more powerful in the latter case than in the former, we have a right to conclude that the cause of the motion in both cases is of a

---

Professor Van den Boss's apparatus.

**Fig. 46.**
Dip of the needle exhibited by means of a galvanic wire.
ELECTRO-MAGNETISM.

like nature, the one proceeding from a southern polarity artificially produced, and the other from the natural magnetic action of the terrestrial sphere, as stated by Mr. Faraday, to whom we are indebted for this interesting experiment.

**Experiment X.**

85. To exhibit the rotation of a magnet round a galvanic wire.

Let A B D E, fig. 48, represent a cup of glass, wood, or any other non-conductor, and N S a small magnet, having a hole drilled at S, whereby it may be fixed by a short piece of silk S C, to the copper wire C C, passing through the foot of the cup; and let mercury be poured into the latter till the needle floats nearly vertical. Conceive, also, Z Z' to be a part of the conducting wire, descending from the zinc side of the battery, and slightly immersed in the quicksilver. If now the contact be made at C with the copper side of the battery, the magnet N S begins to rotate about the wire Z Z', passing towards the lefthand of the observer, situated according to the principles of art. 49. This rotation will be greater or less, according to the power of the battery, and will continue while there is sufficient force in the latter to overcome the resistance of the quicksilver to the motion of the magnet. If the descending wire proceed from the copper side of the battery, the motion will take place in a contrary direction, that is, from left to right.

Or, if the contact remain the same, and the magnet inverted, then also the motion will be reversed; but if the contact and magnet be both reversed, the rotation will be the same as in the first instance.

This highly curious and important experiment, which is due to Mr. Faraday, of the Royal Institution, is immediately explained by our hypothesis; according to which, the extremity N of the magnet is always acted upon by two forces, one the galvanic force, which is tangential to the wire, and the other the tension of the silk S C, in the direction of the magnet. Let this latter be resolved into two forces, one vertical and the other horizontal, and we shall find the extremity N under the influence of two horizontal forces, one always central and the other tangential. The result of which must be a rotation of that point about the wire; and it will be made with the position and arrangement shown in the figure, from right to left, the observer supposing himself situated as in art. 49.

**Experiment XI.**

86. To exhibit the rotation of a galvanic wire about the magnet.

Let A B D E, fig. 49, be a cup or vessel of wood or glass, and N S a magnet passing tight through its foot; Z Z', a conducting wire descending from the zinc side of the battery, and rendered free to move by the chain connection at g. Let mercury be poured into the vessel till the extremity of the wire is slightly immersed in it. Then the contact being made at C, (which, by means of the wire D C, communicates with the quicksilver,) the wire g z will immediately assume a rapid rotatory motion, much greater than in the former case, the resistance being very considerably diminished by the mode of suspension. The direction of the motion, according to the arrangement in the figure, being from left to right, to a person coinciding in position with the magnet. It may, however, be reversed by reversing the magnet, or by changing the contact, as in the preceding cases.

This experiment is also due to Mr. Faraday, and its explanation is the same as in the last; for since when the magnet is free it will, as we have seen, revolve about the wire from right to left, it follows that, when the magnet is fixed and the wire free, the latter will revolve in an opposite direction, (the action and reaction between the wire and the magnet being reciprocal,) which is still however towards the lefthand of a person supposed now as coinciding in position with the magnet, and his head to the north.

87. The same otherwise.

The resistance being very inconsiderable in this experiment, it may be exhibited in a more simple manner. For instance, instead of piercing the foot of the cup, as in the figure referred to, it will be sufficient to use a tea-saucer, or any other shallow vessel, and to bring a strong magnet near to it as possible under the table, when the motion will take place precisely in the same manner as above.

By this means also we may establish a most important fact; viz. that it is indifferent, as to the result of the experiment, what may be the position of the magnet; that is to say, if we keep the extremity of it as nearly as possible under the centre of the vessel, we may hold it either vertical or horizontal, or incline it in any angle, and at any azimuth, without greatly changing the rate of the rotation; it being always understood that the magnet should be of considerable length, in order that its other pole may not affect the motion of the wire. This result ought necessarily to be obtained, for in explaining the cause of the motion of the magnet about the wire, in Experiment X., we have made no reference to the position of the magnetic particles themselves; the motion, according to the principles we have adopted, would take place exactly the same (except as far as regards the mechanical difficulty) if the magnet could have been placed horizontally instead of vertically, and therefore the rotation of the wire about the magnet ought to be the same in both cases; viz. with the magnet placed either vertically or horizontally, and consequently also at all intermediate angles of inclination. This result was supposed by Mr. Barlow to be at variance with the theory of M. Ampere; but the latter philosopher, as well as M. Savary, has shown that it is in no-wise contradictory, but confirmatory of the doctrine in question.

**Experiment XII.**

88. Exhibiting the two preceding rotations by Mr. Faraday’s apparatus.

The machine for the exhibition of these motions, according to Mr. Faraday’s construction, is shown in
To exhibit the rotation of a galvanic wire on its axis by the action of a magnet.

Let \( N S \), fig. 53, be a magnet, represented as a magnet loaded with a piece of platinum attached to the cylinder \( z \), and the other wire into the cup \( C \), the motion is produced exactly as above described: the greatest freedom of motion is, however, given by the apparatus shown in the figure.

The explanation of this rotation is very obvious according to the hypothesis we have adopted, for the tangential force of the wire acting upon the magnetic particles on the surface of the magnet, must necessarily produce the rotation in question, on precisely the same principles as the magnet is made to rotate about the wire in the fifth experiment.

**Experiment XIV.**

90. To exhibit the rotation of a galvanic wire on its axis by the action of a magnet.

Let \( N S \), fig. 53, be a magnet, represented as a magnet loaded with a piece of platinum attached to the cylinder \( z \), and the other wire into the cup \( C \), the motion is produced exactly as above described: the greatest freedom of motion is, however, given by the apparatus shown in the figure.

The explanation of this rotation is very obvious according to the hypothesis we have adopted, for the tangential force of the wire acting upon the magnetic particles on the surface of the magnet, must necessarily produce the rotation in question, on precisely the same principles as the magnet is made to rotate about the wire in the fifth experiment.

**Experiment XV.**

91. To exhibit the rotation of the wire and magnet when both are combined in one system.

In the preceding experiments relative to the rotation of the magnet and wire, the one has been the wire fixed, and the other free, or they have both been free as in Experiment XII. In this experiment the two are invariably connected, but the rotation still takes place. E F C D, fig. 54, is a cup filled with mercury, \( N S \) Fig. 54, a magnet loaded with a piece of platinum T S to give it verticality in the fluid. LM is a wire, with a small cup of mercury Z, for making the connection with the battery. The ends LM of the wire pass through a piece of card, or any light substance, (in which also the magnet is fixed,) and thence descends into the mercury. The connection being now made with the battery at Z and C, the wire LM will rotate, as in the last experiment, carrying with it the magnet NS.
**ELECTRO-MAGNETISM.**

This experiment, which is due to Mr. Faraday, shows that the tangential force which causes these rotations does not take place between any fixed point in the magnet and wire, but that it exists between the particles of the fluids in the two bodies, and that the magnetism being accumulated at N, the action is the same, whether the magnet be in motion or at rest, as we ought *a priori* to have expected according to the hypothesis advanced in art. 43.

**EXPERIMENT XVI.**

92. To exhibit a quicksilver vortex by means of a galvanic wire and magnet.

To perform this experiment it is only necessary to take any shallow non-conducting vessel and put into it a quantity of pure mercury, into which to be inserted the conducting wires Z, C, proceeding respectively from the zinc and copper sides of the battery. And if now the north end of a strong magnet be brought under the vessel, the quicksilver round the wire C will begin to revolve about the same, forming a beautiful vortex, the direction of the motion being from left to right. If the magnet be removed under the other wire, the same kind of motion will be produced, but its direction will be reversed, and the same change of motion will take place, of course, in each case, by changing the end of the magnet.

The explanation here is precisely the same as in Experiment XIV.; the moveable part of the conductor in this case, owing its mobility to its fluid nature, whereas in the former it is due to the peculiar mode of suspension.

This very elegant experiment is due to Sir H. Davy.

**EXPERIMENT XVII.**

93. To exhibit the rotation of the galvanic wire independently of the galvanic battery.

For this purpose we must employ the apparatus exhibited in fig. 55, where A B C D is a small copper vessel about ½ inch high, and the same in diameter; a b c d is another small cylinder of copper, of the same height, soldered to the former vessel at its lower end d c, a hole being left in the bottom of the former to receive it. The cylinder a b c d is therefore open, and will admit a cylindrical magnet to be passed up, and it will at the same time hold a quantity of dilute acid within the space A D a b c B C; z z' is a zinc cylinder, very light, of rather less altitude than the copper one. To the cylinders a b and z z' are soldered two copper wires, as shown in the figure; the upper one having a steel point proceeding from E downwards and resting in a small metal hole at F, and consequently the cylinder z z' will be free to move upon its point of suspension F.

Things being thus prepared, and the acid placed in the cell as above described, insert through the interior cylinder the north end of a strong cylindrical magnet, and balance the whole apparatus upon it; when immediately the zinc cylinder will begin to revolve, with a greater or less velocity, according to the strength of the acid, the freedom of motion, and the power of the magnet. We have frequently with this simple apparatus produced a motion amounting to 120 rotations per minute. The only difference, between this and the other rotations above described, is, that the galvanic power is here produced by the apparatus itself, instead of having recourse to the battery.

For it is obvious that the wire from z z' to E, may be considered as a conductor proceeding from the zinc, and the wire from a b to F, as one from the copper side of the battery; and consequently, the same effect is to be expected here as in the preceding cases. It is unnecessary to add, that with the north end of the magnet upwards, the motion is from left to right, and the contrary with the magnet reversed.

This experiment is due to M. Ampere.

**94. The same otherwise, by Mr. Marsh.**

A very pleasing addition has been made to this Mr. Marsh's apparatus by Mr. J. Marsh. It consists in having a second point descending from F, which is made to rest in an agate cup, fixed on the top of the magnet, and upon which the whole machine is balanced, having a perfect freedom of motion; and to preserve this balance, the magnet is placed vertically in a foot. The machine being now charged with acid, a compound motion takes place, the zinc cylinder revolving in one direction and the copper vessel in another, producing thus a very pleasant effect; the latter, however, is by no means so rapid as the other, in consequence of the weight of the acid, and in fact that of the whole machine being supported on the lower point.

**EXPERIMENT XVIII.**

95. To show the effect of a horse-shoe magnet on a freely suspended galvanic wire.

Let Z z, fig. 57, denote a part of the galvanic Oscillatory wire, freely suspended by the chain connection at a, proceeding from the zinc end of a battery, its lower extremity being amalgamated and slightly immersed in a reservoir of pure mercury, having a connection at C with the other extremity of the battery. N S is a horse-shoe magnet, posited as shown in the figure.

The contact being now made at C and Z, the hanging part of the wire o z will be thrown out of the mercury into the position o z'; the contact being thus broken, it falls by its own gravity into the mercury, by which means the contact being renewed it is again projected, and so on with an extraordinary rapidity; and if the position of the magnet be reversed, or the contact be changed, the direction of the motion will be changed also, but the effect will be the same.

This singular motion may be still explained by the hypothesis that has been advanced; for the wire having a tendency to pass round the north end of the magnet to the right hand, and round the south end to the left hand, is urged by equal forces directly in a line with the open space of the magnet, the equality of the two forces preventing the rotatory motion about either, but both conspiring to give to the wire the rectilinear motion which has been described.

This experiment is also due to Mr. J. Marsh.
36 E L E C T R O - M A G N E T I S M.

**Experiment XIX.**
96. To exhibit a wheel and axle rotation by means of a horse-shoe magnet.

The machine by which this motion is produced is represented in fig. 58, where A B is a rectangular piece of hard wood, C D an upright wooden pillar, D E a piece of stout brass or copper wire, and a b a somewhat smaller wire, soldered upon it at F, on the lower side of which the wheel W, of thin copper, turns freely; h f is a small reservoir for mercury, sunk in the wood, and g is a narrow channel running into it: H H is a strong horse-shoe magnet. Mercury being now poured into the reservoir f g, till the tips of the wheel are slightly immersed in it, and the surface covered with weak dilute nitric acid, let the connection with the battery be made at i and D, and the wheel W will immediately begin to rotate with a great velocity. If the contact be changed, or if the magnet be inverted, the motion of the wheel will be reversed; but in general, the best effect is produced when the wheel revolves inwards. The suspension of the wheel, which is found to answer the best, is shown in fig. 59. This, which is due to Mr. Barlow, is a necessary consequence of the motion described in the last experiment, by which it was suggested, and the motion is explained on the same principles.

**Experiment XX.**
97. To exhibit a compound wheel and axle rotation with two horse-shoe magnets.

The machine for producing this motion is shown in fig. 60; A B G D is a rectangular piece of board, having two grooves, about half an inch deep, cut in it parallel to its length. C P, Z q are two wires having cups for connection at Z and C, and each passing into its respective groove a b, c d, filled with mercury; into which are slightly immersed the points of the wheels W W': these being fixed on an axle W W', and resting upon the two supports m n, r s, brought to a fine edge at n and s, in order to reduce the friction as much as possible, and to give the greater freedom of motion. N S are two horse-shoe magnets, posited as in the figure, with the like poles interior and exterior of the wheels.

The apparatus being thus prepared, and the contact made at Z and C, the wheels will begin to rotate, and in a very short time will acquire a velocity exceeding very considerably any of the motions hitherto described.

It is unnecessary to say that by changing the contact, or by inverting the magnets, the direction of the rotation will be also changed. The usual precaution of covering the surface of the mercury with weak dilute nitric acid, will increase the rapidity of rotation, but it is not actually necessary in this case. This experiment is also due to Mr. Barlow.

**Experiment XXI.**
98. To produce a rotation of the galvanic wire by means of the terrestrial magnetism.

This interesting experiment is due to Mr. Faraday, and it proves, in the most satisfactory manner, the influence of the terrestrial magnetism in the production of a rotatory motion. It is performed as follows: a very light copper, or platinum wire, about six inches long, is suspended very freely from a larger wire proceeding from either end of the battery, by means of the chain connection described in several of the preceding experiments, and at its lower extremity a small piece of cork is attached in order to keep the wire buoyant on a basin of pure mercury, about ten inches in diameter. The wire by which the above small moveable piece is suspended, is then so much depressed that the proposed revolving wire slopes at an angle of about 46° with the horizon; in this state the circuit of the battery is completed through the mercury in the basin and the other conducting wire, when immediately the short wire commences a rotation, as it would do about the south end of a magnet, but in a proportionally less degree, as the directive power of the earth is less than that of a magnet of the kind here supposed.

This similarity of action naturally leads us to infer a similar cause, and that this cause is no other than the terrestrial magnetism; still, however, in order to render this conclusion the more indisputable, Mr. Faraday changed the inclination of the wire, making it first equal to the angle of the dip; and when under these circumstances the wire was placed so as to coincide with the dip itself; viz. when placed in the magnetic meridian, sloping from south to north, there was no motion; and when the angle was still further increased, so as to exceed the angle of the dip, it was projected in two different directions, according as it was made to slope to the north or to the south, which is precisely what ought to be the case on the supposition of the motion being caused by the magnetism of the earth.

For let o z, o z', in fig. 61 and 62, represent the fig. 61 and freely suspended wire in the plane of the meridian, 62, sloping respectively to the north and south; and let N S in both figures denote the direction of the terrestrial magnetism; then it is obvious in the first of these figures, that whether the slope be towards the north or towards the south, it will be always on the same side of the line N S, and will in both cases be projected in the same direction with respect to the observer, situated, as supposed in art. 49, and consequently in opposite directions as referred to the circular rotation of the extremity z or z'. But when the slope is less than the dip, then the wire in its two positions being found on opposite sides of the line of direction, and passing still to the same hand of an observer situated in the wire, a rotation will ensue similar to those that have been described in our Experiments XI. and XII.

**Experiment XXII.**
99. To exhibit the action of two galvanic wires on each other.

The apparatus which may be employed for this purpose is shown in fig. 63, where A B represents a rectangular board, and D, E, two upright pieces of wood, carrying each a cross-piece at top with several holes for receiving the cups m n', n n' which exhibited by these means may be placed at different distances; a little mercury is poured into each of these so as to communicate with the wires inserted through the side of the cup, and terminated with fine points. The
wires \( w w', w b b' w' \) are bent as shown in the figure, and have small holes drilled at \( a a' b b' \), whereby they may be hung freely upon the points of the wires \( m m', &c. \) and carrying small weights \( w w', &c. \) in order to bring the points of suspension to correspond as nearly as possible with the centre of gravity, whereby the wires are moved by the least force. The conducting wires from the extremities of the battery \( Z Z \) and \( C C \) are terminated as represented in the figure, and being each brought to the respective cups, so that \( z z' \) are respectively inserted in the cups \( m n, \) and \( c' c \) into the cups \( m' n' \), the circuit will be made through the two wires \( a a', b b' \) in the same direction, and these being free to move about the points in the respective cups, will be strongly attracted towards each other, even at the distance of several inches.

Let now the branch \( z \) of the conducting wire \( Z z \) be lengthened so that it may pass round the board and be inserted in the cup \( n' \), while \( z' \) is inserted in the cup \( m \) as before; lengthen also the branch \( c' \) of the conducting wire \( C c \), passing it round the board and dipping it into the cup \( n \), while \( c' \) is immersed in \( m' \) as at first; by this means the circuit passes from \( z \) to \( c \) along the wire \( b b' \), and from \( z' \) to \( c' \) along the wire \( a a' \); in short, the circuits in the two wires are now made in opposite directions, and the wires experience and exhibit a mutual repulsion. Hence we learn, that two galvanic wires, parallel to each other, and in which the circuit is made in the same direction, are attracted towards each other; but they are mutually repelled when the circuit passes in opposite directions, a result first deduced by M. Ampere, and which has made the foundation of his theory of electro-magnetism, by assuming that the powers exhibited by artificial and natural magnets are due to currents of the galvanic fluids circulating in planes perpendicular to their axes; and, that those currents, when parallel to each other and passing in the same direction, are attracted, and when in opposite directions, repelled. We have already offered some observations on this theory, in art. 70, et seq. It is certainly highly ingenious, and will, most probably, lead to important results.

### 100. Experiments exhibiting various rotations induced by thermo electric magnetism.

At the conclusion of Professor Cumming's paper, referred to in art. 57 on Thermo Electricity, he has proposed a combination, intended to produce rotation by the action of a magnet on a rectangle of platinum and silver. Mr. Marsh, of Woolwich, in endeavouring to copy this apparatus, found that it had, a slight tendency to rotation, only not sufficient to give it a very decided character. He then attempted some little variation in the form of the rectangle, and a different application of the magnet, and ultimately succeeded in producing a very rapid rotation. An account of these combinations and experiments on them, was afterwards published by Mr. Barlow in No. 307 of the Philosophical Magazine, to which work we are indebted for them. They are stated nearly as follow:

On constructing a machine precisely from the description given by Professor C., it was found that it had indeed a tendency to revolve, but so small that it was very difficult, if not impossible, to exhibit the phenomenon in a satisfactory manner. It turned out, however, while carrying on the experiment, that, although a magnet in the interior of the wire would not produce any but a weak tendency to rotation, a magnet applied exterior to it was capable of producing the most decided effect, as will be seen as we proceed to describe the following experiments.

For this purpose four rectangles, fig. 64, 65, 66, 67, fig. 64, 65, were made of platinum and silver combined, as 66, 67, shown in the figures, where the thicker lines indicate silver wire, and the lighter ones the platinum; a ring being formed below to admit the prop upon which they were to revolve; and a fine steel point brazed to the upper side to rest in the agate on the top of the prop. The stand with a rectangle suspended is shown in fig. 68, where A B is a board, c d a brass prop Fig. 68. with its agate at top, and N S a magnet placed as nearly as possible to the wire. The spirit-lamp being now applied at D or E, the rotation will commence, either to the right or left, according to circumstances, and which will be reversed by reversing the pole of the magnet. Fig. 69 shows the same stand Fig. 69. with two magnets.

These being premised, the reader will easily follow the detail of the following experiments, observing that when the motion is said to be to the right or left, he must imagine himself coinciding in position with the wire about which the machine turns.

**Exp. 1.** The rectangle, fig. 64, being applied upon the stand, fig. 68, and the lamp at E, the rectangle was projected to the right till D reached the lamp; it was then propelled back again, and after a few oscillations it remained at rest at right angles to its first position.

**Exp. 2.** The rectangle adjusted as before, and the lamp applied at D, the wire was projected to the left with similar results to the preceding.

**Exp. 3.** The rectangle adjusted so that D was next the magnet, and the light then applied at D. The wire projected to the right.

**Exp. 4.** The rectangle still in the same position, but the light applied at the other extremity. The wire was projected to the left.

**Exp. 5, 6, 7, 8,** were made under precisely the same circumstances with the rectangle, fig. 65; and the results were similar, but much weaker, and the motions all reversed.

**Exp. 9, 10, 11, 12,** were made with the rectangle, fig. 66. The motions the same as with the rectangle, fig. 64, except that generally a rotation was obtained when the light was applied as in Experiments 2 and 4.

**Exp. 13, 14, 15, 16,** were still the same experiments, but with the rectangle, fig. 67. The results were as in the above case, but reversed in respect to direction, and inferior in force.

A similar set of experiments was made with the south pole of the magnet opposed to the wire, and the results were similar, but all in the reverse direction.

As it was obvious from these experiments that the rectangle, fig. 66, either from its more accurate balance, or from the nature of the combination, was the most powerful, it was alone made use of in the following experiments, in which two magnets were employed.

**Exp. 17.** The rectangle, fig. 66, being suspended as
shown in fig. 69, and the lamp applied at E, a rotation immediately commenced to the right, which soon increased to thirty revolutions per minute.

Exp. 18. The rectangle adjusted as before, and the lamp applied at D, the rotation to the left, at the rate of thirty revolutions per minute.

Exp. 19. The compound rectangle, fig. 70, was now suspended and opposed to the north end of the magnet, as in fig. 71, and the lamp applied successively at E, D, G and F. The following were the results:

Lamp at E, rapid rotation to the right.
Lamp at D, rotation to the left, thirty per minute.
Lamp at G, rotation to the left, thirty per minute.
Lamp at F, no tendency to rotation.

Exp. 20. The magnet reversed, the lamp applied as before.

Lamp at E, rapid rotation to the left.
Lamp at D, rotation to the right, thirty per minute.
Lamp at G, no tendency to rotation.
Lamp at F, rotation to the right, thirty per minute.

Exp. 21. The same experiments were repeated with two magnets with contrary poles opposed, as shown in fig. 72.

The results as above, but more rapid: in the last experiments there were obtained about thirty revolutions per minute, but it was impossible to count them in these, when two strong magnets were employed.

It should be observed that in no case could any strong tendency to rotation be observed when a magnet was employed for a support, and the exterior of the latter point is to the right, and all the other to the left; and so on, for any wire to which the lamp is immediately applied: and of course the contrary to this all ought to happen when the south pole is applied.

Let fig. 75, 76, 77, and 78, represent the four applications of the lamp as stated in Experiment 19; 77, 78, and the several arrows the direction of rotation as excited by the magnet and lamp in these four cases.

Then it is obvious that in fig. 75, answering to the case of the lamp applied at E, the tendencies to rotation are all in one direction, and we ought therefore to expect, as is actually the case, the rotation to be very rapid. In fig. 76, two of the forces are in one direction, and two in the other; and therefore if these forces were all equal, we ought to have no motion. But the force at D is very considerable in comparison with that at F or G, both on account of the immediate application of the lamp at E, and the division of the circuit into three branches at O; and the direction of the two latter forces on the respective levers, which being oblique are necessarily less effective in producing rotation. Again, the force at E is also considerable in consequence of the proximity of the magnet; so that the superior forces at D and E, conspiring in direction, will overpower the other two weak and oblique forces, and produce a very considerable rotation, although inferior to the former.

In fig. 77, the forces at E and G will be the superior forces; and as they conspire in direction, they will overpower the two inferior forces at D and F, which are opposed to them, and a considerable rotation will again ensue.

In fig. 78, the two superior forces also conspire, but with this peculiarity, that the moment the rotation ensues, and the arm F arrives at F', the direction of these two forces no longer assists in giving rotation, these being then both in the direction of the radii from the centre, and the resultant acts to bring the machine directly towards the magnet, and thereby to convert the rotation into direction, which the experiment strongly exhibits.

When the south pole of the magnet is opposed to the wire, all these directions of motion will be reversed, and then of course the point of neutralization will be at G, fig. 77; which explains the apparent anomaly of the point of no action being to the right hand of the north pole, and to the left of the south pole.

In fig. 77 we have seen that with the lamp applied at G the motion is to the left; and when at E, as in fig. 75, it is to the right; it follows, therefore, that between these two there ought to be some position of equilibrium as G', fig. 77, and where no motion of course ought to ensue. But in this case,
ELECTRO-MAGNETISM.

Fig. 79. Instead of the forces at G' and E' being directed from the centre as in the case of fig. 78, they are directed to the centre. So that this state of equilibrium differs from the former in this—that in the former, the equilibrium is one of stability, and in the latter of instability, and consequently very difficult to exhibit: in fact, the slightest inclination of the flame of the lamp in this situation of it, will give rise to a slow rotation in either direction according to the circumstances of the case. The same principles will enable us to explain the increase of acceleration produced by two magnets with their opposite poles applied as in fig. 69 and 72, and the cause of the non-action of a central magnet, except as in the apparatus of Professor Cumming, where one of the branches is carried further from the centre; in which case a slight tendency to rotation is exhibited equal to the difference of the two opposite forces.

We see thus the marked difference between the electro-magnetic rotations, produced by the application of the lamp, as in the cases above, and those produced by the galvanic machine; in the latter case it is essential to have the magnet central, whereas in this the magnet must be exterior to produce the desired effect; and the reason is obvious (referring for example to our Experiment XIV.) for here, and in all similar cases, the fluid being transmitted from the centre passes down the several branches in the same direction, and is therefore acted upon by the central magnet in all one sense; whereas in these, the fluid being ascending in one branch, and descending in the other, the forces on one side counterbalance those on the other, and the machine remains quiescent.

Since the publication of the above experiments in the work referred to, Mr. Marsh has contrived the literal apparatus, fig. 74, so that it may be placed horizontally, as in fig. 79; by which construction the necessity of employing two magnets, in any case, is completely avoided.

Fig. 79.

Marsh's portable electro-magnetic apparatus.

101. At art. 81 we have mentioned a portable apparatus, constructed by the above ingenious artist. An account of this has just appeared in the 41st volume of the Transactions of the Society of Arts, to which we are indebted for the following description:

"The whole apparatus is included in a box fourteen inches and a half high, fifteen inches broad, and ten inches and a half wide, which, when folded out, forms a convenient table for the operator. Fig. 80 is a perspective view of the box ready for use, the flap a being raised up and supported by the leg b, which screws into it. The voltaic battery, with its appendages, occupies about half the box, and consists of a plate of copper, with a plate of zinc on each side. Fig. 82 and 84 are a front and transverse view of the battery; the two exterior or zinc plates are united at each corner by metal fastenings, and the intermediate or copper plate is cut away at the corners just sufficiently to prevent it from contact with the fastenings of the zinc plates, and is secured in its position by pieces of wood: i i are two copper feet upon which the battery rests when in action. Two brass pipes c and z are soldered, the former to the copper plate, the latter to one of the zinc plates; they are intended to hold a little mercury, for the purpose of forming a perfect connection between the conductors c and z, fig. 80, and the battery; in order still farther to secure the connection, the ends of the conductors that are inserted into the pipes are first tinned, and afterwards amalgamated, as well as the other ends on which the spiral wires fig. 88, forming the poles of the battery, are fixed. The battery, when not in use, is lodged in the cell e, fig. 80 and 81, which is lined with wood and varnished; the two jointed handles, by means of which it is raised, being laid down into notches cut in the partition between the two cells. The cell d is somewhat wider than the other, and is lined with sheet copper; into this the exciting fluid (dilute muriatic acid) is poured when the battery is intended to be put into activity, and the united copper and zinc plates being raised, by means of the two handles, out of the cell e, are to be gently let down into the fluid, resting on the bottom of cell d, by means of the two copper feet i i already mentioned. By this arrangement the battery forms a series of three copper and two zinc plates, the lining of the cell forming the two exterior copper plates, and consists of about eight square feet of metallic surface. Two pieces of varnished wood, g h, fig. 81, are fixed to the sides of the cell to prevent the zinc plates from coming in contact with its copper lining; a small tray f is also placed on the flap e, in order to retain any fluid which may be accidentally spilled during the experiment.

"Fig. 84 shows the general arrangement of that part of the box, covered by flap a, fig. 80, in which the different articles of apparatus are deposited. The lowest compartment, represented more at large in fig. 85, contains a pair of horse-magnets, a cylindrical Fig. 85. magnet, a pocket compass, some spare copper wire, and two tin boxes, in one of which are contained iron filings, in the other spiral wires of copper, tinned and amalgamated. Over this is placed the lower shelf, fig. 86 and 87; the under projections of Fig. 86 and which secure in their places the articles already mentioned. The three upper shelves, fig. 89, 90, 91, are Fig. 89, 90, 91, cut out in the forms represented, in order to admit, 91, in the most secure and compact manner, the various pieces of apparatus described and figured in Mr. Barlow's Treatise on Electro-Magnetism, to which the reader is referred.

We must here conclude our treatise on this infant science, which at present has furnished many highly curious and interesting results, and which, in the course of a few years, will, in all probability, lead to important discoveries relative to some of the most mysterious natural phenomena, particularly all those connected with Terrestrial Magnetism.

The works we have consulted, in writing the preceding treatise, have been referred to as we proceeded; they may, however, be generally enumerated as below: Phillip's Annals of Philosophy; Tilloch's Philosophical Magazine; The Edinburgh Philosophical Journal; The Journal of the Royal Institution; The Transactions of the Royal Society; The Transactions of the Philosophical Society of Cambridge; Recueil d'Observations Electro-Dynamiques, by M. Ampere; and Barlow's Essay on Magnetic Attractions, 2nd edition. A Memoir has also been published by M. Savary on this subject, of which M. Ampere speaks very highly; but which we were unable to obtain in time to avail ourselves of it in the composition of the foregoing treatise.

W. Lowry &
ELECTRICITY.

In attempting to give a short abstract of the history of that branch of Physics now universally termed Electricity, it will be perceived that a single fact observed in the earliest ages, and as far as our information can reach, at first recorded by the Greek philosophers, has by the subsequent addition of analogous phenomena, created and given name to a separate and important science.

Thales of Miletus, who flourished about 600 years before the Christian era, is reported by subsequent writers to have described the power developed in amber by friction, by which it was enabled to attract bits of straw, and other light bodies; and an attempted explanation of this phenomenon is given as one of his philosophical dogmas. In the treatise of Theophrastus upon stones, we have the earliest description extant B.C. 321. of this property, "αριστος και τό αμέρον κάθος, και πνάρ όρφιν τό περί ανθρωποκλάκια και τάτοις ἣ τοῦ ἐλευθερίαν ἕκεν καί ακολουθεῖς." Theop. de Lapid. p. 134, Hill's edit. Speaking also of the Lyncurium, he says, "ἐν τοιαύτῃ τάσσεται τό ἐλευθρον ἐν ἐλαφιν ἐν μοινὸν κάλαθι και ἐξολυν, ἄλλα καὶ χαλκον καὶ ιατρον, εἶνας τός επτάν ὀπτέρ καὶ Δισελήθειες." p. 134.

It does not appear that Pliny's knowledge upon this subject, extended beyond that of Theophrastus: he states of pieces of amber that "attritus digitorum accepta, vi caloris attrahunt in se paleas et folia arida, ut magnes lapis ferrum." Plin. lib. xxxvi. cap. iii. and " nec folia autem aut stramenta in se rapere, sed aris aut ferris laminas?" like Theophrastus he also mentions the lapis Lynceus as possessed of the same property. In the same chapter he adds, "In Syria quique fominas verticillos inde facere et vocare harpast, quia folia, et paleas, vestimenta sخدم ad se rapit." Similar quotations might easily be adduced from the writings of Priscian and Solinus. Salmasius, in his commentary upon the latter author, asserts that karabe, the word by which amber was known among the Arabs, is said by Aviceenna to be of Persian origin, and to signify the power of attracting straws. (Hyl. Int.)

The ancient naturalists were well aware of another interesting electrical phenomenon in the shocks of the torpedo. Aristotle says that "this fish causes or produces a torpor upon those fishes it is about to seize, and having by that means got them into its mouth, feeds upon them." He further adds, that this fish "hideth itself in the sand and mud, and catches those fish that swim over it by benumbing them, and of this some have been eye-witnesses: the same fish has also the power of benumbing men." Pliny says that "this fish if touched by a rod or spear even at a distance, paralyses the strongest muscles, and binds and arrests the feet however swift." Nat. Hist. xxxii. ch. i. Galen the physician has given a similar description, (de locis affect.) Oppian describes the organs by which the Oppian animal produces this effect, (lib. ii. ver. 62.) and Claudian has a short poem upon the subject. The Claudian medical writers speak of applying the shocks of the torpedo for the cure of diseases. Scribonius Largus, Scribon. (cap. xii.) relates, that Anthero a freedman of Tiberius, was by this means cured of the gout. Dioscorides A.D. 50. advises the same remedy for invertebrate pains of the head. (lib. ii. art. Torpedo.) Further notices of this application may be found in Galen, Simp. Med. lib. xi. Galen, &c. Paulus Egineta, lib. v. Such is a summary of the knowledge of the ancients upon electricity; but the curious reader will also find much interesting matter on this subject in a dissertation by Dr. Falconer, contained in the third volume of the Memoirs of the Manchester Society, wherein it is rendered exceedingly probable that the use of conductors for attracting lightning from the clouds, was not unknown even in these early times.

The scanty fragments of information which the literature of the middle ages affords on this and every other scientific subject may be passed over in silence, and it may fairly be asserted, that from the time of Pliny until the end of the fifteenth century, no advance whatever took place in the branch of natural philosophy now before us. There is however mention made of more than one electrical phenomenon in the scholia upon Homer by Eustathius, Bishop of Thessalonica, Eustathius, A.D. 1160; one of these passages relating to A.D. 1160. Walimer, the King of the Goths, who commenced his reign, according to Du Fresnoy, A.D. 415, is too singular to be passed by unnoticed. "Βαλίμερ ὁ Θεωδόρης πατὴρ, ὁ κατακατήριος Ἰταλίας βασιλῆς ἀνάσης, τοῦ οἰκείου σωματος συνήθισεν ἐπί τέλλαλε. καὶ τιν ἐλ σοφος παλαισ θρησις πρὶς ἑαυτῷ, ὅτι ἑκουσιον ποτε καὶ ἑκουσιον αὐτω, συνήθισεν ἐπὶ ὑπονοιαν ἐξοντίοι, συνὴ εἰς εἰς κατ' ὑπονοίαν ὑποτε. ἐνώπιον ἐν καὶ φλογες ὅλαι κατάλαμπεν, φως το
Electricity.

Eustath. in H. E. p. 515, lin. 4, ed Rom.

"Wallimer the father of Theodoric, (uncle Πατρὸς?) who conquered as they say the whole of Italy, used to emit sparks from his own body; and a certain ancient philosopher says of himself, that once when he was dressing and undressing himself, sudden sparks were emitted occasionally, cracking; and sometimes he says, entire flames blazed from him, not burning his garment."

Although it is clear that philosophical speculations upon the natural properties of matter, were by no means valued or pursued in what we should now call a truly scientific manner; yet the following singular passage from St. Jerome may afford a sufficient proof that the facts which had been before recorded, were neither lost nor forgotten. "Arguit in hoc loco Porphyrius vel stultitiæ meorum qui statim secuti sunt salvatorem, et Julianus Augustus, vel imperiam historici mentientia, vel stultitiam eorum qui statim secuti sunt Salvatorem, quasi irrationabiliter quamlibet vocentem hominem sint secuti: cum tante virtutes, tantaque signa processerint, quæ Apostolos antequam erederent, vidisse non dubium est. Certe fulgur vpxe, et majestas divinitatis occulteraque eis in humand facie relucat, ex primo ad se veluentis trahere poterat aspectu. Si enim in magnete lapide et succinis hanc esse vis dictur, ut anulos et stipulam et festucas sibi copulat; quanto magis Dominus omnium creaturarum ad se trahere poterat quos vocabat." Sti. Hieronymi, Presb. lib. i. Com. in Matt. cap. ix.

As a science justly entitled to the name by resting upon judicious reasoning and careful experiment, electricity may be said to have originated with the publication of the treatise on magnetism by Dr. Gilbert, a.d. 1600, in which treatise as connected with his subject, several new electrical phenomena are brought forward. After adding the supposed origin of the name electrom for amber, ("Graci vocant ηλεκτρον quia ad se palea trahit attritu calefactum, unde ἄρας dictur et χρωσφόρον ab aureo colore, k.) Gilbert de Magnete, cap. ii.) he then gives a fair history of the state of philosophical knowledge in his own time, in the following sentences. "Quisvis sententiae res pulmomente, multis allicit. Dioc. lib. v. cap. 92.) diamond, sapphire, carbuncle, iris gemma, (quartz crystal, "quia quando radios solares excipit arcum coelesti similim jacit in parietem," Johns. Lex. Chem. opal, amethyst, vincentina, (Bristol stone,) beryl, and crystal. Glass, especially if pellucid, paste for false gems, glass of antimony, slags of furnaces, and blemishes; also sulphur mastic, sealing wax, hard resin, and arsenic but feebly, sal gem, lapis specularis, (mica,) and rochealum; the three last scarcely at all under the unfavourable circumstances of a moist atmosphere. He says that these substances not only attract straws but all metals, wood, leaves, stones, earths, water, and oil, in short all other substances. These experiments he directs to be performed by bringing the excited body near to the end of a light needle of any metal balanced, and turning freely on a pivot like the magnetic apparatus. Dr. Gilbert next speaks of the three kinds of attraction mentioned by Galen, and enters into a refutation of the opinions of some of his predecessors on the cause of electrical attraction, such as Cardan, Pictorius, and Fracastorius. He states that there are many substances which do not possess electrical properties except upon friction; but that there are other bodies which however well polished do not attract at all. Such are, emerald, agate, cornelian, pearls, Jasper, chaledony, alabaster, porphry, coral, marble, Lydian stone, flints, hematites, amyriss, (emery or corundum,) bones, ivory, hard woods, such as ebony, cedar, juniper, and Cypress, metals and natural magnets.

Having also observed how unfavourable was the presence of moisture or moist air to electrical experiments, he draws a parallel between electrical and magnetic attraction, which though sometimes erroneous, is for the most part ingenious, and must at that time have been instructive. His theory of electrical action supposes the emission of certain effluvia, which having previously existed in the amber or other electrified substance, were called into activity by the friction, and he compares the nature of these attractions to that of cohesion. Much that is erroneous in Gilbert's reasoning arises from the uncertainty which then existed respecting the true nature of bodies; all solids were considered as having formerly been fluids which had then become hardened, and as a specimen of the use he makes of this hypothesis, the following sentence may be selected. "Resina terebintiana liquida non allicit, teri enim non potest; at si concrævitur in mastichæn allicit." Gilbert then proves that the electric fluid does not affect the air, by showing that if its action takes place through the flame of a small taper, the flame does not move, and he infers that therefore the air adjacent to it is not put into motion. Mentioning two pieces of flint in the dark, he says that the silex emits an inflammable matter convertible into heat and light, but that the electric fluid is widely different, being so much attenuated that it does not take fire nor serve for combustion. The effect of fire in destroying the power of some electrics is also noticed, but the experiments of Gilbert on this point are fallacious.

The hypotheses of Sir F. Bacon, Cæcrops the Jesuit, Bacon, &c. Sir Kenelm Digby, Gassendi, and Des Cartes, may be passed over in silence, because however ingenious their speculations may have been, they are proved by subsequent facts to be erroneous; and produced no addition to the experimental department of the science.

Mr. Boyle will however demand some further degree of attention: his Experiments and Notes about the Mechanical Origin of Electricity, published in 1675, contains additional matter for the history of our subject. He speaks as follows of the opinions of the writers whose names we have just mentioned. "It is not necessary that in this paper where I pretend not to write discourses but notes, I should consider all that has been, or I think may be said for and against each of the above-mentioned hypotheses; since they all agree in what is sufficient for my present purpose,
Electricity, namely, that electrical attractions are not the effects of a mere quality, but of a substantial emanation from the attracting body; and it is plain that they all endeavor to solve the phenomena in a mechanical way, without recurring to substantial forms and inexplicable qualities, or so much as taking notice of the hypostatical principles of the philosophers. Wherefore it is evident that in this place I mention some of the phenomena that in general make it probable that amber, &c. draw such light bodies as pieces of straw, hair, and the like, by virtue of some mechanical affections either of the attracting, or of the attracted bodies, or of both the one and the other." p. 7. Boyle having found the advantage of warming the electric bodies, explains this by saying "that it is known that heat by agitating the parts of a fit body solicits it as it were to send forth its effluvia, as is obvious in odoriferous gums and perfumes, which being heated, send forth their fragrant steams both further and more copiously than they otherwise would." His next experiment teaches him that to warm a piece of amber first, and then to submit it to friction, was the most effectual mode of excitement.

The power of amber to remain in its attractive or excited state some time after the cessation of friction, was established by experiments upon a delicate steel needle suspended after the method proposed by Gilbert; and it appeared advantageous that the surfaces of the electric should be as smooth as possible; but Mr. Boyle mentions one diamond in its rough state which exceeded all the polished ones in his possession. To the list of known substances capable of electric excitation he added the following. The resinous cake remaining after the partial evaporation of turpentine, the dry residuum after the distillation of a mixture of petroleum and strong spirit of nitre, glass of antimony, glass of lead, white sapphire, white English amethyst, the almost diaphanous spar of lead ore, the carnelian, and a green stone which had been supposed an emerald, but which from its hardness, the lapidary considered a sapphire; to the two last Gilbert had denied this property. He describes also very philosophically the electric attraction of the curls of some ladies hair. In a very just spirit of investigation, he ascertained that the converse of all the experiments upon the relative motion of the attracted and attracting body was also true; namely, that if the substance to be attracted were fixed, and the excited electric capable of motion, their union would still take place. In order that he might ascertain whether electric attraction depended upon the ambient air, he introduced an excited mass of amber into the receiver of an air pump. The amber was suspended over a straw or feather, and after the exhaustion of the vessel, was lowered towards the light body which was attracted as before. We now know, however, that this had experiment, had been performed with rigid accuracy, a contrary result would have ensued. Mr. Boyle's theory, as might be expected from the passage we first quoted from his work, did not greatly differ from those of his immediate predecessors, he supposed that the electric body emitted a glutinous effluvium, which laid hold of, or became entangled in the pores of small bodies as they egress, and upon its return to the body which had emitted it, carried them back with it.

Contemporary with Mr. Boyle was the celebrated Otto Guericke, a burgomaster of Magdeburg, the inventor of the air pump, who also became a distinguished contributor to electrical science. His experiments were commenced by casting a globe of sulphur in a glass sphere; the glass was then broken and removed, the sulphur mounted upon a revolving axis in a wooden frame, and excited by the application of the hand. With this instrument he verified the experiments of preceding writers, and discovered in addition the light and sound accompanying strong electrical excitation; the light he compares to that produced by breaking lump sugar in the dark.

Guericke clearly demonstrated that a light body, after it had by attraction been brought into contact with an excited electric, was repelled by it, and could not be again attracted, until it had been touched by some other body. The most important of his experiments is one which has only met with a full explanation subsequent to the most improved state of our science; he found that if light bodies were suspended within the sphere of action of an excited electric, they themselves became possessed of electrical excitation. Thus if threads were suspended near to his excited globe, they would be repelled by the approach of his finger; and that a feather suspended and repelled by the globe always turned the same side towards it.

Experimenter of the air pump, who also became a distinguished contributor to electrical science. His experiments were commenced by casting a globe of sulphur in a glass sphere; the glass was then broken and removed, the sulphur mounted upon a revolving axis in a wooden frame, and excited by the application of the hand. With this instrument he verified the experiments of preceding writers, and discovered in addition the light and sound accompanying strong electrical excitation; the light he compares to that produced by breaking lump sugar in the dark.

Guericke clearly demonstrated that a light body, after it had by attraction been brought into contact with an excited electric, was repelled by it, and could not be again attracted, until it had been touched by some other body. The most important of his experiments is one which has only met with a full explanation subsequent to the most improved state of our science; he found that if light bodies were suspended within the sphere of action of an excited electric, they themselves became possessed of electrical excitation. Thus if threads were suspended near to his excited globe, they would be repelled by the approach of his finger; and that a feather suspended and repelled by the globe always turned the same side towards it.

In the year 1675, Sir Isaac Newton communicated to the Royal Society a singular and important electrical experiment; from which it would appear that he was the first who remarked that excited glass would attract light bodies, even to the surface opposite to that upon which it had been rubbed. "Having laid upon a table a round disc of glass about two inches broad in a brass ring, so that the glass might be one-eighth of an inch from the table, and then rubbing the glass briskly, little fragments of paper laid upon the table under the glass, began to be attracted and to move nimbly to and fro. After he had done rubbing the glass, the papers would continue a considerable time in various motions; sometimes leaping up to the glass and resting there, and then leaping down and resting there, and then leaping up and down again; and this sometimes in lines seemingly perpendicular to the table, sometimes in oblique ones; sometimes also leaping up in one arch and leaping down in another, divers times together, without sensibly resting between; sometimes skipping in a bow from one part of the glass to another, without touching the table; and sometimes hanging by a corner, and turning often about very nimbly, as if they had been carried about in the midst of a whirlwind, and being otherwise variously moved, every paper with a different motion. Upon his touching the table, the papers, as they hung under the glass, would receive some new motion, inclining this way or that way, according as he moved his finger." Birch's History of the Royal Society, vol. iii. p. 260. The phenomena of electricity are also for other purposes alluded to in Newton's Optics, p. 314—327, ed. 1721.

In just chronological order the researches of Mr. Haukesbee next claim our attention. In the year 1705 he noticed that mercury in broken glass reduced a light visible in the dark, and that when the density of the air is diminished to one-half, the light becomes much more brilliant. He ascertained that...
Electricity this was caused either by the friction of mercury against glass, or of the air, but could not satisfy himself by which. In his next series of experiments he showed that light was produced by rubbing together in vacuo, amber and flannel, glass and flannel, glass and oyster-shells, woollen and woollen, and glass with glass. He ascertained also that if glass be rubbed against glass, either in the air or under water, the same evolution of light takes place; but he could not produce the same effect with any of the other bodies tried. It is singular that in these and many such among his early experiments, it did not occur to him that the light thus produced was electrical. He produced a vivid light by rubbing an exhausted glass globe with his hand; also by agitating mercury in a varnished vessel, under an exhausted receiver, by breaking loaf sugar, or a lump of calomel, and at first supposed that these effects were due to some peculiar quality in the glass. By the admission of air into the glass globe, the light was diminished; but if the friction was continued, and a person brought his finger near to the globe, the light appeared on the point of the finger. His experiments on attraction and repulsion were performed by a wire-ring, round which he had tied short pieces of thread. When this hoop was brought near to an excited globe or cylinder, he found that in whatsoever position it was placed with regard to the excited electric, the threads all were attracted towards the centre of the globe, or towards a point in the axis of the cylinder. When in this state of things, he presented his finger to the threads; if very near, they would be attracted to it, but if the finger were about an inch from the threads, they would be repelled. He then tied two threads to the axis of a globe and cylinder, and found that when the globe or cylinder was turned round and excited by friction, the threads diverged in straight lines from the axis. The threads also were repelled by a finger held near to them without the glass, even though the finger did not touch it; but sometimes they would suddenly jump towards the finger. He found also, that when the threads were brought close within the glass, if he blew upon them at a distance of three or four feet, the threads would by their motion manifest that electric attraction was excited in the glass. If the threads were suspended freely in an unexcited globe, and any excited electric was brought even within a considerable distance of the exterior of the globe, attraction was developed. As this experiment did not succeed equally well in moist weather, he concluded that "the moisture on the surface of the glass prevented the free passage of electricity through it." In attributing this diminution of effect to the influence of moisture he was correct, but he erred as to its mode of action; for considering that the electric attraction passed through the substance of the glass, whereas in fact the side of the glass opposite to that approached by the excited body, became itself electrified by induction, a matter to be hereafter explained.

In Mr. Haukesbee's later experiments, he had arrived at the construction of the electrical machine, not differing essentially from some in use at the present time. His machine was in fact a glass globe, instead of the sulphur ball of Guericke; capable of being whirled round in a wooden frame. When a hand of air, and turned briskly, the application of his hand would produce a strong light on the inside; and by re-admitting the air, light appeared on the exterior also; but with this singularity, that it appeared to stick to his fingers, or to other bodies held near the globe. By bringing an exhausted globe near to an excited one, he found that a light was produced in the former, which soon disappeared; but which immediately reappeared in great beauty if the latter were again put in motion. Mr. Haukesbee considered that he had established that when friction is performed in vacuo no electrical attraction could be produced; but that though this effect required the agency, both of external and internal air, yet that light required the presence of but one of them for its evolution; because "either a glass globe full of air rubbed in vacuo, or with its air exhausted and rubbed in pleno, would either way produce a very considerable light." The following experiment must at that time, and indeed long after, have been considered one of great singularity. More than half of a glass globe coated with sealing-wax, exhausted and put in motion: on application of the hand without, for the purpose of excitation, the form of the hand was distinctly seen on the inner concave surface of the wax; thus appearing to give transparency to the wax, which in some parts was an eighth of an inch thick, and in the thinnest parts would only just allow the flame of a lighted candle to be seen through it in the dark. Even when the wax did not strictly adhere to the glass the effect remained the same. The same experiment succeeded when pitch was used instead of wax; and Haukesbee was surprised to find that on the admission of air, all parts of the interior of this mixed surface, attracted equally as if not coated at all. With melted flowers of sulphur, this experiment did not succeed, but with common brimstone it did. If the quantity of this sulphur was greatly increased, the light became four times as great, but the distinctness of the image of his fingers was diminished. By admitting a small quantity of air to the globe thus prepared, the light disappeared from the coated part, but remained upon the uncoated part. The following experiments were made upon the electrical effects of some other substances. A wooden cylinder was coated thickly with sealing-wax, and submitted to friction upon the machine. By the hoop and threads it was shown to be strongly attractive, leaf brass also was attracted by this apparatus. In comparing these effects with those of the glass cylinder, Haukesbee comes to a conclusion, which we now consider erroneous: "so that the electrical qualities of these two bodies, (glass and wax,) are the same as to all the most general properties. They differ only in degree, the effluvia of glass producing more powerful effects than those of wax." And yet he afterwards observes, from experiments made in the dark, that "none of the luminous matter would be communicated to one's finger when held near it; whereas in the lights produced from glass it was otherwise." In the same manner cylinders coated with sulphur and resin were tried; the former had not a very powerful effect, but the latter while warm exceeded glass, and even attracted leaf brass without friction, at the distance of an inch or two. By trials in vacuo, he found that sulphur would emit no light, but that sealing-wax emitted more than even when freely exposed. Mr. Haukesbee conceived active motion produced in bits of leaf brass lying on a table, and covered by a flat-bottomed glass, when an excited stick of sealing-wax is held above; he says, "this shows the
Electricity. penetration, subtlety, and very great activity of the effluvia (at least of these) electrical bodies." Enough has now been selected from Mr. Haukesbee's writings, to exhibit him in the light of a very zealous and successful experimentalist. Of the difference between the two electricalities he had no suspicion, though at times he was struck by results dependent upon their distance, and in such cases he did not fail to point out the discrepancy of his results. The cases by which he convinced himself, that the electrical power was not intercepted by solid bodies, were as we now know frequently the effects of electricity by induction, but were ascribed by him to the subtile nature of the effluvium, which enabled it to pass through the substance of glass and other bodies. The term effluvium which he employs, accords well with his notion of its being a substantial emanation; and even now, though we are unable to prove that it is a material substance, we continue to employ the words electrical fluid, as a convenient verbal designation. We reason upon it as if it were an actual tangible substance, and apply the physical laws of matter to account for its distribution and arrangement upon the surfaces of bodies, as if its particles could be made the immediate objects of our senses. Mr. Haukesbee did not remark the distinction between electricity and non-electricity; for after trying in vain to produce electric light by the friction of brass, he observes, that "if there be any such quality as light to be excited from a brass body, all the attraction of the several bodies I have used for that purpose, have been too weak to force it from it. And, indeed, considering the closeness of the parts of metals, and with what firmness they adhere, entangle, and attract one another, a small degree of attraction is not sufficient to put their parts into such a motion as to produce an electrical quality, which quality, under the forementioned circumstances, I take to be the appearance of such a light in such a medium."

Wall. During the publication of the above experiments, Dr. Wall communicated in a paper to the Royal Society, certain other electrical phenomena. He speaks of Boyle's artificial phosphorus, leading him to amber; and seems to consider the light emitted by it upon friction in the dark as his own discovery, and then adds "Amber directed me to the diamond, from its being electrical as the other, which is also a natural phosphorus, or rather a noctiluca exceeding all others, and may without any exception, be called a mineral phosphorus." He also mentions the luminous properties of gum lac and sealing-wax; but as Haukesbee's experiments appear in the Phil. Trans. from 1705 to 1711, and Dr. Wall's in 1708, while Guericke's had been some time in print, the claims of all these to the discovery of electrical light must give place to those of the Magdeburg experimentalist.

Grey. The history of electricity must now pass over a space of about ten years, in which no additions of importance were made to the science. That the discoveries of Haukesbee should not have excited a greater interest, and impelled philosophers to further experiments, may appear singular; but Priestley has, with great appearance of probability, suggested that the brilliant discoveries of Newcomen, in other branches of science, possibly have engrossed the whole attention of the scientific world, thus inducing a degree of neglect over all electrical inquiries. The Philosophical Transactions for 1730, contain the first of Mr. Wheler's papers on electricity, followed by others in the years 1731 and 1732, 1735 and 1736. He first states, that having tied a down-feather to a small stick, and brought near to it an excited glass tube, the fibres of the feather were at first attracted towards the glass, would on removal of the tube, attach themselves to the stick; he thence inferred, that some electrical property must have been communicated to either the stick or the feather. Hence he was led to inquire, whether if the feather were drawn through his fingers, it might not produce the same effect by acquiring some degree of electricity. In this experiment he succeeded, and by proceeding in a similar manner, he obtained indications of electricity in hair, silk, linen, woollen, paper, leather, wood, parchment, and gold-beaters skin. From some he obtained luminous appearances in the dark, but in most cases found it necessary to warm the substance before he attached it to experiment. Phil. Trans. 1730, p. 107. The next series of experiments by Mr. Grey, contains a discovery of some interest, namely, that bodies in which electricity is not capable of being excited, might nevertheless receive it by communication from regularly excited electrics. He had failed in attempting to make metals electric by heating, rubbing, and hammering them; but yet as they would receive electric light from glass in the dark, he considered that they might receive general electricity also. At this period it must be remarked, that attraction was considered the only absolute proof of the presence of electricity. In February 1729, Mr. Grey informs us he made the following experiments. He procured a glass tube three feet five inches long and nearly 1/2 in diameter. Its ends he closed with two corks to exclude the dust; he first established that by these corks, the attractive power of the tube was not diminished; and then found that a feather was attracted to the cork, as by the tube itself. To the cork he then affixed an ivory ball by a short stick, and then found that this attracted and repelled the feather even more strongly than the cork had done. The stick was then lengthened, and finally pieces of wire were substituted in its place, without any diminution of effect. The wire was found to attract the feather throughout its whole extent but not so forcibly as the ball. For wires he then substituted strings, and instead of the ivory ball he suspended a great variety of substances; towards all of which he was able to attract small light bodies, by exciting the glass tube at the other end of the string. Having, by this mode of suspension, with canes, rods, and pack-thread, proved that he could convey the electro-attractive property a distance of fifty-two feet perpendicularly; he was desirous of attempting the same thing in a horizontal direction. In his first experiment he suspended a pack-thread upon nails affixed to a beam; but in this case though he failed in his experiment, he attributed the failure to the right cause, namely, that the beam had carried off the electricity. Mr. Wheler, to whom Grey had mentioned this difficulty, proposed to suspend the pack-thread by silken-threads; and the expedient was readily adopted by Mr. Grey, from a belief that the smaller substance of these threads, would, in a great degree, prevent the abstraction of the attractive power. The experiment was completely successful, and the effect produced at a distance of 147, and subsequently 293 feet. On the breaking of their silk lines of sus-
Electricity.  

Electricity was thought of as a substitute, being of still smaller diameter; but here again all effect was lost, and they therefore concluded, "that the success they had before, depended upon the lines that supported the line of communication being silk, and not upon their being small." Again returning to silk lines more judiciously affixed, they conveyed electricity a distance of 666 feet. In an experiment of this kind made without doors, they perceived that when the dew appeared in the evening, no effects could be obtained. Phil. Trans. 1731, p. 32.

It is conjectured by Priestley, that about the same time hair, resin, glass, and some other substances, besides silk, were discovered to be non-conductors. Magnetism was found not to interfere with electricity; and that even large surfaces, such as a map and an extended table-cloth might be rendered electrical; that electricity might be communicated in several directions at the same time; that a poker being heated, was not thereby prevented from receiving the effluvium. The next experiment related, is an interesting one, in which a hair line eleven feet long was affixed to its lower end. When the excited glass tube was brought near to the lower part of the hair line, but without touching it, the lead gave signs of electricity, by attracting brass leaf; but if the tube was held high up near to the beam, the effect did not take place. They then attempted to ascertain by solid and hollow cubes of wood of equal magnitude, whether the electric attraction were proportional to the quantity of matter contained in the attracting bodies. Without coming to any decision on this point, Grey was of opinion, that the electricity passed through every part of the solid cube, though no part except the surface attracts. In his next trials, Mr. Grey electrified a wooden rod without touching it as he had done the hair line; he then tried the attractive power of metal hoops, suspended in different positions by hair lines, in order to show that the effect upon the hoops which were not touched by the glass tube, might be conveyed both in vertical and horizontal circles. In these and many such experiments, he was employing what we now call electricity by induction, but he was not aware of the importance, and having no means of ascertaining the presence of electricity, beyond the attraction of light bodies, he could not recognise the difference of the two electrical states of bodies. Mr. Grey's next experiments embrace a totally different class of bodies. In order that he might ascertain the conducting power of liquids, he blew a common soap-bubble with a tobacco-pipe; and having electrified the pipe, he found that small pieces of Dutch metal were attracted by the lower pendant part of the bubble. Having suspended a boy by means of hair lines, he found that the human body is a good conductor; Mr. Wheler having proved the same of a chicken before. From such experiments Mr. Grey infers, that "animals receive a greater quantity of electrical fluid than other bodies;" and yet throughout all these attempts it never occurred to him, that the moisture in several of the substances was the cause of their conducting properties. At the close of the same paper, he mentions some results at which he had arrived, showing that different colours differed in their attractive properties; these, however, were proved by M. du Fay to be erroneous. The next paper in 1732, is to show that a body of water when placed upon an insulating stand of glass or resin, might by passing an excited tube over it a few times be made to exhibit electrical attraction; also that an excited tube held over small cups quite filled with water, would cause the water to rise up in conical mounds; and that a stream of light passed from the tops of these cones visible in the dark, carrying with it a small quantity of moisture which was deposited upon the surface of the tube. p. 230. Quicksilver was found capable of an elevation, similar in kind, but less in degree, in consequence of its superior specific gravity. His next series of experiments was made upon nineteen substances, consisting of resins and sulphur, these he found after having been fused in an iron ladle and suffered to cool, acquired a strong electrical property; and by wrapping the bodies up in worsted, their power continued unimpaired until the time of his writing, which, with respect to some of them, included a space of four months. Their attractive property was manifested whenever required, by holding to them a stick with a bit of thread tied to the end of it. The most powerful of these was a cone of sulphur, cast in a large drinking glass, which, whenever the glass was lifted off, exhibited strong electrical properties; and in fair weather the glass would attract also. Some further essays, published about the same time by Grey and Wheler, in conjunction, add little to the real knowledge on this subject, and refer principally to different modes of varying the means of communication between the excited electric, and the attracting ball.

The discoveries of M. du Fay will for the present Du Fay interrupt the series of Mr. Grey's papers. This excellent foreign experimentalist communicated his essays to the Academy of Sciences at Paris, in eight memoirs, published during the years 1733, 1734, and 1737; but he also transmitted a succinct abstract of his labours to the Royal Society, which is published in the Transactions for 1734. From this paper, as better suited to the brevity of our present purpose, we extract the substance of his discoveries. He found that "all bodies (metallic, soft, or fluid ones excepted,) may be made electric by first heating them more or less, and then rubbing them on any sort of cloth." He then ingeniously proves that Mr. Grey's inference, of different coloured substances attracting differently, depended upon the colouring matter, and not upon the colour itself. The next experiment is to show that the pack-thread used in Mr. Grey's experiments, transmitted electricity much better by being wetted, and that it might be supported upon glass tubes instead of silk lines. Having suspended himself upon silk lines, in the manner of the child in Mr. Grey's experiments, he found that when he held the pasteboard disc on which was the gold leaf in his hand, no part of his own body would attract it, but that it would be attracted by any part of a second person, not so suspended. Also, that by the approach of another person's hand to any part of his
Electricity, body, a spark would pass from himself to the hand, and cause a pricking sensation to both parties. The Abbé Nollet, who accompanied him in these experiments, says he shall never forget the extraordinary phenomenon occasioned to both parties. In repeating the experiments of Guericke, he says he discovered a very simple principle which accounts for a great part of the irregularities that seem to accompany most of the experiments on electricity. This principle is, "that all electric bodies attract all that are not so, and repel them as soon as they become electric by the vicinity or contact of the electric body. Thus leaf gold is first attracted by the tube, and acquires an electricity by approaching it; and of consequence is immediately repelled by it. Nor is it retracted while it retains its electric quality. But if while it is thus sustained in the air, it chance to light on some other body, it straightways loses its electricity, and consequently is retracted by the tube, which after having given it a new electricity, repels it a second time, which continues as long as the tube keeps its electricity. Upon applying this principle to the various experiments of electricity, one will be surprised at the number of obscure and puzzling facts it clears up."

This application to the experiments of his predecessors Du Fay proceeds to make. In the next place he says, "Chance has thrown in my way another principle more universal and remarkable than the preceding one, which casts a new light on the subject of electricity. This principle is, that there are two distinct electricities very different from one another, one of which I call vitreous electricity, and the other resinous electricity. The first is that of glass, rock crystal, precious stones, hair of animals, wool, and many other bodies: the second is that of amber, copal, gum lac, silk, thread, paper, and a vast number of other substances. The characteristic of these two electricities is, that a body of the vitreous electricity, for example, repels all such as are of the same electricity, and on the contrary, attracts all those of the resinous electricity; so that the tube made electrical will repel glass, crystal, hair of animals, &c. when rendered electric, and will attract silk, thread, paper, &c. though rendered electrical likewise. Amber on the contrary, will attract electric glass, and other substances of the same class, and will repel gum lac, copal, silk, thread, &c. Two silk ribands rendered electrical will repel each other; two woollen threads will do the like; but a woolen-thread and a silk-thread will mutually attract one another. This principle very naturally explains why the ends of threads, of silk, or wool, recede from one another in form of a pencil or broom when they have acquired an electric quality. In order to know immediately to which of the two classes of electricity belongs any body whatsoever, one need only render electrical a silk-thread, which is known to be of the resinous electricity, and see whether that body rendered electrical attracts or repels it. If it attracts it is certainly of that kind of electricity which I call vitreous; if on the contrary it repels, it is of the same kind of electricity with the silk, that is of the resinous."

Phil. Trans. p. 265.

M. du Fay concludes this paper by stating that a body so insulated, as to be capable of retaining electricity, continues to retain the same species of electricity which is at first communicated to it. He remarks, that in the case of two bodies similarly elec-

trified for the exhibition of repulsion, there is to be this limitation, that the bodies be made equally electric; for if one were weakly electrical, and the other strongly so, attraction would take place, be the kinds of electricity what they might. In this view of the question, that there are two distinct species of electricity, the continental philosophers have with some few exceptions remained to this day; but as we shall hereafter find, another theory was subsequently proposed by Dr. Franklin, which has also for its patrons some experimentalists of distinguished eminence.

In resuming the detail of Mr. Grey's experiments, contained in four papers communicated to the Royal Society in 1735 and 1736, we shall have little of importance to select. He repeated and varied the experiments of M. du Fay, and in company with Mr. Wheler and some others, observed the cone of electric light formed by diverging rays from the point of a metal rod attached to an electrified body. One passage in his writings has been deservedly selected to prove the sagacity of this very judicious experimentalist. Speaking of the effects of electricity communicated to insulated conducting bodies, he says, "Although these effects are at present but in minimis, it is probable in time there may be found out a way to collect a greater quantity of the electric fire; and consequently to increase the force of that power; which by several of these experiments, "si licet magnis componere parvos," seems to be of the same nature with thunder and lightning." It will hereafter appear how completely these predictions were verified in the discovery of the Leyden jar, and in Franklin's experiments with the electrical kite. The remaining researches of Mr. Grey may here be omitted almost without further notice. It has been clearly shown that he was in truth a benefactor to electrical science; but in his last experiments upon the rotation of pendulous bodies from west to east, under circumstances of electrical attraction, he probably had deceived himself; some of these were communicated to Dr. Mortimer the day before his death, and this gentleman upon a subsequent trial seems to have thought that he had obtained results, similar to those of Mr. Grey. Mr. Wheler also together with some members of the Royal Society, undertook the examination of Mr. Grey's results, and at last gave it as his opinion, that a desire to produce the motion from west to east was the secret cause that determined the pendulous body to move in that direction, by means of some force impressed by Mr. Grey's hand, as well as by his own; though he was at the same time persuaded that he was not sensible of giving any motion to his hand himself.

From the papers of Mr. Wheler published about this time, he seems to have made a series of observations with results which led him to the same conclusion at which M. du Fay had arrived: and from the dates of their respective papers it would appear that each had established the same facts with regard to the opposite states of electrical excitation, independently of the other.

Eight memoirs in the Phil. Trans. comprise the desaguliers labours of Dr. Desaguliers on this subject, and in 1745, i.e. the date which his last paper bears, he published an excellent essay on electricity, which gained the prize from the Bourdeaux Academy. Few new experiments of importance are brought forward by this writer; but he systematized and arranged the discoveries of his predecessors, introducing some judicious terms of nomen-
Electricity. 

Ludolf of Berlin also showed, that the light seen in agitating the mercury of a barometer, was truly an electrical phenomenon, and that the glass tube became excited in consequence. Boze proved by many experiments, that the weight of bodies was not affected by giving to them, or abstracting from them, electricity. Several ingenious electrical toys, which will be hereafter described, date their origin from this period. Dr. Miles in 1745, observed the pencil of luminous rays proceeding from an excited electric, even without the approach of a conducting body. The same year (1745) brings us to the discoveries of Dr. Watson, the details of which are contained in the Phil. Trans. He first repeated the experiments of the Germans on the firing of spirits and gunpowder, by the electric spark. This had been performed by a person holding the substance in a metallic spoon, and thus receiving upon it the spark from the conductor of a machine. He reversed the experiment, placing the substance in contact with the conductor, or in the hands of an electrified person, and then produced ignition by receiving a spark from it. In 1746 he describes the difference of colour in the electric sparks, if received from different substances, and says that the fire is much redder from rough surfaces, such as rusty iron, than from polished iron or steel, however sharp the point from which it is taken. He supposed, however, that this difference was owing to some variation in the reflection of the light, rather than to any real difference in its colour. He next proves that the electric fluid suffers no refraction in its oblique passage through bodies; and that its passage through glass was much facilitated by the glass having been previously warmed. He showed that in electrifying conductors of considerable extent, electricity is first accumulated or developed at the part which is most remote from the excited electric. Also that electric fire is neither increased nor diminished by ordinary heat or cold; and that both smoke and flame were conductors of electricity.

The discovery of a method for accumulating and preserving the electric fluid in large quantities, appears to have been made in the year 1745, by Kleist a monk; and simultaneously by Muschenbroeck at Leyden, from which circumstance it still bears the name of the Leyden jar or phial. According to Dallibard however, the inventor's name was Cuneus. From the accounts handed down to us, it would appear that this great addition to electrical apparatus was due to more deliberate reflection, and if so, great credit is due to these sagacious experimentalists. Muschenbroeck and his friends observed that excited electrics soon lost their electricity by exposure to the atmosphere, which is replete with conducting matters of various kinds; they therefore supposed that if the electrified bodies could be surrounded by more perfect non-conductors, the change would be greater and more permanent. With these views, they attempted to change some water contained in a glass bottle, and at first with no very marked result. At length however when a communication had been made between the water and the prime conductor, and at the same time one of the party had held the outside of the bottle in his hand; on attempting to disengage the wire passing from the prime conductor to the water, he experienced a sudden shock in his arms and breast, which it would seem the party had not gone far enough in their speculations to foresee. We must here pass by the numerous absurd accounts which the repetition of these experiments produced; doubtless these early electricians may have given to each other some severe shocks, but the novelty of the circumstance aided by fear, can alone account for the marvellous descriptions of their effects. Watson made some important observations connected with this experiment. He noticed the flash of light which accompanies the discharge of the jar. He found that the power of the shock was ceteris paribus, as the surface of conductors in contact with the outside of the jar. Reasoning from this circumstance, Dr. Bevis suggested the application of tin foil to the outer surface of the jar, extending it almost to the top, in which case it was found as might be expected, that as powerful a shock was obtained, by touching this outer coating with wire, as if the hand were applied to the surface itself. Watson also found that the discharge proceeds by the shortest course, supposing it to have the choice of conductors equally good. Smeaton about this time suggested the coating a glass plane on both sides within an inch of the edge, and Bevis tried the experiment with complete success. On this hint Watson completed the electric jar in its present form, by coating the inside and outside equally with tin foil or silver leaf.

In Mr. Wilson's essay he informs us, that as early as the year 1746, he discovered a method for giving the shock to any part of the body without affecting the rest. He communicated also by letter to Mr. Smeaton his attempt to discover the law of accumulation of the electric matter in the Leyden jar, and found that it was in proportion to the thickness of the glass.
Electricity. to the surface of the glass, and to that of the conducting surfaces in contact with the inside and outside of the jar. In this same work, mention is made of Mr. George Graham’s having discharged a jar, causing the shock to pass through several persons at the same time, by joining of hands, as is now common.

Mr. Canton found that if a charged jar were placed upon an insulating stand, a spark might be taken from the wire communicating with the interior, and from the exterior coating alternately, and that thus the jar might be entirely discharged. The publications of Nollet and Le Monnier exhibit at this period a view of the progress of electricity in France, but their experiments differ little from those of our own electricians of the same era.

The distance to which electricity might be conveyed, and the rate of its motion, were the points that next engaged the attention of both the English and French experimentalists. In France, the discharge of the Leyden jar was effected through circuits of nine hundred; and two thousand toises in length; in one experiment, the basin in the garden of the Tuilleries was taken into the circuit, having a surface of about an acre of water. M. le Monnier on trial could not find that however long the circuit, any appreciable time was occupied in the passage of the fluid. The researches of the English on this subject were conducted on a most magnificent scale. The party consisted of Mr. Folkes the President, and several Fellows of the Royal Society, with Dr. Watson at their head, as chief operator. They first received the shock by passing the wire along Westminster Bridge, and making the water of the Thames through its whole width, part of the chain of communication. In July 1747, they conveyed it by wires on land 800 feet, and by the water of the New River, at Stoke Newington, 2000 feet. Also 2500 feet by land, and by water 8000. It subsequently appeared, however, that here the fluid had taken a shorter course by traversing the intervening land. By further experiments made on the 5th of August 1744, at Highbury Barn beyond London, they found the fluid conveyed by the wire, and that the effect was much increased by insulating the conductors, as well as the persons who held the rods to receive the shocks. Their last attempt was to ascertain whether the electric shock were perceptible at a distance much greater than that to which they had before carried it, through ground perfectly dry, and to distinguish, if possible, the respective velocity of electricity and sound. On the 14th of August, 1747, the experiments were made at Shooter’s Hill, when during the preceding five weeks only one shower of rain had fallen. The wire communicating with the iron rod which made the discharge, was 6732 feet in length, and supported upon baked sticks throughout, as also was the wire communicating with the coating of the jar, this wire being 3868 feet in length, the observers being distant from each other two miles. The result of the discharge demonstrated to the satisfaction of the parties present, that the circuit performed by the electric matter was four miles, viz. two miles of wire, and two of dry ground, the latter being the space between the extremities of the wires. A gun was discharged at the instant of the explosion, and the observers had stop watches to note the moment when they felt the shock, but as far as they could distinguish, the time in which the electric matter performed that vast circuit, might have been instantaneous.

The period with which we are now occupied, was Nollet’s, one fertile in electrical research; it may be made to comprise the principal labours of Watson in England, and of Nollet in France. Of these the most important in theory is due to the former, who proved that glass tubes and globes did not contain the electric power in themselves, but were as he phrased it, “movers or determiners” of that power. This he discovered by finding that while he stood upon a cake of wax, in order as he expected, to prevent any of the electric power from discharging itself through his body to the floor, no spark could be obtained from his body, but that if a person not electrified held his hand near the tube, he himself received a shock of electricity, and sparks might be taken from him. The conditions under which electrical excitation may be effected with regard to the insulation or not of the rubbers and conductors, are principally the result of this gentleman’s researches; he expresses his ideas on the subject, by laying it down as a law, that in all electrical operations, there is an afflux of electrical matter to the globe and the conductor, and likewise an afflux of the same electric matter from them. Upon this view, however, he shortly afterwards improved, observing that in the case of two insulated persons, the one in contact with the conductor, and the other in contact with the rubber, both would give sparks; but that either could communicate a much stronger spark to the other than to any bystander. The electricity of the one becomes more rare he says, than it naturally is, and that of the other more dense; so that the density of electricity between the two persons differed more than that between either of them and another person standing upon the floor. This discovery was in fact identical with that of the celebrated Dr. Franklin in America, who thus explained the theory of plus and minus electricity. Watson also proved that electricity passes through the substance of a conducting wire, and not along its surface, by coating a wire with a cement of wax and resin, and discharging a jar through it. The same was subsequently shown by M. Jallabert, Professor at Geneva, who at the same time proved ice to be a conductor.

In 1746 also, Le Monnier showed that electricity is not communicated to homogeneous bodies in proportion to their masses, but rather in proportion to their surfaces. The various memoirs of Watson, Winkler, Hales, Nollet, and Ellicot, inserted in the Philosophical Transactions about this period, are replete with interesting and well-directed experiments, many of these it is not in our power here to notice; but the ingenious experiments of the Abbé Nollet in some other branches must not be entirely passed over. He found that in open vessels electricity increased the evaporation of fluids, that it did not affect the power of the magnet, neither did it accelerate or retard the heating and cooling of bodies, and that it greatly accelerates the afflux of fluids through capillary tubes. Mr. Maimbray at Edinburgh had electrified two myrtle-trees during the whole month of October 1746, and concluded that vegetation had been accelerated thereby, as the plants put forth leaves and blossoms sooner than other specimens which had not been electrified. These results were confirmed by M.
Electricity. Nollet, also by M. Jallabert, M. Boze, and the Abbé Menon. It was also proved by the latter gentleman that animals lost weight by being electrified for five or six hours together; his experiments were made upon cats, pigeons, sparrows, and chaffinches. In extending these experiments to human subjects the Abbé found that these also lost weight, and rather increased in appetite, with a slight feeling of fatigue. He could not perceive that they became sensibly warmer, or that the rapidity of the pulse was increased.

Connected with these applications of electricity, we must here mention, though but slightly, a number of extraordinary medical results, said to have been obtained by its agency. Johannes Francisco Pivati published at Venice, in 1747, the first of a series of errors and deceptions (whether intentional or not) which required much labour, and numerous elaborate experiments entirely to disprove. He enclosed a quantity of balsam of Peru in a glass cylinder, so that before its excitation no smell could be emitted. With this cylinder he electrified a man having a pain in his side. The patient returned home, fell asleep, and perspired; so effectually were we told had the virtue of the balsam been thus conveyed to the patient, that his clothes and his hair were impregnated with the balsamic effluvium. In another experiment a similar effect was produced upon a person in health, who was not made acquainted with Pivati's intention, and in whom the odoriferous emanation became perceptible to himself and others half an hour after. Winkler, of Leipsic, professed to have repeated similar experiments with success. Pivati next began to apply these powers to medical purposes, he professes to have cured, or rather discussed an abscess in the foot of a young gentleman by electrifying him with a glass cylinder filled with certain drugs. His next patient was Signor Donadoni, Bishop of Sebenico, seventy-five years old, and greatly afflicted with the gout. The joints of his fingers had become fixed, and he had lost the power of bending his knees. Pivati tells us that he proceeded to the cure by filling a glass tube with discutient medicines, and so managing that the electric virtue might enter into the patient. The Bishop presently felt some unusual sensation in his fingers, and "in two minutes, his lordship opened and shut his hands, gave a hearty squeeze to one of his attendant's fingers, got up, walked, smote his hands together, helped himself to a chair, and sat down won't a thing at his own strength; and hardly knowing whether it was not a dream. At length he walked out of the chamber down stairs without any assistance, and with all the alacrity of a young man." This and another similar cure said to have been performed upon an old lady of sixty-one, may well account for the sensation that these experiments seem to have occasioned. Winkler, as we have before mentioned, professed to have verified them, and the English and French experimentalists immediately commenced a similar attempt. In this, however, they completely failed, and after receiving from Winkler some tubes properly prepared, these also were submitted to a fair trial; and the conclusion at which they arrived was, that electricity had no effect in forcing odoriferous effluvia through the substance of glass vessels. The zeal of the Abbé Nollet even carried him into Italy, that he might witness these wonderful performances for himself, but he also came back convinced that the odours were not transmitted through the glass, and that the enclosed drugs had no medicinal effect, although in certain cases of paralysis, &c. the electricity itself was clearly beneficial. Dr. Bianchini also of Venice published an elaborate refutation of these fallacious experiments; Winkler, Phil. Trans. vol. xlv. p. 202; Baker, Id. p. 270; and the refutation by Watson, Id. vol. xlvii. p. 348; Winkler, Id. vol. xlviii. p. 231; and Watson, Id. p. 236.

At length we arrive at the interesting and fertile period of Dr. Franklin's discoveries. Hitherto electrical researches had been confined to the philosophers of the old continent, but the twilight of a brilliant day now began to dawn in America. Whether we consider the importance of his researches, the patience of his investigations, or the candid and unassuming manner in which he promulgated them, we shall find ourselves compelled to assign to Franklin a distinguished page in the history of electricity. Even in his lifetime, a period when an author is never judged with the greatest candour, he excited the admiration of the philosophic world, and his writings were translated into most of the languages of Europe.

His first communication to Mr. Peter Collinson of the Royal Society is dated March 28, 1747, and his last letter on electrical subjects is in 1760. Although Watson had about the same time discovered, and published, the explanation of the real action of the glass and rubber, Franklin's first papers show that he had arrived at similar conclusions. He says, "the electrical fire is not created by friction, but collected, being really an element diffused among, and attracted by other matter, particularly by water and metals," and he proceeds to prove the truth of this hypothesis much in the same manner as Watson had done before him. Franklin's theory of plus and minus electricity was more fully explained, and in fact more clearly conceived than that of Watson. One sentence selected from his letter to Collinson will explain this theory with that brevity which suits our present purpose. "To electrize plus or minus, no more needs to be known than this, that the parts of the tube or sphere that are rubbed, do in the instant of the friction attract the electrical fire, and therefore take it from the thing rubbing; the same parts immediately as the friction upon them ceases, are disposed to give the fire they have received to any body that has less." It is probably owing to his clear and just explanations that this theory was considered entirely the discovery of Franklin, when in fact it was only Watson's more completely developed. This justly celebrated American did not attempt to slight the labours of his contemporary, but mentions them in his own description, only correcting what he considered an erroneous explanation of an experiment, on the part of Watson. The Leyden jar, the construction and discovery of which has been already noticed, received an easy explanation upon this theory, by supposing that when the jar was charged, the inner coating had received more than its ordinary quantity of electricity, and was therefore electrified plus, while the outer coating having had its ordinary quantity of electricity diminished, was electrified minus; and the retraction of equilibrium between these two reservoirs was accompanied by the spark and shock, or as it is familiarly phrased the jar.
Electricity is discharged. The converse explanation of the charging of the outside coating is precisely similar, but will be entered upon more fully hereafter. Franklin shows, clearly, that when the jar is charged, the outside and inside coating give evidence of possessing the opposite electricities, this being proved by the alternate attraction and repulsion of a cork ball. He made many experiments to show, that in charging a coated phial as much electricity was lost from one side as was gained by the other. Among Franklin's earliest experiments we find him examining the power of receiving and giving out electricity by bodies of different forms. He electrified an iron cannon ball, and found that to deprive it of its electricity, he might present a pointed rod of wire, which would silently abstract the fluid from the ball; but that a rod terminated by a ball, would not draw off the fluid except by bringing it very near to the shot and receiving a spark. If left by itself, the shot retained its electricity a considerable time in the air, but the charge was soon dissipated if a needle had been laid upon the shot. Thus, pointed bodies absorb and dissipate electricity with great rapidity, while obtuse bodies, large globes or planes, do not readily abstract electricity, nor yet do they readily part with it by mere contact of the air. Franklin was soon enabled to apply these canons to one of the most sublime discoveries that had ever crowned the efforts of human ingenuity.

Very early writers had compared the electric spark to the flashes of lightning, but perhaps the Abbé Nollet produced a more distinct statement of this suspicion than any preceding writer. He declares that he had long been meditating their points of analogy, and expresses a hope, that some one might pursue the investigation. Nollet, Léçons de Physique, vol. iv. p. 34. Whether this had been seen or not by Franklin, can not now be clearly ascertained, but this distinguished French philosopher attributes to Franklin the bold thought of verifying this hypothesis, and in the collection of the letters and essays of the American experimentalist, there is one without a date, but standing before that of July 28, 1750, in which he brings together under one view, numerous points of similarity between the electrical discharge and the flash of lightning. Of these the following are the most important. The lightning does not move in a right line, neither does the electric spark, if passing through any considerable space from one conductor to another, and from substances of irregular form. Lightning strikes the highest bodies, and most readily those that are pointed. Electricity also is more readily attracted and emitted by conductors of the same form. Lightning sets fire to combustible bodies; so does electricity. Lightning chooses for its mark and path the best conductor, so also does electricity. Both lightning and electricity are capable of fusing metals, and of rendering non-conductors or imperfect conductors in their passage. Persons have been struck blind by lightning, and a pigeon which Dr. Franklin had intended to kill by the shock, was found to have withstood the discharge, but had lost its sight. Both discharges are rays without destroying animal life. Magnets had their polarity reversed, and common sewing needles were made magnetic, by suffering the electric discharge to pass through them, and similar changes had been recorded as the effects of lightning. Thus strongly impressed with a belief of the identity of these two phenomena, the natural and the artificial, Franklin anxiously waited the erection of a spire in Philadelphia, by which he proposed to verify the conjecture. In the meanwhile, however, impatience stimulated his ingenuity, and produced a substitute for the spire. This was no other than a kite made by stretching a silk handkerchief upon two cross sticks, and affixing a tail on the common principle. This he raised at the approach of a thunder-storm, and so fearful was he of the ridicule attaching to a failure, that his son was the only assistant in the experiment. At first no electrical appearances presented themselves, but at length some loose fibres of the hempen string by which the kite was elevated, began to stand out, manifesting electrical repulsion. The hempen string was tied to a silken cord, by which it was held, and a key tied on where the hempen cord terminated, served to distribute the electricity to jars or conductors according as the experiments might require. At first but feeble electrical effects were perceived, but when the string had become wet by a shower of rain, an abundant stream of electricity was produced. Afterwards the Dr. contrived a pointed iron conducting-rod and affixed it to his house, with a bell to give him notice when any atmospheric electricity was collected by his rod. Thus was this most brilliant discovery achieved, but as the Dr. had published his method and intentions, the same experiment had been successfully performed in France about a month before. It remained only that the application of the discovery to a purpose of practical utility should crown the work, and this did not escape the penetration of Franklin; he proposed the conductor such as is now in use, viz. a pointed rod of metal extending above the top of a building, and terminating in the earth, or in water, whereby a cloud highly charged with electricity, might be discharged in safety through the perfect conductor to the earth. Of this we shall have to speak more particularly hereafter.

The remaining experiments of Franklin are chiefly of a miscellaneous nature, and are intermixed with those of his friend Mr. Kinnersley at Boston in New England. It was the general opinion at this period, that an excited electric were in fact surrounded by an atmosphere of electric fluid; but although the term fluid was, and still is made use of for the sake of convenience in description, it became a question with Franklin, how far the presence of this electrical atmosphere interfered with the ordinary atmosphere, usually considered to be in contact with all natural bodies. He satisfied himself, that the electrical atmosphere did not require the displacement of the other, by the following experiment. A thick wire passed through a cork into an air-tight phial; in the same cork there was also inserted a glass tube open at both ends, having in it a drop of red ink, by the motion of which any expansion or contraction of the air in the bottle was readily made apparent. On communicating a charge of electricity to the wire, or on again removing the same, no alteration was perceived in the position of the drop of ink; and therefore no air had been displaced from its natural position round the brass wire within the bottle. Mr. Kinnersley is said about the same time to have noticed the two contrary electricalities of glass and sulphur, a fact which Du Fay had before remarked, and the state of electrical science at the time enabled him to identify them with the
Although it may slightly interfere with the chronological order of some contemporary experimentalists, it will be convenient next to bring together some of the most important of Mr. Canton’s discoveries. Of these, that which perhaps tended most to the real advancement of electrical science, was the overturning of an opinion which the electricians of that period had hitherto never doubted; viz. that by any given electric, the same species of electricity was invariably developed; thus, that glass always became excited by positive, and sealing-wax by negative electricity. Canton, however, showed that if a glass tube be made rough, by grinding its surface with sheet lead and emery, the friction of a woollen cloth upon it produced negative or resinous electricity. He subsequently found that even the smoothest glass would receive the same electricity by drawing it over the back of a cat.

Some curious subsequent extensions of this discovery will be noticed in their proper place. Mr. Canton next proved, by the construction of a most ingenious apparatus, that it was possible to electrify a body of air in a state of rest; that thus, if dry, a part or the whole of the air in a room might be charged with either plus or minus electricity, and so remain for a considerable time. Some experiments which Canton had made upon the electricity, developed by removing glass and other bodies from mercury, into which they had been plunged, connected with the early observations of the electrical light exhibited by agitating the mercury of an electrical machine. The last, and by no means the least, among the researches of this very able philosopher which our plan permits us to notice, was the discovery, on which Guericke had in fact touched, that even the smoothest glass would receive the same electricity by drawing it over the back of a cat.

In 1753, Beccaria published, at Turin, a treatise Baccaria. Dell’ Elettrismo Artificiale e Naturale. In many particulars his experiments were similar to those of Mr. Canton; he also noticed the communication of permanent electricity to the air in contact with electrified bodies. He showed that the electric fluid was not instantaneous in its passage through even the best conductors, the metals. He arranged a wire 500 feet in length, and observed that when electricity was communicated to one end of it, the other end did not give signs of electrical excitation till after one vibration of a half-second’s pendulum. In the case of a similar circuit of hempen cord, five or six vibrations elapsed, but the time was diminished to three or four vibrations by moistening the cord. His experiments on the passage of the electric shock through fluids are highly interesting, although perhaps the results in some cases admit of explanations widely differing from those he assigned to them. He considered that air and the electric fluid were mutually repulsive, and that therefore when an electric spark passed from one conductor to another, the air was entirely displaced. He proved that water is a very imperfect conductor, and showed that in transmitting a shock through it, the volume of the water was a material consideration. Small tubes filled with water would scarcely transmit a shock, which larger ones suffered to pass with facility. There is in this matter a singular resemblance to the recent discoveries connected with common magnetism, and that developed by galvanic agency.

In the transmission of an electric shock through an imperfect conductor, in the passage of magnetism through a metal bar between the poles of a common magnet, and in the transmission of electromagnetism through wires, it appears certain that the larger the conductor is made, the more complete will be the
Electricity. Transmission of the fluid. Beccaria exhibited the electric spark, even in its passage through water, by bringing the extremities of two wires very near to each other in a small glass tube filled with that fluid. At the instant of the discharge, these tubes burst in pieces with great violence, though frequently made of glass more than half an inch in thickness. To this author we are also indebted for a valuable series of experiments on atmospheric electricity. Sir Torbern Bergman, of Upsala, also verified Beccaria's experiments upon the imperfect conducting power of water, showing also that ice is a still worse conductor than water.

Between the years cited in the margin, Mr. Delaval communicated to the Royal Society several curious experiments; these were principally directed towards ascertaining the conducting powers of the same body in different states. Thus he showed that although the metals were the best known conductors, their oxides were non-conductors. Several of the researches of this gentleman have a singular analogy with some others of the present day, whereby it is proved that the same substance, undergoing a change of temperature, is at some given points of its heat a conductor, and at others a non-conductor.

At this period M. Æpinus announced to the Berlin Academy the electricity of the tourmalin, produced simply by heating the gem, and he noticed the development of the opposite electricities on opposite points of the stone. Mr. Wilson, the Duke de Noya, and Bergman, occupied themselves with further researches on this curious property. Symmer, Phil. Trans. 1759; and Cigna, Mem. Accad. Tur. 1765.

The labours of Mr. Robert Symmer in this country, and those of Johannes Franciscus Cigna, though not precisely contemporaneous, may come under our notice at the same time, as the remarks of the latter are in fact but a continuation of those of the former experimentalist. Symmer, after describing the electricity produced by separating two stockings, the one of silk, the other worsted, which have been worn a few minutes on the same leg, proceeded to vary the experiment. He obtained sparks, and charged jars, from stockings thus excited. Drawing the stockings through his hand proved an equally efficacious and a more convenient mode of excitation; and he found that a black stocking gave abundant signs of electricity, while a white one could scarcely be made to affect a delicate electrometer. Subsequently, he made use of two stockings both of silk, the one black, the other white, remarking that after the two had been passed through his hand very little electricity was manifested so long as the stockings were in contact, but on their separation very marked electrical effects were produced; the black stocking became highly negative, and the white one positive. Reasoning from this and several similar experiments, he was led to entertain certain theoretical views, which differed considerably from those of preceding electricians; he arrived, in short, at that theory which is now embraced by much the greater number of continental philosophers. As we shall have occasion to advert to this matter hereafter, it may be sufficient here to state, that Du Fay had considered the two electricities which he discovered, as not only totally different in themselves, but also totally independent of each other, and at those distinct properties of natural bodies. Watson and Franklin had viewed them as different states of the same body, with reference to a given quantity of fluid always the same, and inherent in all non-conducting substances, in one case indicating excess, and in the other defect, from the natural standard quantity contained by the body. Mr. Symmer contended for the existence of two electric fluids, but, unlike Du Fay, he urged that they were always coexistent, were not independent of each other, and were simultaneously developed in every case of electrical excitation. The form of the bur which was raised by the passage of an electrical discharge through several sheets of paper, and in certain cases having tinfoil interposed, was pressed into the service of Symmer's reasoning, but is not now viewed as throwing much light upon the subject. Cigna, who repeated Symmer's experiments, and varied them, making use of ribands instead of the stockings, attempted an explanation of these phenomena upon Franklin's hypothesis, but expresses himself as being by no means satisfied of the superiority of one theory over the other.

We feel the more disposed to make specific mention of the theoretical views of Symmer, because they are the foundation of the theory of electricity which has at present the greater number of admirers; and because the French writers on this subject are inclined to forget the circumstance, and to attribute all the merit of this hypothesis to Du Fay. The Germans, however, who may be considered impartial judges, distinctly attribute the present prevailing theory of two fluids to Symmer. (Fischer, Physique, p. 323.) We should be most unwilling to appear to offer the slightest injury to M. du Fay, to whom electricity is unquestionably under great obligations, and whose writings evince a most honourable degree of regard to equity and candour; but that we may further strengthen the position we have taken up, we will quote M. du Fay's own passage on the subject of two electricities, and then give an extract from the history of Dr. Priestley, who was a contemporary of Mr. Symmer, and having been hostile to his theory, may therefore fairly be considered good evidence upon this subject:—

"Chance has thrown in my way another principle, more universal and remarkable than the preceding one, and which casts a new light upon the subject of electricity. This principle is, that there are two distinct electricities, very different from one another; one of which I call vitreous electricity, and the other resinous electricity. The first is that of glass, &c.; the second is that of amber, copal, &c. The characteristic of these two electricities is, that a body of the vitreous electricity, for example, repels all such as are of the same electricity; and, on the contrary, attracts all those of the resinous electricity." Du Fay, Phil. Trans. vol. xxxviii. p. 264.

"It had hitherto been universally supposed that all the phenomena of electricity were produced by the action of one electric fluid. Even M. du Fay, at the time that he imagined that he had discovered another electric fluid, distinct from that of glass, and peculiar to resin, &c. thought however that it was quite independent of the other, and that their operations were never combined. Dr. Watson and Dr. Franklin thought it was very evident that the difference between the two electricities, consisted in the one being a redundancy and the other a deficiency of the same matter. And all the experiments that had been made concerning..."
Electricity.

The two electricities seemed to confirm this hypothesis. At length, however, Mr. Symmer produces a great number of curious experiments relating to the subject, and infers from them the probable existence of two electric fluids, not independent, but always coexistent, and counteracting one another. Priestley's History of Electricity, p. 267.

Mr. Wilcke's Disputatio Physica experimentalis de Electricitatibus, published at Rostock, in 1757, added to the stock of electrical knowledge an entirely new branch of investigation; in fact, pointed out a new source of electrical excitation. This he produced by melting the resinous and other non-conducting bodies, and suffering them to cool spontaneously. If sulphur were melted in an earthen vessel, and suffered to cool, standing upon a conducting body, the sulphur after cooling exhibited strong electricity; but if the vessel had been placed upon glass, or any non-conductor, no effect was produced. Melted sulphur poured into a glass vessel becomes highly electrical in cooling, whether the glass stands upon conductors or not, the glass itself also exhibiting the opposite electricity. These facts also we shall more fully enter upon hereafter. Wilcke also appears to have discovered that, under a variation of circumstances, the same substance might be made either of the electricities; and he gives a table of bodies, arranged in order, so as to show by the friction of any two together, which will exhibit the positive and the negative electricity. It is clear that he was unacquainted with Canton's researches on the same point, for he states that glass is positive with whatever substance it be rubbed.

Æpinus, 1759.

From the researches of Mr. Wilcke, we proceed to those of Æpinus, whom we have already incidentally mentioned; a name justly celebrated in the annals of electrical science. He first repeated the experiments of Mr. Wilcke on spontaneous electricity, and subsequently meeting with that philosopher at Berlin, they pursued their discoveries in concert. Of these the most interesting, both in progress and result, relate to the electricity induced or developed in bodies by bringing them within what has been called the electrical atmosphere of other excited bodies. One of their most curious attempts was to electrify two surfaces of a plate of air, so as to obtain a shock from the discharge of these surfaces, exactly on the principle of the Leyden jar. In this they perfectly succeeded, and thence made the obvious inference, that a cloud and the earth might similarly form the conducting substances for electrifying a plate of air contained between them, the discharge of which would produce the clap of thunder, and the flash of ordinary lightning. The name of Æpinus is however rendered much more famous by his ingenious and profound mathematical speculations, by which he was enabled to demonstrate and explain every known electrical phenomenon. Of the first causes in these wonders he was ignorant, and we are scarcely more wise; but the laws to which he reduced all cases of electrical excitation, afforded a beautiful specimen of philosophical generalization, founded upon Franklin's theory of plus and minus electricity. The title of this curious treatise is Tentamen theorie Electricitatis et Magnetismi; it was first published at St. Petersburg, in 1759.

Priestley, 1767.

In 1767, Dr. Priestley published his History of the present state of Electricity, with original experiments; a work accurately describing the progress of the science up to that period. His experiments, though numerous, did not bring forward any very important discovery, but are far from being uninteresting. He ascertained that charcoal was an excellent conductor, and that electrical discharges take place more readily and more completely through a short conductor than through a long one of the same diameter and the same substance. Two years afterwards, Priestley published his Introduction to Electricity, and in the following year Additions to the History of Electricity. The most interesting of his researches are detailed also in the Phil. Trans. of this time.

Passing over another Introduction to Electricity, Cavendish, by Mr. James Ferguson, which contained little of novelty, we arrive at the researches of that acute philosopher the Hon. Henry Cavendish. His first and most elaborate electrical paper is published in vol. lxi. of the Phil. Trans. It appears that he had formed the design of attempting to reduce all the phenomena of electrical attraction and repulsion to rigid mathematical investigation, and that he had completed his task before he was made acquainted with the labours of Æpinus on the same subject. On examining the Tentamen, of this latter electrician, he found that he had been anticipated; but as Mr. Cavendish's memoir was actually prepared to be submitted to the Royal Society, and as he considered that as his theoretical views differed somewhat from Æpinus, and his calculations were more rigid, he determined not to suppress the paper he had thus prepared for publication. In these calculations he, like Æpinus, proceeds upon the hypothesis of one electrical fluid. Previous to this time several curious observations had been published by Walsh, Hunter, and others, on the benumbing power of the torpedo, which had been justly considered to be due to electricity; and in 1770, Mr. Cavendish described in the Phil. Trans. an artificial torpedo, which he had made, and with which he was able to exhibit the ordinary properties of this singular fish. Some of the earliest electro-chemical experiments were also made by this admirable philosopher. He repeated the experiments of Warltire, forming water by the explosion of hydrogen with common air, and with oxygen: pursuing this subject, he obtained nitric acid by using electricity for determining the combination of oxygen and nitrogen.

If there be any one philosopher to whom electrical Coulomb, science is more indebted than to all others, it is M. Coulomb, to whose elaborate researches we shall hereafter have occasion again frequently to revert. The first step towards obtaining any true knowledge of the laws of electrical attraction and repulsion, was evidently to search for an accurate measure of minute forces estimated by their effects. This Coulomb obtained in what he called his Torsion balance. He found that if fine wires, of sufficient length to undergo no real disturbance of particles were twisted, the force with which they tended to untwist themselves, or to return to their first quiescent position, was exactly as the angle through which they had been twisted. In other words, that the force of torsion varies as the angle of torsion. Being able then to measure this angle with any required degree of accuracy, an exact comparative measure is obtained of any forces which can be made to operate in producing a torsion of the wire; and it is evident that electrical
Electricity.

attraction is of this nature. Coulomb, however, made
many successful applications of this instrument and prin-
ciple to other branches of physical science. In electricity,
he showed that the attractive or repulsive force
varies as the inverse square of the distance. He ascer-
tained the rate of dissipation of electricity, under various
circumstances of atmospheric pressure and moisture.
The dissipation also from imperfect insulators, and
the modes of distribution of the fluid adhering to
them. The mode or form of arrangement of strata of
free electricity, arranged at the surfaces of bodies,
and acted upon by the electricity of other bodies
placed near to, or in contact with the former; with
many other interesting problems of a similar nature,
to be considered hereafter.

Considering, as we do, electricity and galvanism
only modifications of the same natural phenomenon,
we cannot pass over the electrical researches of Volta
unnoticed, much as they are surpassed by the brilli-
cy of his discoveries in that distinct branch, which
from him has been called voltaic electricity. In 1776,
he discovered, or at least made known, the properties
of the electrophorus; a sort of perpetual reservoirof
electricity, and applied the principle of it to the con-
struction of a condenser, an instrument for rendering
visible very small portions of electricity.

The order of time demands that we should next
record the discoveries of M.M. Lavoisier and La
Place, on the electricity developed by the evaporation
of fluids, and the solution of solids in acid menstrua.
There is little doubt, and indeed some recent researches
of M. Bequerell, in Paris, seem to prove that in all
cases of chemical solution electricity is evolved.
These experiments were made public in 1781. Volta
published researches on the same subject in 1783, and
M. de Saussure in 1786.

As the highly important results which many recent
electricians have obtained, will form a considerable part
of our statement of the present knowledge on this sub-
ject, we have need only to mention, with respect, the
names of Cavallo, Nicholson, Van Marum, Cuthbertson,
Henley, Read, Morgan, and Brooke. The Abbé
Haty, so well known by his laborious investigation
of crystallographic mineralogy, made considerable
additions to our knowledge of the electrical proprie-
ties of minerals. Coulomb had considered the dis-
tribution of electricity upon spherical bodies, and
La Place. M. le Comte la Place has subsequently investigated
the same problem, with reference to ellipsoids of
history.

In this outline of the history of electricity, we have
purposely omitted all mention of that extraordinary
discovery of Galvani, which contained the germ of a
vast and fertile branch of electrical science. From
the year 1790, in which Galvani first noticed the
muscular contractions of animals by the contact of
metals, and Volta, by his acute investigations, created
as it were a new science, only about thirty years have
elapsed; but in this time such a body of facts has
been accumulated, and such a chain of important con-
sequences has been deduced from them, as to claim a
special place in our system of physical science. At
present, although it certainly is the prevailing opinion
that electricity and galvanism are but modifications of
the same agent; yet both the facts made known by
experiment, and the theories deduced from them have
so few points in common, that it is expedient to treat
electricity and galvanism almost as two distinct sub-
jects. Connecting links appear to exist between every
branch of physical science; and as electricity and
galvanism are now clearly proved to exert an over-
ruling power in magnetic phenomena; and it is exceed-
ingly probable that the secret agency of the former
may be traced in every operation of the latter, it
would be rash to advance any absolute classification
of these sciences as the fixed order of nature. All that
we presume to act upon is this, that certain phe-
nomena, which have long borne the name of electrical,
will be treated of under the same grand division; that
another such division will be occupied by a class of phe-
nomena analogous to electricity, but to which usage
has appropriated the name of Galvanism. And the effects
of both these nominal agents upon another series of
classified phenomena, designated Magnetism, being
known and measured as pure magnetic effects have
been considered under the Treatise bearing that title.
Definitions. Whatever may be the theoretical suppositions adopted concerning the primary cause of electrical excitation, whether we consider it a distinct fluid resident in bodies, and possessed of certain properties, or only as a peculiar affection of the molecules of matter, we shall here treat solely of its effects. We shall consider it purely a science of experiment, and the first part of our article will consist of a classification of facts, either accidentally noticed, or studiously developed by the ingenious researches of philosophers; while in the second part we propose to give such an outline, as the nature and limits of our undertaking may permit, of those physico-mathematical laws, from which the effects of electrical action seem to receive the most complete and satisfactory elucidation. This exclusion of all theoretical speculation upon the origin of electricity, must not be understood to extend to those hypotheses which have been framed for the purpose of binding together the scattered links of our chain of facts. Hypotheses like those of Du Fay, Symmer, or Franklin, may sometimes bear the name of theories also, but they are theories of a different order from those which would attempt to explain the primary cause of gravity, heat, magnetism, or electricity, and are in fact only efforts to bring all the observed phenomena under one general law of action. It will be observed that we constantly have to speak of "the electric fluid," but let it be understood that this is only a term made use of for convenience of expression. We know not whether such a fluid exists; and all that we mean by the phrase is, that the effect we observe is similar to that which would take place on the supposition of a fluid subject to certain laws of action, assigned to it by actual experiment.

Attraction. (1.) The earliest observed phenomenon may serve for an example of what we consider electrical effects. Let a piece of amber, sealing-wax, or smooth glass be smartly rubbed upon the sleeve of a coat, or any other dry woolen substance, and it will be found to have acquired the property of attracting to itself bits of straw, paper, fragments of gold-leaf, or any small and light bodies. The amber is then said to be excited, and the attractive power thus developed is called electric attraction.

(2.) Next, let a small ball of cork, or what is still better, of dry elder pith, be freely suspended from a dry silken thread, the ball being about as large as a pea, and the thread a foot long. Take a glass tube of considerable size, and after it has been well rubbed with a dry silk handkerchief, present it to the pith ball, and an attraction similar to that already described will be produced, the ball approaching and adhering to the tube. After these bodies have remained a few seconds in contact, the ball will separate, or may easily be shaken from the tube. If now the glass be again brought towards the ball, instead of the attraction at first exhibited, the ball will recede, and avoid the tube. Here then is (in effect) repulsion. Let the Repulsion. pith ball now be touched with the finger, or a metallic rod for a few seconds, and upon the removal of this touching body, a repetition of the two original phenomena may be obtained. If instead of the glass tube, a stick of sealing-wax be employed, the same series of effects, viz. attraction and repulsion, may be produced, and in the same consecutive order as before. Here, as in the case of the amber, the glass or the wax is excited, its electric property is called into activity, and, as may be proved by experiment, is distributed upon the excited part of the surface of the body. The pith ball by the contact receives a portion of electric fluid thus set at liberty, and as it afterwards recedes from the originally excited body, it is clear that either the pith ball in its new state, or the fluid which it has received, is in some way or other repelled by the fluid remaining upon the glass tube, or stick of wax.

(3.) Let us now combine the effects of these two opposite simple pieces of apparatus. Excite the glass tube as electricities before, and communicate electricity to the pith ball, so that the two bodies may become repulsive of each other. While things are in this state, the pith ball remaining electrified, excite the stick of wax, and bring it near to the ball; instead of repulsion, a manifest attraction now exists between the wax and the ball. Conversely, if the pith ball be first touched by the wax, until repulsion be produced, and if then the excited glass be brought near to it, attraction again takes place. Obviously then the effects produced by the friction of the same substance upon glass and wax are of a nature directly opposite to each other; and hence it is evident, that there are either two states of the same electric fluid, or that there are two distinct electric fluids, having properties dissimilar, although the laws of action in each individual fluid may be the same. Hence arise the terms vitreous and resinous, to designate these different electrical states or properties. The law according to which these attractions and repulsions are manifested, will form the subject of future consideration.

(4.) It may have been remarked, that in the above Conducting experiment, a direction was given to touch the electrified ball with the finger or a metal rod; by this method the ball was reduced to its natural state, that is to say, its electricity was conveyed away. Now had a glass rod been made use of, it would have been found
Practical inefficient, and the ball would have remained in its electrified state. Here then is a palpable distinction between metal and glass; the former is capable of conveying away electricity, the latter is not; the former then is termed a conductor, the latter a non-conductor; thus two general divisions are formed, under one or other of which, with certain limitations, all bodies may be arranged. It was formerly the supposition that these two classes of substances might also be called non-electrics and electrics; the former name indicating an incapacity for electrical excitation, and the latter marking the contrary property. This, as we shall hereafter show, is inaccurate, and the terms will consequently fall into disuse.

There is one other electrical property, which may be exhibited by methods equally simple with those we have already noticed. If the glass tube before-mentioned be excited by a brisk friction, the experiment being made in a dark room, slight flashes of light will be perceived upon its surface. Perhaps, however, a more easy mode of exhibiting electrical light, is to take a long slip of coarse brown paper, well dried before the fire, and, while it is yet warm, let it be drawn quickly between the body and the left arm, holding it fast between the thumb and finger of the right hand, if it be immediately drawn along near to the surface of any metallic body, small sparks and flashes of light will be apparent in the dark, and a crackling noise will be heard.

Such is a very faint outline of the phenomena of electricity, given for the purpose of explaining the terms made use of, which, as ought to be the case with all descriptive designations in any science, are applicable to every possible case of electrical excitation. For example's sake, friction has been selected as the means employed for the development of electricity; but, as will be hereafter pointed out, there are ten or eleven methods at present known, partly natural and partly artificial, by which electrical energies are produced. In some cases of effects decidedly electrical, it is very problematical whether the operating causes are simply electric, or are due to that modification which has been termed galvanism, such are De Luc's column, and the contact of dissimilar metals. We have before acknowledged our belief that all these singularities are but modified effects of one primary cause, an opinion which has now gained considerable currency in the scientific world, and is strongly supported by the beautiful experiments of Dr. Wollaston.

For the purpose of conveniently separating the doctrines of free and induced electricity from each other the following arrangement has been adopted, in which the three first chapters apply to the former department of our subject only.

**CHAPTER I.**

*Electrical phenomena developed by the common machine, with the construction of other apparatus of the same nature.*

5.) In the preceding introductory matter, we have endeavoured to render the ordinary terms employed in this science familiar to the reader, and we now design to enter upon the construction of an electrical machine, selecting, from the many that have been proposed, one of the most common and most useful. With this instrument, or of course with any other of tolerable construction, all the ordinary experiments which exhibit the peculiarities of electrical excitation may be performed; and, at the conclusion of this chapter, a few more of the best or most curious forms for the arrangement of an electrical apparatus will be noticed.

In fig. 1, A B is a hollow glass cylinder, supported at the two ends, in the direction of its axis, as the plate represents, and capable of a rotary motion upon that axis, communicated to it by means of a small wheel C, which is itself put in motion by a cord or catgut from a larger wheel D, turned by a common handle. F is a cushion of silk or soft leather, stuffed with hair, and supported by a glass insulating stand, L. By means of a screw at G, this stand may be fixed farther from or nearer to the cylinder, as a rough adjustment, to regulate the pressure of the cushion upon the cylinder; but in the most complete machines this purpose is effected by a spring placed at the back of the rubber, and capable of regulation, by a screw with a large spherical head, as seen in the plate. From the upper edge of the rubber there proceeds a flap of silk, or of silk varnished, extending over the cylinder to within about half an inch of the row of
points, protruding from the prime conductor. K is a brass chain hanging loosely from the knob connected with the cushion, and communicating with the earth. H is the prime conductor, made of thin brass, having spherical caps at its extremities, and supported upon a strong glass pillar I, fixed into a circular wooden stand. At that end of the conductor which is nearest to the cylinder a row of points is inserted, having each end of the transverse wire from which these points project terminated by a varnished wooden ball, in order to guard against the accidental dispersion of electricity. These points extend to within about half an inch of the surface of the cylinder. The pivots upon which the cylinder is supported at each end are fastened into brass caps, which close two large orifices, one at each end of the cylinder, by means of which the interior surface of the glass is made perfectly clean and dry before it is mounted; and a sufficient bed of some resinous cement is melted into each cap, on the inside, so that no communication can take place between the external air and that within the cylinder. As the electricity is developed at that part of the cylinder which is applied to the cushion, a portion of each end of the glass, near to the vertical pillars of the supporting frame, is covered with a varnish of gum-lac, the more effectually to prevent the transmission of any portion of the electric fluid from the cylinder to the metal caps, and thence to the ground, through the frame of the machine... 

(6.) Now let us suppose the wheel D to be set in motion by its handle, in the direction which the arrow points out; it is obvious that the smaller wheel C and the cylinder will move in the opposite direction. By the friction of the glass against the cushion electricity is excited, and this effect is greatly assisted by the application of an amalgam to the surface of the cushion. The electric fluid thus evolved is confined to the surface of the cylinder by the oil-silk flap; and at the point where that terminates it appears to be eagerly absorbed by the metal points attached to the prime conductor. In part we may suppose there is an actual transmission of electricity from the edge of the oil-silk; and in part we must attribute the charge received by the prime conductor to another species of action which we shall be better enabled to explain in a future part of this article. The sharp form of these points is, as we shall hereafter find, of all others the best adapted for the reception of electricity. Thus the prime conductor, which being of metal allows of the free transmission of the fluid, becomes strongly electrified throughout, and affords a convenient reservoir from which the fluid may be readily abstracted for all purposes of experiment.

(7.) We have already seen that there are two states, or perhaps kinds, of electricity; that which the machine now described communicated to the conductor is invariably produced by friction upon smooth glass, and is therefore termed vitreous electricity; but, in a future chapter, devoted to the peculiarities of friction variously applied, and to substances differing in their nature, it will be seen that this effect is subject to numerous modifications. It has also been proved, that whenever one electricity is developed, the other also is simultaneously produced; and in the machine before us, whatever vitreous (positive) electricity is delivered to the conductor from the glass cylinder, an equal quantity of the opposite kind, the resinous (negative) electricity, is manifested at the rubber; hence, if another conductor be made to communicate with the rubber, it becomes also charged and is called the resinous conductor. An excellent machine upon this principle, by Mr. Nairne, will be hereafter described; but, for a reason which we are unable at present to enter upon, whenever the resinous conductor is to be plentifully charged, it is necessary that the rubber should be made to communicate with the great reservoir of electricity, the earth, which explains the occasion of the chain seen at K; and, conversely, if it be required to obtain a charge of resinous electricity from the cushion, the chain is removed, and affixed to the opposite conductor, forming also a communication with the earth.

(8.) Some other points of detail connected with the insulation of an electrical machine, may require a few words of explanation. Much depends upon the perfect insulation produced by the glass parts of the apparatus, and in this matter the great enemy to be guarded against is moisture. The working of even the best machine is decidedly superior in dry or frosty weather, to what it is when the air is loaded with aqueous vapour; and as glass is very apt to effect the condensation of moisture upon its surface, which greatly impairs its insulating property, it is usual to apply to some parts of the stands and cylinder a coat of some resinous varnish, by which this effect is in some degree obviated. For this purpose a varnish made by dissolving sealing-wax in spirits of wine, is frequently employed; but it is much better, if possible, to apply the wax at once, by heating the surface which is to be coated. As gum-lac is a better insulator than sealing-wax, delicate varnishes formed from this substance are found to be peculiarly efficacious.

In all seasons, electrical experiments should be performed in a warm and dry room; and when a machine has remained long in disuse, it is usual to heat it by applying it to a convenient distance from a fire, in order that the moisture it may have received may be dissipated, and the machine brought more rapidly into action.

(9.) In fixing the glass stands into their sockets, and cement for many similar electrical purposes, a strong cement is required, which may be softened by a gentle heat, and applied with the greatest convenience. One, which is found to answer exceedingly well, is made by melting together five pounds of resin, one pound of bees-wax, one pound of red ochre, and two tablespoonfuls of plaster of Paris. The two last ingredients are to be well dried and gradually mixed with the wax and resin while in fusion.

(10.) From the first amalgam, introduced by Canton, amalgam (which consisted of mercury and tin, in the proportion of two parts of the former to one of the latter, with the addition of a little chalk,) to the present time, numerous other compositions of a similar nature have been proposed. The following is certainly a very good one, and was recommended by the late Mr. Singer. "Melt together two ounces of zinc with one of tin, and while this compound is in a fluid state, let it be mixed with six ounces of mercury, and then let the whole be shaken in an iron or thick wooden box till cold. It is then to be reduced to a very fine powder in a mortar, and mixed with sufficient lard to form a paste."
In the application of the amalgam, it should be spread evenly upon the surface of the cushion, so as to meet the under edge of the silk flap, which is joined to the upper edge of the cushion, but is not to extend over any part of the varnished silk. From time to time it is found necessary to wipe the surface of the cushion, the flap, and the cylinder; for a part of the electrical effect of the cylinder is to attract dust, which the cushion wipes off; an accumulation of dirt rapidly takes place, and black specks and lines are seen fixed upon the surface of the cylinder. These may very easily be removed, by a rag moistened with spirits of wine. It is also convenient to have a piece of smooth leather, about five inches square, covered with amalgam, by the application of which to the cylinder with one hand, while the machine is in motion, a powerful degree of excitement is rapidly produced.

The substance of Mr. Nicholson's directions, for bringing a machine into good action, consists in, first, cleaning the cylinder from spots, by a little spirit of wine upon a rag; second, wiping all dust from the silk flap. To work the cylinder against a leather, with some tallow upon it, until the glass becomes dim; and lastly, to work the cylinder a short time, applying the amalgam from a leather upon the hand, as before directed. (Philosophical Transactions, 1789.)

(11.) To Professor Winkler, of Leipzic, we are indebted for the introduction of the cushion instead of the human hand, which had been employed by all former experimentalists. Several variations have been made in the mode of fixing this important part of the apparatus, but we limit ourselves to a delineation of the prime conductor, fig. 2, and differs from the plain cushion only by having a space of half an inch, interposed between the cushion itself and its wooden back. Within this space, there is a bent steel spring, by means of which a proper degree of pressure is maintained upon the surface of the cylinder, but which allows the cushion to recede, should this pressure be increased to such an extent as to endanger the safety of the cylinder. In the old machines, the tallow which was used, until the glass becomes dim, was interposed between the cushion and the cylinder, and from which it may readily be removed. In general the prime conductor is cylindrical, having hemispherical ends; but if the diameter of this cylinder be small, it becomes necessary that the two extremities should be formed of portions of spheres of considerable magnitude, to prevent the spontaneous dispersion of the electric fluid. Conductors formed of thin copper or brass are the best, because they are little liable to injury, and may be made perfectly free from all asperities; but cylinders of wood or pasteboard, coated with tin-foil, or gold-leaf, if clean and in good repair, are found to answer very well. There should be, in different parts of the prime conductor, round holes about the size of a goose-quill, into which balls, or points, or other pieces of apparatus may be inserted. The end nearest to the cylinder has a similar hole, for the insertion of the brass series of points seen in fig. 3. Secondary conductors, as they have been called, are but rarely employed in this country; their principal use would be in obtaining large sparks from a machine of slight power; but as a larger machine, capable of producing more electricity in a given time, may be almost as easily procured, we do not feel bound to enter very minutely into the details of their construction. They consist of one or more conductors, suspended by silk cards from the ceiling of a room, all connected with each other, and with the prime conductor of the machine, thus affording a more extended surface over which the electricity developed by the cylinder may be dispersed, and from which it may readily be withdrawn for experimental purposes.

The following instruments are also required for the performance of certain experiments, which we shall shortly proceed to describe.

(12.) It is by no means a matter of certainty what kind of glass is best adapted for the formation of cylinders for electrical purposes; they are at present principally made of flint glass, and as thin as possible to allow of sufficient strength. In choosing a cylinder, it ought to be free from knots and veins, and as nearly cylindrical as possible; in order that the pressure given by the cushion may be equitable throughout the whole of its revolution. It is not uncommon for school-boys to make very tolerable little electrical machines of a glass jar, or even of a common green glass quart bottle.

It has been proposed to coat the inside of cylinders with a resinous cement; but this is now seldom done, although it would doubtless sometimes improve the action of a bad cylinder. The process is simply to melt together four parts of Venice turpentine, one part of resin, and one of bees-wax, and to boil the whole for about two hours, in an earthen pipkin, over a gentle fire. The cylinder is to be carefully heated, and a portion of the liquid cement poured in; then, by turning the cylinder about while the cement remains fluid, a sufficient coating may be applied to every part of its interior surface.

(13.) Various substances have been proposed for the construction of the prime conductor, but the only essential condition to be fulfilled, is that it may have a metallic surface at the exterior. A solid metal conductor can contain no more electricity than one that has the same superficial extent and form, however thin it may be; for it will be hereafter shown, that all the electric fluid disposed in a conducting body resides within the body but indefinitely near to its surface. In general the prime conductor is cylindrical, having hemispherical ends; but if the diameter of this cylinder be small, it becomes necessary that the two extremities should be formed of portions of spheres of considerable magnitude, to prevent the spontaneous dispersion of the electric fluid. Conductors formed of thin copper or brass are the best, because they are little liable to injury, and may be made perfectly free from all asperities; but cylinders of wood or pasteboard, coated with tin-foil, or gold-leaf, if clean and in good repair, are found to answer very well. There should be, in different parts of the prime conductor, small round holes about the size of a goose-quill, into which balls, or points, or other pieces of apparatus may be inserted. The end nearest to the cylinder has a similar hole, for the insertion of the brass series of points seen in fig. 3. Secondary conductors, as they have been called, are but rarely employed in this country; their principal use would be in obtaining large sparks from a machine of slight power; but as a larger machine, capable of producing more electricity in a given time, may be almost as easily procured, we do not feel bound to enter very minutely into the details of their construction. They consist of one or more conductors, suspended by silk cards from the ceiling of a room, all connected with each other, and with the prime conductor of the machine, thus affording a more extended surface over which the electricity developed by the cylinder may be dispersed, and from which it may readily be withdrawn for experimental purposes.

The following instruments are also required for the performance of certain experiments, which we shall shortly proceed to describe.

(14.) A stool with glass legs. The top is made of a piece of mahogany, or other strong hard wood, and should be baked, and then varnished. The legs may be six or eight inches long, formed of solid glass rods, fixed into holes on the under side of the stool by cement; and, for greater security in insulation, these legs should all be covered with a coat of some resinous varnish, fig. 4.

(15.) Brass rods, terminated by balls and points, fitted into the prime conductor, fig. 5 and 6. Similar balls and rods, fixed to insulating glass handles, fig. 8 and 9. A few pieces of brass chain, for making communications from one part of the apparatus to another. Small spheres of rush pith, elder pith, or cork, suspended by silken threads, and others by fine silver wires, or threads of hemp, which should be previously steeped in salt and water, and then dried.

(16.) We have already stated that there are two
kind of electricity, to which, for distinction, the terms vitreous and resinous are usually applied. Two bodies, A and B, similarly electrified, repel each other. Two bodies, A and B, dissimilarly electrified, attract each other; and one body, whether charged with the vitreous or resinous electricity, is attracted by another body, to which no charge of free electricity has been communicated. It may be well to illustrate these fundamental laws of electrical action by a very simple experiment. Provide a glass stem, fig. 10, about a foot long, having at the top a curved brass wire, with a small knob and hook at the end. From this hook let there be suspended a fine double silver wire, having a pith ball at each extremity, so that the wires may hang freely, and the balls be in contact. Excite a stick of wax, by rubbing it upon dry flannel, and pass the surface of the wax along the bent part of the wire. By this operation a portion of the resinous electricity is communicated through the brass to the wire and the balls, and these, being similarly electrified, will manifest their mutual repulsion by the divergency of the threads.

Touch the brass part of the apparatus with the finger, so that all electrical charge may be removed, and repeat the experiment, only making use of a smooth glass tube instead of the wax, and repulsion will again take place between the balls, proving that when they are similarly electrified with vitreous electricity also, the same effect is produced.

Next, take two of these insulating stands, fig. 11, having a single wire and a single ball suspended from each. While they are standing at some distance from each other, communicate to the one vitreous and to the other resinous electricity, and then bring the two stands gradually near to each other, by moving either of them. The two balls will be seen to deviate from their position of vertical suspension, and to tend towards each other. Lastly, let the stands be separated, the tubes remaining charged, and bring near to either of them the large ball, fig. 7, holding the opposite end in the hand. The pith ball will tend towards the metal, and thus every case of the enunciation is easily and satisfactorily demonstrated. In the experiments here recited, we are limited to the supposition that the balls are formed of elder pith, or some conducting substance, otherwise electricity could not be transmitted to them through the supporting wires. The same proposition is however perfectly true of all bodies, whether conductors or non-conductors; but of course it is more difficult to induce, either by communication or by excitation, a charge of free electricity upon a ball of non-conducting matter, for the purpose of making this experiment.

(17.) It may have been remarked, that we frequently make use of the terms attraction and repulsion, but let us here pause, and inquire strictly what it is we mean by those terms. What is attracted? What is repelled? Experiment teaches us that all bodies upon which free electricity is disposed have a tendency to move either to or from each other. But by what mechanism is this effect produced? Is the force causing these motions dependent upon the immediate mutual action of the electric fluids, or must we take into consideration the intermediate agency of some third body?

To obtain an answer to these questions, let us first review the state of our actual knowledge of facts bearing upon this point. It has been proved that electricity has no peculiar affinities by which its molecules attract at a distance different substances with different degrees of force. It is extremely probable that the pressure of the air is the principal force which detains the electric fluid within an excited body; for if an electrified conducting body be placed under an exhausted receiver, the electricity is no longer retained, but rapidly escapes from the body as the exhaustion proceeds. An excited non-conductor also, under the same circumstances, soon parts with its electricity, but the process does not go on with such rapidity as in the case of the conductor. We may then fairly suppose that the air alone acting as a stratum of non-conducting matter, confines the electricity within a conducting body; although, from the freedom of motion which the molecules of the fluid possess within that substance, they may arrange themselves in forms dependent upon the forces that act upon them from without; and upon the diminution of the pressure of that insulating envelope, the air, may spontaneously remove to other bodies acting upon them according to the ordinary laws. A non-conducting body is found not to lose its electricity with such rapidity as a conductor does, supposing both to be placed in vacuo. The electric fluid can traverse all the interior substance of the latter body with inconceivable rapidity; but its molecules seem to have no power of moving among the particles of matter of the former kind. There is then some kind of a force attendant upon non-conducting power, which, as it enables the particles of matter possessing this property to retain in some degree the electric molecule, may of course, if means be found to set the electric molecule in motion, communicate motion to the particles of the non-conducting matter also. Perhaps therefore we may conceive two forces tending to detain the electric fluid upon a non-conducting body; one, the ordinary and acknowledged pressure of the air, and another, though less powerful one, either accompanying or arising from the non-conducting power itself. It has been proved also, by accurate experiment, that the repulsive forces of molecules of the same electricity, and the attractive forces of molecules of the opposite electricities, vary according to the inverse square of the distances. Hence, the arrangement that the electric fluid will assume upon any excited conductor may be calculated. It follows also, from theoretical considerations, that the reaction upon the surrounding atmosphere exerted by strata of the electric fluid varies as the squares of the thicknesses of these strata.

Let us now proceed to apply the action of these forces to account for the observed attraction and repulsion of electrified bodies. For the sake of convenience, we may trace these effects upon spherical bodies; but it is obvious that whatsoever is true of masses of matter in that form, will be true in quality, of matter arranged in any other form, although the laws we shall hereafter mention may produce some variation upon the quantity of that effect.

Adopting in part an illustration from M. Biot, we may consider the conditions of two electrified spheres A and B, considering the former fixed and the latter movable; for whatsoever is proved on this supposition will be true also in quality, if both the
Electricity.

Practical bodies have freedom of motion. Three cases present themselves.

1. A and B, both non-conductors.
2. A, a non-conductor; B, a conductor.
3. A, a conductor; B, a conductor.

In the first case, the electrical molecules being fixed upon the non-conducting matter, by certain forces to which we have alluded, the bodies themselves must partake of the motions communicated to the electrical molecules. Every molecule upon each of the balls will exert a repulsive force upon every other molecule upon the same ball; but the resultant of all these forces can produce no effect upon the motion of the centres of gravity of each sphere respectively. In the next place, we have the attraction or repulsion of the fluid upon one sphere towards the fluid upon the other sphere; and as the bodies are non-conductors, whatsoever order of distribution the fluid upon each sphere has at first received, the same order will be retained. Suppose that the electricity are equally disposed around the spheres respectively. In this case each sphere attracts or repels the other sphere, in the same manner as if all the electrum were collected at its centre. The force then with which the fluid upon B is attracted or repelled towards the fluid upon A, is due to the joint action of the two fluids upon each other; and the motion which is thus impressed upon the fluid with which B is charged, must, for reasons already given, cause the body B to be either attracted towards or repelled from A, as the case may be.

In the second case, we may consider the molecules of the fluid upon B, when acted upon by the molecules of the fluid A, as arranging themselves within the body B, (in which they can move freely,) according to that law of attraction or repulsion to which they are subject. Let fig. 12 and 13 roughly represent this case, supposing the former to be sections of a conducting and a non-conducting sphere, charged with opposite electrifications, and the latter to be sections of two similar spheres charged with the same electricity. It is evident, that in both these cases the space between the dotted lines, and the full lines marking the surfaces of the spheres, may roughly represent the sections of the strata of fluids arranged according to the conditions of the respective cases. With regard to the sphere B, since it is formed of conducting matter, we cannot suppose any such force uniting the electric molecules to the material particles, as to be capable of producing a motion in the latter; and the only effective force which we have to consider is, that which arises from the pressures of the air and the electric fluid upon each other. Whatever intensity of electrical charge may have been communicated to the spheres, the reaction of the electric molecules upon the air is proportional to the square of the thickness of the electrical stratum at different points. In fig. 12, since the thickness of the electrical stratum is by the arrangement of the fluid much greater on the side O of the sphere than on the side M; the sum of the squares of all the lines drawn in the direction of radii for measuring the thickness of the stratum, is much greater on the side O of the sphere than on the side M of the same sphere; and therefore the reaction in the direction M O is greater than the reaction in the direction O M. Now the ordinary atmospheric pressures upon the sphere at the points M and O are equal, and in opposite directions; but, being unequally resisted, motion will ensue, and the sphere B will recede from the sphere A, as the arrow points out. By a similar course of reasoning, the sphere B, in fig. 13, will be shown to move in the opposite direction towards the dissimilarly electrified sphere A.

The consideration of the third case, proceeding upon similar principles, will lead us to results of the same kind; and, in fact, the third case becomes identical with the second, after the masses of fluid in each of the spheres have assumed those positions to which they are impelled by the mutual action of the molecules of fluid on one sphere, upon those of the fluid upon the other sphere. It is obvious also, that although in these supposed cases, for illustration, we have considered the sphere A as fixed, the same results in nature would have been obtained if both the spheres had been movable, only that the quantity of motion would then have been divided between the two bodies.

Should these illustrations meet the eye of the experienced electrician, it may be to him a matter of surmise whether the effects produced by the decomposition of the natural electrificities of the bodies (when they are conductors) have not been here adverted to. The truth is, that as these effects do not diminish, but rather increase in all ordinary cases the actions here described, we omit for the present all the phenomena arising from induced electricity, in order that we may devote to that subject a portion of more undivided attention hereafter.

The explanation that has been given in the recent paragraphs of the mechanical agency of the air in producing many of the sensible effects of electrical attraction and repulsion, enables us to avoid the improbable supposition, that in their electrified state the particles of matter exert upon each other any new attractive or repulsive forces different from that with which they are endowed in their unelectrified state. It leaves to matter the power of being acted upon, but takes from it all active agency in these phenomena. As a proof that similar movements may be produced simply by the mechanical action of the air, without any real attraction or repulsion of material particles towards each other, M. Biot adds the following elegant illustration. Let A B, fig. 14, represent a glass vessel filled with some heavy fluid, such as water, or mercury, suspended vertically from a fixed point, S. The vessel itself will remain motionless, and the fluid which it contains can produce no motion in an horizontal direction, because the lateral pressures at the same depth in opposite directions A B, B A are equal to each other. But suppose that by means of a burning mirror M, we direct a cone of light upon the point A, and thus make a small perforation in the side at that point. The fluid now escaping freely from this aperture, the pressure in the direction B A diminishes, and the pressure in the direction A B remaining constant, and being no longer counteracted, the vessel will move from the mirror as if it were repelled by it. Thus also a hole made in the opposite point B might produce an apparent attraction, although in neither case is there any real attraction or repulsion, but only an effect of simple hydrostatic pressure, depending upon the fluid contained in the vessel A B, and the surrounding atmosphere.
Whatever may be the nature of electrical attractions and repulsions, the effects produced are among the most subtle manifestations of physical force; for the interposition of glass, resins, and non-conducting bodies does not destroy these effects. An excited stick of wax, suspended in a glass flask or tube, will still attract light bodies to the surface of the glass. This appearance might however be accounted for on the principles of induction, without supposing the glass to be permeable to the direct influence of electricity.

(18.) Being now in possession of the electrical machine, and in some degree prepared to comprehend the principles upon which the experiments performed with it depend, we shall select a few of the most interesting of these experiments, from the countless numbers already published, as further illustrations of the objects to which this chapter has been specifically devoted.

Experiments depending upon electrical attraction and repulsion.

(19.) Exp. Remove the prime conductor from an electrical machine; let the cylinder be put in motion by turning it with one hand, while the back of the other hand is brought near to that part of the cylinder which is just beneath the termination of the silk flap. A singular sensation is perceived, something like that which is produced by touching a cobweb. The cause of this sensation is to be sought for, partly in the ordinary attraction exerted upon the fine hair covering the surface of the skin, but principally in the actual accumulation and progress of resinous electricity towards the vitreous electricity excited by the cylinder of glass.

(20.) Exp. Adjust the prime conductor to the machine, so that the row of points may be as near to the cylinder as possible without touching it. Let the conductor be electrified by putting the machine in motion; and then, holding a linen or silver thread by one end, bring the pith ball, attached to the other end, near to the excited conductor. The ball will be immediately attracted, and will continue to adhere to the conductor as long as any free electricity remains upon the conductor.

(22.) Exp. Let a few pieces of thread, about a foot long, be tied together by a knot at each end, and having attached one end to the prime conductor, let the other end hang loosely in the air. Upon turning the machine, the threads become similarly electrified, and therefore repel each other, consequently, the central part of the fasciculus will swell out, like the meridians drawn upon a globe, and the lower knot will, of course, be electrified towards the conductor.

(23.) Exp. Insert one end of the pointed brass rod, fig. 5, into the conductor, and while the machine is in action, let the point of the rod be moved about over the inner surface of a dry glass tumbler. Place a number of small pith balls or fragments of paper rolled up into balls, upon a surface of tin-foil, or a metal plate, and reverse the tumbler over the balls. A violent system of attractions and repulsions immediately takes place, the balls jumping up and down alternately, between the glass and the metal, until all the electricity, which was disposed upon the surface of the glass, has been removed.

(24.) Exp. Suspend a disc of pasteboard or wood, coated with tin-foil from the prime conductor, by linen threads, and place underneath this disc a similar one communicating with the ground by a chain, and capable of being fixed at different distances from the former plate. Let a number of fragments of gold-leaf, or paper, or small painted figures, be placed upon the lower plate. These light bodies, upon putting the machine in motion, will be immediately attracted and repelled alternately between the two plates, and a sort of electrical dance is performed.

(25.) Exp. Fig. 15 represents an elegant experiment on the same principle, called the electrical bells. A glass stem is surmounted by a brass ball A, having two transverse bars, also of brass, from the extremities of which four chains support four small bells B, B, B, B. Upon the lower part of the glass rod, a fifth bell B is affixed, having a chain C to communicate with the earth. Four silken threads from the transverse bars serve to carry four small brass balls, which play between the four exterior bells and the central one. Upon a communication being made between the ball A, and the electrified conductor of a machine, the four brass balls strike the four outer bells, and the inner one, alternately; and thus the electricity is transmitted from the cap A to the outer bells, and thence carried by portions upon the balls to the inner bell, from whence it escapes to the earth.

(26.) Exp. Employing the pointed wire fig. 5, let a small piece of sealing-wax be affixed to one end of it, while the other end is inserted into the hole at the end of the prime conductor. Let the wax be softened by the flame of a candle, and then put the machine in motion. The melted wax becomes a conductor, and...
Electricity.

in consequence of the repulsion of its electrified particles, fine filaments of wax are thrown out from the melted mass, and may be collected in the form of a polished plane surface, or by oblique refraction through a pile of glass plates.

In atmospheric air, and under the ordinary pressure; when electricity passes by explosion from one metallic body in order to enter another metallic body, the light is white; but if we present a finger to an electrified conductor, the spark produced is violet. If one of the bodies concerned in the explosion be a green plant, or water, or ice, the light is red. Lastly, even between the same two metallic conductors, the colour may vary from the most brilliant white to the most delicate violet; according to the distance through which the electricity is transmitted, and according to the resistance of the medium which it is compelled to traverse.

To prove the former of these propositions; affix a metallic wire, terminating in a sharp point, to the extremity of the prime conductor of a machine, arranged for the production of vitreous electricity. Having set the machine in action, present towards the point of the wire one of the metal balls of fig. 7. When the surface of the sphere is near to the point, the transmission of electricity will take place in a continued succession of small sparks of brilliant whiteness, passing to the nearest part of the metal sphere. This whiteness will decrease and tend towards a red colour, as the striking distance of the bodies is gradually increased. The explosions will no longer be directed towards one point upon the sphere, but will strike various points throughout a certain extent of its surface; and at last, at some greater distance, there will no longer be a sharp explosion, but a cone of feeble violet light will diverge from the extremity of the point, and will extend its base over the nearest half of the sphere. In this case, instead of the cracking which the sparks produced, we hear only a sort of continued hissing; the cone of light will gradually become more feeble as the distance increases, and at some distance of separation it will altogether cease to be perceptible.

Such is the effect produced by an increased distance in a medium of which the density remains constant; but the same effect may be produced, the distance remaining invariable, by causing an alteration in the density of the medium. Take a glass vessel in the shape of an ellipsoid, fig. 16, pierced at the two extremities of its major axis for the reception of two metallic rods, each terminated by the half of a metal sphere. These wires are to pass through an air-tight plug, so that by sliding them up or down, they may be fixed in the interior of the vessel at any required distance from each other. Let one of the apertures be furnished with a stop-cock and screw, by which it may be fitted to the plate of an air pump. Having made the upper wire communicate with the prime conductor of a machine, while the lower one communicates with the earth, transmit the electrical current through the two rods, and adjust their two extremities so that the transmission may be effected by an almost continual succession of vivid sparks from one hemisphere to the other. In this case the light is white, as in the former experiment, when the sphere was sufficiently near to the point for the electricity to pass by explosion. But now let the density of the air within the receiver be gradually diminished, the transmission from one ball to the other will take place before the electricity shall have attained to the...
ELECTRICITY.

Practical Electricity. same degree of intensity upon the hemisphere. In this case the whiteness of the light is seen to diminish, and it gradually changes to a violet tint. Thus, in these two experiments, the progressive changes in the colour of the light are attendant upon the diminution of intensity in the electricity transmitted. The only difference in the two cases is, that in the former the diminution is occasioned by the increase of the distance, by which the communicated electricity is expanded throughout a greater space; while in the latter, of the rarefied air, the intensity of the electricity is weakened by the diminution of resistance in the medium, which allows of its escape through a given distance, at a lower degree of intensity. According to this view, we might suppose that in different experiments, where the same degree of rarefaction is employed, the more intense the electricity transmitted, the whiter would be the light. And this is found to be the case, for if we make the discharge of a strong electrical battery pass through a small tube, exhausted as completely as is possible by the best air pump, the light produced by this highly accumulated electricity is of the most brilliant whiteness.

The luminous trace which electricity produces in passing through the air out of conducting bodies, varies also with their figure. When a spherical and uninsulated conductor is presented at a distance toward a fine point vitreously electrified, we have already seen that a luminous cone is formed, having its vertex at the extremity of the point. Should the sphere be removed, and the point remain in the air, the cone becomes changed into a small luminous brush or pencil of diverging rays. This pencil is much more beautiful and powerful if the point, instead of being extended, is a little rounded at its extremity; so that a powerful condensation of electricity may take place, not only upon one minute point, but may extend over rather a larger surface, though with a somewhat diminished intensity. We have supposed the point to be vitreously electrified, but when resinous electricity is communicated to it, the pencil of light is no longer seen, but only a minute star of bright light.

M. Biot considers that it is at present impossible to account for these differences of appearance, but that it is probable that they depend upon the nature of the two electricities, and upon the manner in which they act upon the air in the circumstance of their transmission; particulars of which we are utterly ignorant. The advocates of Franklin’s doctrine consider that these experiments upon electrical light, are favourable to the hypothesis of one electrical fluid, as we shall hereafter explain.

(31.) From all these researches, we learn that the intensity of the electrical light depends always upon the ratio existing between the quantity of electricity transmitted, and the resistance of the medium through which it has to pass. There can be no doubt but that at the instant of the explosion, this medium is struck, compressed, and suddenly driven back upon itself; also when it is elastic it undergoes a momentary expansion, which we may make apparent by a direct experiment. For this purpose we may employ what is called the electrical air thermometer of Kinnersley.

In fig. 17, A B is a wide glass tube, having its ends closed by two air-tight caps A and B. Through these caps two wires, T, T, slide in the direction of the axis of the tube, terminated by brass balls, so that by regulating the distance between these two balls, a strong spark must be collected to pass through the interval of air between them. At the lower extremity there is adapted to an aperture in the cap another small tube, t t, bent at right angles, and through this tube a sufficient quantity of mercury is introduced, to fill the lower part of both the tubes. Having formed a communication between one wire T and the earth, and leaving the other wire to communicate with the prime conductor of an electrical machine in action, the electricity will pass by sparks from one wire to the other, and at each spark the air in the cylinder being dispersed by the repulsive force, presses upon the surface of the mercury, which is thus compelled to rise in the smaller tube, but descends again immediately after the explosion. This motion then demonstrates the separation produced between the particles of the mass of air through which the discharge takes place; and if we take into consideration the unmeasured and immense velocity of the motion of electricity, we shall plainly perceive that the particles of air, immediately exposed to its impact, ought, at the first instant, to undergo individually all the effect of compression. From that cause alone they ought to disengage light, the same as when they are subjected to any other mechanical compression. Thus one part at least of the electrical light is necessarily due to this cause, and there is, moreover, no experimental ground for supposing that any other cause assists in the production of this phenomenon.

It may possibly be adduced as an objection to this hypothesis, that the electrical light is produced in a vacuum. But let it be remembered, that what we inaccurately term a vacuum, is, in truth, only a space entirely devoid of some metallic vapour, even by those methods which have so long been supposed perfect in this respect. (Sir H. Davy, Phil. Trans. 1822.) By employing the very best air pump, although the rarefaction of air appears to us great, yet its pressure is not reduced to the thousandth part of what it was at first; and in the best possible barometric exhaustion, the apparent vacuum is never filled by the vapour of mercury only. A medium of this kind, though appearing to our ideas greatly attenuated, must offer some resistance, and oppose some degree of reaction to a velocity so great as that possessed by electricity. In such a case the widely separated molecules of which it consists, may be acted upon by an electrical discharge, tending to push them aside with a rapidity greater than they are able to accommodate. By this effect, they must undergo compression, with a disengagement of light and heat, but to a much less extent than would have taken place in a denser gas, exposed to the same discharge.

Should it be objected that electricity of great intensity is capable of producing a spark also under water, as may be proved by discharging a battery through conductors at a very small distance from each other immersed in water, the argument can not avail much; for in all water there is a portion of air, in the state of mechanical admixture, among its
Experiments on electrical light.

(32.) Perhaps the most simple and not the least interesting experiments upon electrical light, depend upon its passage from one conducting body to another. 

Exp. Let a number of small circles of tin-foil be pasted in a spiral form round a glass tube, fig. 18, so that the discs may be about ¼ th of an inch from each other. If this tube be held towards the prime conductor of an electrical machine in action, or in any other way placed in an electrical circuit, the simultaneous passage of the sparks from one disc to another, will produce a spiral line of light identical with the course of the tin-foil round the tube. In a similar manner any word or picture may be arranged upon a glass plate, so as to become illuminated by the transmission of electricity in the dark.

(33.) Exp. Place a lump of sugar in contact with the exterior coating of a charged jar; bring one of the balls of the discharger, fig. 82, into contact with the sugar, and let the other ball be extended so as to touch the knob of the jar; upon the passage of the discharge through the sugar, its whole mass will become beautifully illuminated, and will so continue for a second or two.

(34.) Exp. "Attach one wire to the outside coating of a charged jar, and another to one of the branches of the discharging rod; and having placed their other ends at the distance of ¼ th of an inch, press the thumb upon the two ends. Bring the other branch of the discharging rod in contact with the knob of the jar, which being thus discharged, the spark will pass under the thumb, and illuminate it in such a manner, that the bone and the principal blood vessels may be readily observed." (Brewster.)

(35.) Exp. Let two pointed wires be inserted obliquely into a piece of soft deal, so that the points of the wires may be an inch distant from each other, and at different depths below the surface of the wood, in the direction of the longitudinal fibre. Upon passing a strong spark from one to the other, the wood will become illuminated, and the spark seen at different depths will appear under different variations of colour.

(36.) Exp. Let a short chain be laid upon a table, one end of the chain being in contact with the outside coating of a charged jar, and let another piece of chain be placed with its extremity within ½ th of an inch of the end of the first chain. Upon these two ends place a glass filled with water, and with the discharging rod form a communication between the latter chain and the knob of the jar. At the instant of the electrical discharge, the whole glass of water will become brilliantly illuminated.

(37.) Exp. "Insulate a large brass ball, and connect with it a silver thread of two or three yards long, the other extremity of which is held in the hand; when sparks are made to strike upon the brass ball, the whole of the thread will be rendered faintly luminous." (Singer.) The same experiment may be performed with a long continuous strip of gold-leaf about ½ th of an inch in width.

(38.) Exp. Let a glass cylinder, three feet long and three inches in diameter, be fitted with air-tight metal caps at each end; so arranged, that by a stop-cock and screw at one end, the cylinder may be fitted to the air pump for exhaustion. Let there be a sliding wire passing through the opposite end, carrying a circular brass disc within the cylinder, so that the disc may be placed at any required distance from the plate closing the opposite end of the cylinder. If now the upper end of the wire be made to communicate with the prime conductor of a machine, and the lower plate with the earth, the air being exhausted from the cylinder, a beautiful sheet of light will pass from the upper to the lower plate. This column of fire will be of more or less perfect continuity and regularity, in proportion to the degree of exhaustion produced within the cylinder by the action of the air pump. (Watson.)

(39.) Exp. Let the plates of the apparatus last described, be placed at the distance of about ten inches from each other, and through this interval discharge a common Leyden jar. The passage of the charge from one plate to another will, if the vacuum be good, produce one continuous and brilliant body of fire. (Watson.)

(40.) Exp. "Seal a short iron or plated wire within one extremity of a glass tube thirty inches long, so that the wire may project a little within its cavity, and screw a ball upon the exterior end of the wire; fill the tube with quicksilver, and invert it in a basin of the same, thus producing a Torricellian vacuum in the upper part of the tube. A spark, which in the open air would only pass through a quarter of an inch, will pervade six inches of this vacuum with facility; and if the quicksilver be connected with the ground, a current of faint light will pass through the upper part of the tube, whenever its ball is brought near to an electrified conductor. By passing up a drop of ether or water, an atmosphere of the vapour of either of these substances may be produced in the tube. In such a medium the current of electrical light assumes various colours, which vary with the density of the medium. In the vapour of ether, a spark viewed near is green, but at some distance it appears of a red colour. By this apparatus the spark may be..."
Practical Electricity.

examineda spark, we are indebted to Messrs. Brooke, Nicholson, and other early electricians. It appears that in a medium of given resistance, such as the atmospheric air, the form of the spark varies with the forms of the conductors from which it is emitted, and by which it is received. Thus, if it be taken from a ball two or three inches in diameter, it will move in a straight line; but if a spark of the same power be taken from a ball half an inch in diameter, it will move in a zigzag direction through the air.

The absolute length of the spark seems to depend upon several circumstances, such as the form and magnitude of the conductors employed for its transmission, and the part of their surface from which it is received, also the intensity of the electricity communicated to them. Mr. Brooke constructed a singular conductor, formed of about twenty rods of wood seven feet in length and 3/4ths of an inch in diameter, coated with tin-foil, and all connected together in the form of a gridiron. The power of giving sparks possessed by this instrument was by no means considerable. A longer spark may be obtained from a brass ball of two inches in diameter, affixed by a stem to the prime conductor, than from any part of the conductor itself. It is, however, unnecessary to multiply these observations, for every case of the kind may be clearly accounted for, and even foreseen from the principles of electrical distribution hereafter to be explained. It may, however, be interesting to exhibit by a few diagrams the differences observed in the appearances of sparks produced by the two opposite electricities. Fig. 19 represents the straight form of a spark passing from a ball A at the extremity of a resinously electrified conductor, to a ball B in its natural state. Fig. 20 shows the ball A is resinous, and B vitreous. Fig. 22, 23 and 24, represent conducting rods placed parallel to each other, under the following circumstances: In fig. 22 B is vitreously electrified, and A in its natural state connected with the earth. In fig. 23 A is electrified resinsonly, and B connected with the earth. In fig. 24 A is resinous, and B is vitreous; the form of the sparks produced in all these cases, will be seen by a simple inspection of the figures.

Having now arrived at the conclusion of those experiments, which may result from the direct action of the electrical machine, we proceed to describe, as far as our limits may permit, a few of the most recent improvements introduced into the mechanical construction of electrical apparatus.

Nairne's electrical machine.

(41.) Exp. Present an insulated sheet of paper to the end of a vitreously electrified conductor at some small distance. A beautiful star of radiant light will be projected upon the paper. If the conductor be charged with resinous electricity, no star will appear, but a cone of rays will be seen, the vertex of which is at the conductor, and the base upon the plane of the paper.

For numerous observations upon the electric spark, we are indebted to Messrs. Brooke, Nicholson, and other early electricians. It appears that in a medium of given resistance, such as the atmospheric air, the form of the spark varies with the forms of the conductors from which it is emitted, and by which it is received. Thus, if it be taken from a ball two or three inches in diameter, it will move in a straight line; but if a spark of the same power be taken from a ball half an inch in diameter, it will move in a zigzag direction through the air.

The absolute length of the spark seems to depend upon several circumstances, such as the form and magnitude of the conductors employed for its transmission, and the part of their surface from which it is received, also the intensity of the electricity communicated to them. Mr. Brooke constructed a singular conductor, formed of about twenty rods of wood seven feet in length and 3/4ths of an inch in diameter, coated with tin-foil, and all connected together in the form of a gridiron. The power of giving sparks possessed by this instrument was by no means considerable. A longer spark may be obtained from a brass ball of two inches in diameter, affixed by a stem to the prime conductor, than from any part of the conductor itself. It is, however, unnecessary to multiply these observations, for every case of the kind may be clearly accounted for, and even foreseen from the principles of electrical distribution hereafter to be explained. It may, however, be interesting to exhibit by a few diagrams the differences observed in the appearances of sparks produced by the two opposite electricities. Fig. 19 represents the straight form of a spark passing from a ball A at the extremity of a resinously electrified conductor, to a ball B in its natural state. Fig. 20 shows the ball A is resinous, and B vitreous. Fig. 22, 23 and 24, represent conducting rods placed parallel to each other, under the following circumstances: In fig. 22 B is vitreously electrified, and A in its natural state connected with the earth. In fig. 23 A is electrified resinsonly, and B connected with the earth. In fig. 24 A is resinous, and B is vitreous; the form of the sparks produced in all these cases, will be seen by a simple inspection of the figures.

Having now arrived at the conclusion of those experiments, which may result from the direct action of the electrical machine, we proceed to describe, as far as our limits may permit, a few of the most recent improvements introduced into the mechanical construction of electrical apparatus.

Nairne's electrical machine.

(42.) One other machine, acting by a glass cylinder, is all that we consider it of importance here to describe. Fig. 25 is a representation of this instrument, the parts of which are sufficiently obvious without any minute and detailed description. The peculiarity of this machine consists in its having two conductors placed parallel to the cylinder, the one A, connected with the rubber, for the reception of resinous electricity, and the other B, near to the termination of the oil-silk flap, for the reception of vitreous electricity. This instrument was made by Mr. Nairne, and for all purposes of experimental research, wherein sometimes one electricity is required, and sometimes the other, it is a most valuable piece of apparatus. If a communication be formed by a chain passing from one conductor to another, no permanent excitation is produced, as the vitreous and resinous electricities immediately reunite; and of course to obtain either electricity in considerable quantity from its appropriate conductor, the other conductor must have free communication with the earth.

Descriptions of several of the earlier cylinder and globe machines, may be seen in Priestley's History of Electricity.

Fig. 26 is a representation of this instrument in one of its most common forms, as first constructed by Mr. Cuthbertson; the arrangement and use of every part is too obvious, from a mere inspection of the plate, to require any more specific description.

The plate machines are, on the whole, perhaps, preferable to those constructed in the cylindrical form; but it was always a matter of great difficulty to insulate the rubbers, as to obtain their resinous electricity if required. To effect this purpose, they have frequently been mounted upon glass feet, by which the whole machine may become insulated; but the elegant contrivance employed in the splendid instrument next to be noticed, has entirely obviated this inconvenience.

(44.) The celebrated machine constructed for the Teylerian Museum at Haerlem, under the direction of Dr. Van Marum, has produced some of the finest experiments with which electricity has yet been enriched. It forms an almost perfect model for the construction of similar apparatus; and as we have, by omitting the inferior instruments, obtained some space which may be devoted to more valuable matter, we feel that we cannot better dispose of some portion of this space than by a description of this magnificent instrument.

Fig. 27 exhibits a perspective view of the machine. The cushions are each separately insulated upon pillars of glass, and are applied nearly in the direction of the horizontal diameter of the plate. The ball, diametrically opposite to the handle, is the prime conductor, and the semicircular piece with two cylindrical ends serves, in the position of the drawing, to receive the electricity from the plate. By the happy contrivance of altering the position of this semicircular branch from vertical to nearly horizontal, the cylindrical ends may be placed in contact with the cushions, and the prime conductor instantly exhibits negative electricity. But as it is necessary that the cushions
should communicate with the ground when the positive power is wanted, and that they should be insulated when the negative power is required, there is another semicircular branch applied to the opposite side of the plate, nearly at right angles to the first. That is to say, when positive electricity is wanted, the second branch, denoted by \( I \) in the section, fig. 28, is placed nearly horizontal, and forms a communication from the cushions to the ground, through a metallic rod from \( K \), behind the mahogany pillar which supports the axis; but when on the contrary the negative power is wanted, and the branch from the prime conductor is placed in contact with the cushions, this other branch from the axis is put into the vertical situation, and carries off the electricity emitted from the plate of glass.

"The axis of the plate \( b b \), fig. 28, is supported by a single column \( A \), which for that purpose is provided with a bearing piece \( K \), on which two brass collar pieces \( D D \), represented more at large and in face at fig. 30, are fixed and carry the axis itself. The diameter of the glass plate is thirty-one English inches. The axis has a counterpoise \( O \) of lead to prevent too great friction in the collar \( D \) nearest the handle. The arc of the conductor \( E E \), which carries the two small receiving conductors \( F F \), is fixed to the axis \( G \), which turns in the ball \( H \). On the other side of the glass plate is seen the other arc \( I I \) of brass wire half an inch in diameter, fixed to the extremity of the bearing piece \( K \), so that it may be turned in the same manner as the arc \( E E \). The two receiving conductors \( F F \), are six inches long, and two and a half inches in diameter. The double line \( P \) represents a copper tube terminating in a ball \( Q \). It moves like a radius upon the stem \( K \) of the ball \( S \), which being screwed into the conductor \( H \), serves to confine the arm \( P \) in any position which may be required. The diameter of the ball \( S \) is only two inches, which, together with certain other less rounded parts of this apparatus, may serve to show that the considerable electricity from this machine is (in Mr. Nicholson's opinion) less disposed to escape than if it had proceeded from a cylinder. The dissipation of electricity along the glass supports, is prevented by a kind of cap \( T \) of mahogany, which affords an electrical well or cavity underneath; and likewise effectually covers the metallic caps into which the glass is cemented. The lower extremities of the cushions are decorated with a layer of gum-lac \( e e e \), to preserve the insulating state of the wooden cylinder more perfectly, and to prevent the cap \( b \) from throwing flashes to the rubbers. The bottom of the cap \( b \), is screwed home upon the tapped extremity of the steel axis \( B \). The base of the cap \( c \), which is four inches in diameter, terminates in an axis one inch thick, and two in length, the extremity of which is formed into a screw. The glass plate is put on this projecting part, and secured in its place by a nut of box wood, forced home by a key applied in the holes \( i i \). Two rings of felt are applied on each side of the glass, to defend its surface from the contact of the wood and the metal; and the central hole in the glass, which is two inches in diameter, contains a ring of box wood, which prevents its immediate application to the axis.

"As it is necessary that the axis \( G \) should be parallel to the axis of the plate, in order that the conductors \( F F \) may move parallel to the plate itself, the pillar \( M \) is rendered adjustable by three brass screws \( R R \) at the bottom, which react against the strong central screw \( T \), and this is drawn downwards by its nut. The conductors \( F F \) are also adjustable by the sliding pieces \( v v \), and the binding screws \( w w \), which also afford an adjustment to bring the axis of each small conductor parallel to the face of the glass plate. A similar adjustment may be observed at the extremities of the arc \( I I \).

"Fig. 31 represents a section of the moving part of the branch \( I I \), one-half of its real size. A brass plate \( a a \) is screwed to the face of the capital \( K \) by three iron screws \( \beta \). To this is screwed another ring \( \epsilon \), which affords a groove for the movable ring \( \gamma \), into which the arms \( I I \) are fixed. This is accordingly applied in its place before the ring \( \epsilon \) is fixed.

"The wooden part of the rubbers \( G G \), fig. 29, is covered with thin plates of iron, excepting the surface nearest the glass. The intention of this is to maintain a more perfect communication between the
Instruments for indicating the presence, and measuring the intensity of free electricity.

(45.) By the term Electroscope we understand an instrument which enables us to observe the presence of free electricity; while the term Electrometer ought to be reserved for some apparatus by which either its quantity or intensity might be measured. The two terms, it is true, have long been used almost synonymously; but as this manifest inaccuracy may lead to most incorrect descriptions, and would certainly vitiate our explanation of certain electrical phenomena, we propose, as far as we may be able, to confine the two terms to their strict etymological meaning.

As yet we are supposed to be unacquainted with the electric fluid in any other than its free state, obtained by the decomposition of the natural electricity inherent to all bodies. The fragment of paper or straw which we have spoken of, as attracted towards the excited amber or glass tube, points out to us the presence of that property or fluid which we term electricity; and therefore these minute substances afford the simplest possible illustration of the electroscope. If we observe with care the different distances at which these effects may be made manifest, we have, indeed, a rude approximation to a measure of the electrical excitement; in short to the electrometer; the two gold-leaves will share with the cap in the electricity received, and will mutually repel each other.

(46.) The attraction of a small fragment of gold-leaf, or a thread hanging loosely from some point of suspension, was the first electroscope employed by the early experimentalists. Here the effect was produced by attraction, but after the repulsive property of two similarly electrified bodies had become known, it afforded a more convenient species of electroscope.

Thus we arrive at the form of the instrument in the hands of the Abbé Nollet, who employed two threads freely suspended and hanging parallel to each other. On communicating electricity to those bodies, they became mutually repulsive, and the degree of their divergence might be measured by observing the shadows of the threads cast upon a graduated arc, traced out upon a board.

(47.) Bennet's electroscope.—This instrument, in its most improved form, (independent of the condenser,) is represented by fig. 32; A B C D is a glass cylinder cemented into a brass stand E, and closed by a plate and rim A B. G is the brass cap of the electrometer, having a wire passing through a glass tube cemented into the plate A B, and to the lower end of this wire two small slips of gold-leaf f f, half an inch in width, and from two to three inches long, are affixed. From the opposite points C and D, two slips of tin-foil are pasted to the inner surface of the cylinder, and rise to a height some little above the ends of the gold-leaf f f, the lower ends of the foil communicating with the brass stand of the electroscope. The cap of the instrument is allowed to turn freely round, and by this motion the two gold-leaves f f are placed opposite to the two slips of tin-foil respectively. If now any electrified body be brought into contact with the metallic cap G, the two gold-leaves will share with the cap in the electricity received, and will mutually repel each other. Should this repulsion be so great as to drive the lower extremities of the leaves to the sides of the cylinder, they there come in contact with the tin-foil, and thus the electricity is conveyed away to the ground, and the leaves again collapse; but a feebleer degree of electrical excitation only makes them recede from each other, as represented by the figure, and of course they continue in this position until the electrical charge is dissipated by the contact of the air with the cap, or by touching it with the finger or some conducting body.

This, on the whole, is one of the most convenient instruments for all ordinary electrical experiments, such as the examination of the nature of that electricity which is developed by any excited substance. Fig. 33 represents a section of the cap and neck of this instrument in its most improved form, in order to obtain more perfect insulation. A B is the top of Singer's cylinder as before, G is the metal cap communicating with the gold-leaves, by means of a wire passing through a varnished cork or plug of silk i, cemented into a varnished glass tube of which K is...
ELECTRICITY.

Practical Electricity.

The lower extremity; this tube being also cemented into the centre of the plate A B. This improvement was introduced by Mr. Singer; its effect depends upon the brass wire, which conveys the electricity to the gold-leaves, being perfectly guarded from all contact with the atmosphere; for the body of air through which it passes being confined within the glass tube, can neither partake of the motions nor hygrometric variations of our common atmosphere. Mr. Nicholson proposed to employ two plates of thin brass instead of the two slips of tin-foil, so arranged, that by means of a tangent screw the upper parts of the plates might be brought very near to the two laminae of gold. By this means more feeble degrees of electricity are made apparent; but the principle on which this improvement is founded, as well as that of the two slips of tin-foil, depends upon induced electricity, a subject which as yet has not fallen under our notice. For a more full account of this last improvement, see Nicholson's Journal, Sept. 1797.

Cavallo's portable electro-scope.

(48.) Cavallo's electro-scope._—Fig. 34 and 35 give a general representation of Mr. Cavallo's electro-scope, which is principally employed in experiments on atmospheric electricity. A is a wooden stand, to which A is a wooden stand, to which a case covering the whole instrument, when not in use, may be affixed by the screw seen in the figure. The glass cylinder and the slips of tin-foil are much the same as in the instrument recently described, except that the glass cylinder is contracted at the top, and terminates in a tube B. Into this tube B, a smaller tube of glass is cemented, the lower part of which is seen at C. Through this latter tube a wire passes to a metal or ivory plate C, perforated for the reception of a very fine silver wire, to the extremities of which two small pith balls are attached. D is a metal cap affixed to the central wire, and serving to protect the upper part of the tube B, whenever the electro-scope is exposed to rain. The whole of the tube B, and the upper part of the glass cylinder are covered with a film of sealing-wax or varnish, for further protection from the penetration of moisture to the interior of the instrument.

(49.) Fig. 36, 37 and 38, represent a convenient pocket electro-scope, employed by the same experimentalist; fig. 36 and 37, are views of a small glass tube 4ths of an inch in diameter, and three inches and a half in length, with a loop of silk at one end; b is a cork in the form of a spindle, so that it may be fitted into the glass tube by either end. To this cork is affixed a double silver wire, having at each of its extremities a delicate cone of cork or elder pith. In one figure the wires are seen deposited in the glass tube as a case, in the other figure they are suspended from its end by the reversing of the cork, and in an excited state. The glass tube serves as a handle, and is varnished throughout the lower half of its extent. Fig. 38 is a wooden case opening at one end by a screw, in which the glass tube is enclosed when not in use. At one end this case is mounted with a piece of smooth amber d, by the friction of which negative electricity is produced, and at the other end is an ivory knob c, insulated by a rim of amber e, for the production of vitreous electricity, which is easily effected by rubbing the ivory knob upon the sleeve of a coat, or any other woollen material.

(50.) The needle electro-scope.—This instrument, undoubtedly the most ancient, the most simple, and one of the most useful, has seldom been described. In fig. 39, A B is a fine metal wire, upon each end of which is a pitch ball of the size of an inch in diameter. At the centre of this needle is an agate cap C, resting upon the point of a vertical wire D, inserted into a circular stand. E is a small slider for the purpose of balancing the two ends of the needle, so that it may remain in a horizontal position. It is essential also, that the concave surface of the agate cap, which rests upon the fine point of the stand, should be rather above the centre of gravity of the wire A B, otherwise the needle cannot remain suspended. The agate cap serves to insulate the needle, and, for further security, the stand may be placed upon a plate of shell-lac, or resin if necessary. There is, however, an additional preservative against the transmission of electricity from the needle to the stand. For if we suppose the cap to be made of metal, and not of agate, and we acknowledge that the pointed wire D will have a strong tendency towards the absorption of electricity; yet from the great length of the needle, compared with its diameter, the electrical charge will be determined towards its extremities; and the inner part of the cap, which touches the point of the needle, will have scarcely an appreciable quantity of electricity distributed upon it.

It is obvious, that if an excited body, such as a stick of wax, or a glass tube, be brought near to either of the pitch balls, an attraction will take place; and if the excited body be presented towards either side of a ball, and in the same horizontal plane, the motion of the needle upon its pivot will bring the ball into contact with the excited electric. The needle will become saturated with electricity throughout, and after separating the two bodies, and again bringing the one near to the other, a vigorous repulsion takes place. In this state the needle, prepared for the trial of the kind of electricity which is developed at the surface of any excited body.

(51.) Haüy's electroscopes for mineralogical purposes.—Haüy's electroscopes.

By a reference to fig. 39, we may also describe one of these instruments. A B is a metallic wire as before, but terminated by two small balls A and B, also of metal. The cap may be of agate or rock crystal, and the supporting stand similar to that already described. By a very simple process, founded upon well-known properties of the electric fluid, we may communicate to this needle either electricity, and yet make use of the same electric for the purpose in both cases. For example, by touching either of the balls with an excited stick of wax, the needle receives a charge of resinous electricity. On the other hand, let the needle be in its natural state, and let the excited stick of wax be brought near to one of the metal balls, but so as on no account to touch it. By this operation the natural electricity of the needle is decomposed, the vitreous electricity is attracted towards the ball nearest to the excited wax, and the resinous electricity of the needle is repelled to the opposite ball. Touch this ball with the finger, or any conducting body, for a second or two, and, lastly, remove the stick of wax. The needle now has a charge of free vitreous electricity; for that vitreous electricity, which was attracted towards the ball opposite to the wax, disperses itself over the whole needle; and the resinous electricity, which before neutralized it, has been removed.
Practical Electricity

70 E L E C T R I C I T Y.

by the conductor which touched the opposite ball.

Henley's quadrant electrometer. The instrument well-known by this title forms a very common appendage to the electrical machine. Fig. 44 represents a wooden stem six or seven inches long, surmounted by a ball. Into the side of this stem is affixed a semicircle of wood or ivory, the arc of which is graduated and figured; the numbers beginning from the lowest point, and terminating at the end of the first quadrant or 90 degrees. At the centre of the circle a pin is inserted, bearing a light index of cane, having a pith ball C at its extremity. Having fitted the pith ball to the stem, place a hole in the stem, by which it is connected with the conductor of a machine, the index rod and pith ball will hang down in a vertical position, parallel to the upright stem, and cover the zero of the graduated arc. But immediately upon the communication of electricity to the conductor, the pith ball is repelled by the bar E, having a metallic sphere at each of its ends, and therefore the index of the instrument will be carried up to the point of the semicircle, which will be obvious, to any one acquainted with the nature of mechanical forces and the action of gravity, that equal degrees upon the paper arc at different distances from the vertical line passing through zero, do not indicate the presence of equal increments of force. This difficulty might however be removed by calculation; but there are also other sources of inaccuracy in this instrument when used for the admeasurement of electricity, which neither calculation nor compensation can overcome. As an electrometer only, it is really a valuable instrument, being possessed of a high degree of sensibility, and not being so liable to injury as the electrosopes made of gold-leaf.

In fig. 45, is an enlarged representation of the mode of suspension, by a plate with two holes, the ingenious contrivance of Mr. Cavallo, by which means friction and rigidity, forces tending to impede the divergency of the wires, are in a great measure avoided.

(53.) Straw electrometer. This instrument, represented in fig. 42, is frequently employed by continental electricians, though but little used in this country. Two very delicate laminae are obtained by splitting a straw in a longitudinal direction, and then suspended by an exceedingly fine silver wire, passing through two holes in a plate connected with the cap of the electrometer. This part of the apparatus is enclosed within a square glass case or cage, having a divided arc of paper affixed to one of its faces, as seen in the figure. It is but in an imperfect degree that this instrument can serve as a measure of the actual intensity of repulsion of the free electricity communicated to it; but of course an estimate is obtained by observing the divergence of the straws in degrees of the graduated arc. It will be obvious, to any one acquainted with the nature of mechanical forces and the action of gravity, that equal degrees upon the paper arc at different distances from the vertical line passing through zero, do not indicate the presence of equal increments of force. This difficulty might however be removed by calculation; but there are also other sources of inaccuracy in this instrument when applied to the admeasurement of electricity, which neither calculation nor compensation can overcome.

An electrometer only, it is really a valuable instrument, being possessed of a high degree of sensibility, and not being so liable to injury as the electrosopes made of gold-leaf.

In fig. 45, is an enlarged representation of the mode of suspension, by a plate with two holes, the ingenious contrivance of Mr. Cavallo, by which means friction and rigidity, forces tending to impede the divergency of the wires, are in a great measure avoided.

(54.) Henley's quadrant electrometer. The instrument well-known by this title forms a very common appendage to the electrical machine. Fig. 44 represents a wooden stem six or seven inches long, surmounted by a ball. Into the side of this stem is affixed a semicircle of wood or ivory, the arc of which is graduated and figured; the numbers beginning from the lowest point, and terminating at the end of the first quadrant or 90 degrees. At the centre of the circle a pin is inserted, bearing a light index of cane, having a pith ball C at its extremity. Having fitted the pith ball to the stem, place a hole in the stem, by which it is connected with the conductor of a machine, the index rod and pith ball will hang down in a vertical position, parallel to the upright stem, and cover the zero of the graduated arc. But immediately upon the communication of electricity to the conductor, the pith ball is repelled by the bar E, having a metallic sphere at each of its ends, and therefore the index of the instrument will be carried up to the point of the semicircle, which will be obvious, to any one acquainted with the nature of mechanical forces and the action of gravity, that equal degrees upon the paper arc at different distances from the vertical line passing through zero, do not indicate the presence of equal increments of force. This difficulty might however be removed by calculation; but there are also other sources of inaccuracy in this instrument when applied to the admeasurement of electricity, which neither calculation nor compensation can overcome.

An electrometer only, it is really a valuable instrument, being possessed of a high degree of sensibility, and not being so liable to injury as the electrosopes made of gold-leaf.

In fig. 45, is an enlarged representation of the mode of suspension, by a plate with two holes, the ingenious contrivance of Mr. Cavallo, by which means friction and rigidity, forces tending to impede the divergency of the wires, are in a great measure avoided.

(55.) Robinson's comparable electrometer. It would Robinson's.

be an act of injustice were we to omit to mention a very elaborate instrument of this species, contrived by that excellent electrician the late Professor Robinson, with which he was enabled to obtain a much more accurate measure of electrical attractive and repulsive forces than any of his predecessors. The instrument is now we believe entirely in disuse, from the greater simplicity and delicacy of M. Coulomb's apparatus; and therefore for a detailed description of Robinson's electrometer, we beg leave to refer our readers to a republication of the physico-mathematical writings of the Professor, by his able editor Dr. Brewster.

(56.) Coulomb's electrical balance. For the present, we propose to content ourselves by cursorily describing a very sensible electrometer, on M. Coulomb's principle of torsion, of greater delicacy than any hitherto mentioned, as a mere indicator of the presence of electricity; and one which, with proper precautions, affords an absolutely accurate estimate of the attractive or repulsive force of the free electricity communicated to a mass of matter of given superficials.

A B, fig. 45, is a cylindrical glass jar, covered at the top by a circular glass plate, with a hole in its centre. Through this hole, a single fibre of the silk-worm's web, or a very delicate silver wire, descends nearly to the bottom of the jar, and carries at its lower extremity a transverse bar. This bar consists of either a filament of gum-lac, or a silk thread or piece of straw coated with sealing-wax; at one extremity is a small pith ball, at the other a disc of varnished paper, as a counterpoise to the ball. The upper end of the wire is affixed to a sort of button C, with a small index, capable of being turned round upon a circular plate F, divided into 360 degrees. One side of the jar is perforated, to allow of the insertion of a small bar E, having a metallic sphere at each of its ends, the one being at the exterior and the other at the interior of the jar. By turning the button C, or the index, the needle may be brought into any required position with regard to the bar E. Now it is found by experiment, that the angle of torsion of the delicate wire of suspension we have described, varies in a direct ratio with the force acting upon it (within certain limits,) and therefore if the bodies D and E be placed in contact, and then similarly electrified, the distance to which they are repelled by the angular motion of the ball D, is a measure of the repulsive force exerted, be the law of that force what it may. Hence, by employing different forces of torsion which are known, and which may be measured upon the graduated head, to an equilibrium between different repulsive or attractive forces, which may be measured upon a graduated arc of paper pasted round the jar, the actual laws of these forces may be calculated.

ELECTRICITY.

CHAPTER III.

On the spontaneous motions of the electric fluid.

INTRODUCTION.

(58.) Under this title we propose to arrange and consider a certain class of phenomena, which (upon the hypothetical assumption that each kind of electricity is a fluid,) may be accounted for by its self-expansive property; that is to say, by the repulsion which all its molecules exert upon each other. It may not at first appear that this class of facts includes the circumstance of an electrified and insulated conductor, apparently losing all its electricity by the contact of another conducting body; but the application of our reasonings will be clearly seen by a careful examination of the conditions of the case in which the supposed difficulty is involved. Let the second conductor which is brought into contact with the electrified body be of finite magnitude and insulated; in this case the electrified body will not lose all its electricity, but a division of the electricity will take place between the two conductors according to certain laws. Again, let us take the extreme case, from which the objection has been framed. Let the electrified conductor communicate for an instant with the earth, and the same mode and law of action will produce apparently an entire abstraction of the free electricity, because in this case the partition of fluid takes place between the whole earth and the electrified body; and as the magnitude of the former bears no appreciable ratio to the magnitude of the latter, there will be no appreciable quantity of free electricity left upon the originally excited body.

It may easily be shown that electricity does possess some property, the effects of which we can explain, and even calculate, upon the supposition of this mutual repulsion existing between the molecules of the same fluid; for if a portion of it, in its free state, be communicated to any one from among the several substances which seem in a greater or less degree to suffer its progress through them, either a complete transmission is effected, or else a distribution of the fluid takes place with regard to both the bodies according to invariable laws. Some substances, as we have already seen, readily afford a passage to electricity, whilst others, with greater or less obstinacy, refuse to do so. This is termed the conducting power, a phrase which does not precisely express the true conditions of the case; for it has been proved that the particles of matter of different kinds, whether from conducting or non-conducting bodies, have no peculiar affinities for the electric fluids. and therefore it is

Practical Electricity.

Strictly speaking, the chord of the arc described is the distance to which the mutual action of the balls extends, and is therefore the true measure of the force; but at present we only attempt to describe the instrument in general terms, and to speak of an approximate result. In a similar manner the distance through which the ball is made to move, i.e. the torsion it is enabled to produce by attraction, when the fixed and movable balls have opposite electricity, may become an accurate measure of the attractive force. A much more minute description of this valuable instrument, in its most improved form, and an accurate investigation of the laws of its action, will form an essential introduction to our theoretical electricity.

(57.) The electroscopes now described, with the addition of the simple stand and pit balls before mentioned, are all that apply to electricity, so far as the plan of this article has as yet made us acquainted with it; that is to say, in its free state. Other and more complicated instruments will be required when we shall be called upon to examine latent or accumulated electricity; but there is yet one important problem to be solved, which has, strictly speaking, its place in the present chapter.

Coulomb's proof plane. It will presently appear that upon an electrified and insulated sphere of conducting matter, the electricity is distributed as a stratum of fluid of uniform thickness throughout; but this is true of masses of matter of no other form. It becomes then desirable to be in possession of some electrometric apparatus, by which we may ascertain the quantity of fluid resident at any given point upon the surface of an excited body. For the solution of this problem we are again indebted to the sagacity of M. Coulomb. He found that by affixing a small circular disc of gilt paper of an insulating filament of gum-lac, he could by a single contact with any excited and conducting body, a charge of electricity upon the conductor, a portionate to the quantity of electricity resident in the conductor at the point where the contact was made. For the success of this method, it is that the disc, which M. Coulomb calls the proof plane, should be small in comparison of the conductor to be touched; so that the addition of the new electrifying body, during the moment of contact, may interfere with the laws governing the distribution of the fluid; and also that the proof plane may, as nearly as possible, only form as it were a second particle, to share electricity with some one given particle belonging to the great mass of the electrified conductor. Having thus acquired the means of removing a quantity of electricity from any point, proportionate to the actual quantity of fluid at that point; or, which is the same thing, proportionate to the electrical intensity at that point; it is easy to measure, by the torsion balance, the repulsion exerted by the proof plane upon the movable ball charged with a known electricity, and thence to infer the quantitative distribution of electricity for that one point. In a similar manner, a series of comparative estimates may be obtained for all other required points upon the excited body, until the general form of the distributed bed of fluid be ascertained.

For other electrometers of this sort see D'Arcy, Mémo Acad. Par. 1749; Richman, Nov. Com. Petrop. vol. iv. p. 301; De Luc, Méthorologie, vol. i. p. 376; Camus, Jour. de Phys. vol. vii. p. 520; Terry, Jour. de Phys. xxiv. p. 315; Canton's improved by Cavallo, Phil. Trans. lxvii. p. 388.
more probable that some term implying a passive property in the substances spoken of, would give a more accurate description of the process. Conducting power is however an established phrase, and therefore will henceforth be employed here in its ordinary acceptation; and the investigation of this property in different substances, will form the subject of the first section of this chapter. In the second, we shall treat of the dissipation of electricity, being the cause of the spontaneous return of an excited body to the natural state of electrical equilibrium; and in the third section, we shall give a summary (as far as fact is concerned) of the mode of distribution or arrangement assumed by the fluid in any electrified substance.

§ I. On the conducting power of different substances.

(59.) Communicate to a gold-leaf electroscope either electricity, so as to produce a divergence between the suspended leaves. If now we touch the cap of the electroscope with a glass rod, no effect will be produced; that is to say, the charge of free electricity is not by that process conducted away or suffered to escape; but if we touch the cap of the electroscope with the finger or a rod of metal held in the hand, the contrary effect is produced, the electricity escapes, and the leaves collapse. Here then we have a familiar example of a non-conducting and a conducting body. With more or less of strict accuracy, under one or other of these two denominations, all substances may be arranged, and such has been the plan hitherto adopted. Thus we have conductors and non-conductors; the latter are also sometimes called insulators.

As is the case however with many systematic classifications, few bodies will be found to belong strictly to either division alone, and several substances might appear with almost equal propriety in both series. There is in fact a progressive order, in which all bodies may be arranged, beginning with that substance which possesses either property in the greatest perfection, and proceeding through the gradations of many other substances to the opposite extremity of the scale; but the precise point where conducting power censes, and the contrary property begins, is in some cases uncertain, and in very many it depends upon a circumstance totally adventitious, viz. the hygroscopic state of the body submitted to experiment. For these reasons we are inclined to depart from the ordinary plan, and to arrange these substances all in one column, beginning with the best known conductors, and terminating with those that are the worst; or, in other words, that are the most perfect non-conductors. There is doubtless some difference in their respective powers, even among the metals, which are the best conductors; but from the high degree of intensity of ordinary electricity, they all seem to transmit the fluid with equal facility. There is however reason to conclude, that delicate experiments would assign to the metals different degrees of permeability; for such is found to be the case with the less intense electricity developed by galvanic agency; and the order assigned to them in the subsequent list, is the result of Sir H. Davy's experiments with the last-mentioned agent.

The following observations of Mr. Singer are applicable to the subject of our present investigation. "The tendency of the charge to pass through the best conductors, offers a measure of conducting power; for if various substances of the same length and size are introduced at once into the circuit, that through which the electric fluid passes is the best conductor. Or, if they are introduced successively, that which conveys the charge most completely may be considered as the best conductor. Metals, although the most perfect conductors we know, oppose some resistance to the motion of electricity; and a charge will even prefer a short passage through air, to a circuit of twenty or thirty feet through thin wire." The inference deducible from these experiments of Mr. Singer has been much strengthened by recent experiments of Professor Cumming, which are given in the first volume of the Cambridge Transactions, wherein it is proved that the analogous fluids, the magnetic, the galvanic, and the thermo-electric are materially influenced as to the rate or perfection of their transmission, by the magnitude of the conductors through which their passage is effected. Again, with regard to the other class of bodies, it has been proved by Coulomb, that no substance can strictly be called a non-conductor; because electricity of great intensity will traverse small lengths of all bodies; but that there are certain limits within which a few substances may in practice be employed as such. Hence the insulating power of rods of substances of this class varies, directly according to some power of their length, and in some inverse ratio of the intensity of the electricity which they are required to insulate.

The black line, forming a division in the following table, is the position, according to Mr. Singer, at which we may suppose the conducting power to cease, and the insulating power to commence. In regard to several substances, placed about the middle of the table, such as the animal and vegetable bodies which contain moisture, and the earths in their ordinary state, we must consider them made up partly of conducting and partly of non-conducting matter; thus the pure earths and alkalis are non-conductors, but from the moisture which usually accompanies them, they become imperfect conductors.

Table of the Conducting Power of bodies, beginning Table of with the most perfect, and ending with those which are the least so, or that most nearly approximate to the property of Non-conductors.

Shell-lac.

(a) According to M. Achard of Berlin, who proved, in 1776, that a rod of ice two feet long, and two inches thick, at 184° Fahrenheit, was a very imperfect conductor; and that at — 13° Fahrenheit it would not conduct at all. He then, having very ingeniously frozen some water, so that it should contain no air bubbles, formed it into a spheroid, and having mounted it upon an axis, was able to employ it as an ordinary electric globe capable of a high degree of excitability. MM. Jallabert and Priestley had before proved that ice of the ordinary temperature, in our warmer climates, is a conductor.

(b) Possibly acting in a manner quite different from all other bodies near to it in the table, for in whatever manner they either transmit or allow the progress of electricity, the action of rarefied air is simply due to the removal of a substance which presents a most powerful resistance to the motions of the fluid. It would appear that in all our attempts to form a more perfect vacuum than that which the air pump will give, we only substitute in place of the air a sort of metallic atmosphere, which, of course, is highly favourable to the transmission of electricity. Such at least is the view we are inclined to take of the matter, although we admit that the subject is one in which considerable difficulties are involved. Walsh, Brooke, and Morgan made numerous experiments to ascertain whether a vacuum was or was not a non-conductor. Morgan inferred (Phil. Trans. 1785,) that it was a perfect non-conductor, because he could produce neither electrical light nor a charge in it. The former is quite consistent with the origin which we have assigned to electrical light, and therefore proves nothing; and we confess that we consider the latter argument as easily set aside by the explanations we shall hereafter give of the motions of electricity. At present, therefore, it appears probable that a perfect vacuum is a perfect conductor.

(c) From Van Swinden's experiments.

(60.) The greatest distance to which electricity might be conveyed, was a question which exercised the ingenuity of some of the early experimentalists, although the velocity with which it traversed the metals was their primary object; of these researches we have already given some account. An electrical charge from a battery is stated to have been compelled to traverse a circuit of four miles; and although Singer, whose opinion is entitled to respect, has doubted the accuracy of these experiments, yet, on examining the papers in which they are described, it does not appear that the result is either improbable, or that any source of fallacy can have escaped the observation of the experimentalists. There does not, in fact, appear anything in the nature of the case, to lead us to a contrary conclusion; for although we admit that an electric discharge will prefer a very short passage through air, to a very long one through a thin wire, yet we still arrive at this point, that electricity of high intensity will force itself a passage through a thin stratum of air, but that at much lower degrees of intensity it is capable of passing through metal; and as the conditions of the case may be so arranged that it shall traverse the air in preference to the metal, there must be some point at which the facilities afforded by these channels are equal. The density, hygrometric state, and thickness of the plate of air might form one side of an equation; and the nature of the metal, together with the thickness and length of a wire formed from it, might constitute the other side. But in this reasoning, we must suppose the intensity of the electricity given, and it would probably prove a more complicated question, were we to attempt to introduce into our formula an element corresponding to variations of electrical intensity.

Of the immeasurable velocity with which the motions of the electric fluid must be conceived to take place, we are able, perhaps, to form some idea, by
Electricity.

Practical Electricity. Considering the great mechanical momentum which it is capable of producing, although as a fluid it seems to us absolutely imponderable.

(61.) The smallest length to which some imperfectly conducting bodies may be reduced without losing their insulating power, has been examined by M. Coulomb, and he found that in each case this length depended upon the intensity of the electricity which the fibres were required to insulate, and the state of the atmosphere at the time of the experiment. It appeared that when electricity was communicated to a ball, suspended by a fibre of any insulating substance, the loss of electricity was at first much greater than could be accounted for from the dispersion in air alone, and therefore this loss was due to the imperfection of the insulation; but that after a time, when the electricity had diminished to a certain degree of intensity, no further diminution took place, except that which was due to the action of the air. Hence, at some degree of intensity in the communicated electricity, (in a given state of the air) a filament of given length becomes a perfect insulator. Or, which is the same thing, these imperfect insulators follow some law according to which some length may be found (on a given day) just capable of insulating electricity of any given intensity. The general law for all fine cylindrical fibres, such as hair, silk, filaments of gum-lac, &c. is, that the intensity of the electricity which different portions of the same substance will insulate, varies as the square root of the length of the fibre. In which case the nature of the substance, the diameter of the fibre, and the dispersive state of the air, are supposed constant.

Few comparisons have been instituted between different substances, but Coulomb found that the density of the electricity, which a fibre of gum-lac would insulate, was ten times as great as that which could be insulated by a silk fibre of equal length and equal diameter.

(62.) The next point for our examination, is one of extreme interest and curiosity. Do all bodies conduct both the electricalities with equal facility? This question has only recently been submitted to any thing like a strict experimental investigation, and it is to M. Erman, of Berlin, that we are principally indebted for our information upon this subject. In these researches, however, he was compelled to employ the weak intensity of galvanic electricity, which we have before hinted might be resorted to with advantage, in examining some other questions connected with the conducting power of substances. M. Erman has proved, that besides the classes of conductors and non-conductors, that are such universally, there are some substances which completely cut off the passage of one electricity, while they as freely suffer the progress of the other. The more minute details of these researches must be reserved for the Galvanic part of this article. (Jour. de Phys. vol. lxxiv.) The experiments of Mr. Brande, described in the Phil. Trans. for 1814, appear more properly to depend, as he has suggested, upon the electrical states of bodies induced by chemical action; and for this reason will be reserved to that part of our article in which the connection between Chemistry and Electricity will be discussed.

(63.) At present we can scarcely be said to have any knowledge of the influence which the other imponderable physical agents are capable of exerting, either for the increase or diminution of the conducting power of substances. As far as experiments have hitherto shown, increased heat neither tends to accelerate nor to retard the progress of electricity through metallic wires; and upon the electric fluid itself, it has not the least perceptible influence; for if powerful sparks be drawn from a mass of iron, they are not found to differ in temperature from similar sparks taken from a mass of red-hot iron; and if the wires by which an electrical or galvanic circuit is completed be made to pass through furnaces, so as to be intensely heated, no appreciable effect upon the electricity is produced. Still there are analogies which would lead us to suppose that there may be such an action, although to us it is at present utterly unprieciable, for among conductors less perfect than the metals, we meet with marked instances of such effects. Upon some of these bodies the addition or abstraction of sensible heat, produces an increase or a diminution of conducting power. Thus charcoal is a better conductor when hot than it is when cold. Glass, when cold and dry, is a non-conductor, but when heated to redness it becomes a conductor. Resins, which in their ordinary state are the best of non-conductors, entirely lose this property, and adopt the contrary one when they are rendered fluid by heat. Ice below 13° Fahrenheit is a non-conductor, but above this temperature it is a conductor. By a further increase of temperature it becomes water, and is still a conductor, and when heated is a still better one than it is at its ordinary temperature; this property continues to it even in the state of vapour. Air, however, has never been made a conductor of electricity, in the true sense of the word, by any degree of heat that has been communicated to it.

The conducting power of charcoal has been found to vary considerably, according to the different degrees of heat to which it has been subjected in its manufacture; it also varies with the different substances from which it may have been formed, so that we may suspect certain slight changes either in its chemical or mechanical structure, to be capable of producing these effects.

In general the chemical nature of substances seems to have but little immediate connection with their conducting powers, beyond the supposed uniformity of action existing between all the metals on one hand, and all the resins on the other; and the only attempt to speculate upon what may be the real nature of the conducting or non-conducting property, has been made by M. Coulomb. The opinion of this admirable philosopher is of course entitled to great respect, but is in this case unsupported by any fact, and is only advanced as a possible supposition. He considers the conducting power to depend upon the relative distances between the conducting particles entering into the constitution of a mass of matter; and that as these particles are at different distances in different bodies, the electric fluid, in its passage from one molecule to another, has a non-conducting space to traverse of variable magnitude. These conducting molecules being uniformly disposed in any given body, it follows that the non-conducting spaces, and therefore the imperfect conducting power, is constant for the same body.

Whatever may be the cause or mode of its action,
Practical Electricity

we must in some sense consider the non-conducting property as a force, for it gives to the particles of matter that are possessed of it, the power not only of preventing the motion of the electric molecules along the surface of a non-conductor, but it enables the body itself to retain them with some degree of power. Such, at least, is the inference we are inclined to draw from the circumstance that of two excited substances, the one a conductor, and the other a non-conductor, placed in vacuo; the non-conductor retains its electricity much longer than the conductor does.

§ II. On the gradual dissipation of electricity.

(64.) It must already have been remarked, that in all cases where an excited body has been left exposed to the action of the air, even in a state of insulation, a partial or total loss of its electricity takes place. Thus the pith balls, described in art. 16, if at first divergent from excitation, will, in process of time, without the contact of any conducting body, again collapse. There appear to be three principal causes cooperating to produce this effect.
1. The imperfection of the insulating property in all known solids.
2. The contact of successive portions of air, of which every particle carries away its own charge of electricity.
3. The deposition of moisture upon the surface of an insulating body, tending to increase its conducting power.

(65.) With regard to the first of these causes, it would appear that there is no such thing in nature as a perfectly insulating body, that is to say, there is no substance known of which any portion, however small, will insulate any electricity however great its intensity. The proof of this is abundantly simple; for if a small cylinder of any substance be taken from among conductingsubstances, the one a conductor, and the other a non-conductor, placed in vacuo; the non-conductor retains its electricity to a practical purpose involving some calculation, and presupposes a knowledge of the exact laws of electrical action, we shall here present such a summary of his results as may be thought essential to the practical applications of our subject, and leave their strict investigation to the more powerful resources of theoretical electricity.

In attempting to avoid the first of these sources of electrical dissipation, M. Coulomb was very successful; for he found that within certain limits, and by adopting certain precautions, its effects became absolutely imperceptible. Thus when the charge of electricity communicated to the body was such as not to produce a high degree of repulsive intensity, a small cylinder of sealing-wax, or gum-lac, half a line in diameter, and eighteen or twenty lines in length, would be sufficient to insulate a pith ball of five or six lines in diameter. That complete insulation, as far as the support was concerned, had thus been obtained, was proved by this fact, that the gradual diminution of electrical intensity measured by repulsion was the same, whether one or more of these cylinders were employed for the support of the electrified ball.

By means of a very delicate torsion electrometer, Coulomb then examined the conjoint effects of the two remaining causes of electrical dissipation; he found that by carefully selecting such substances as were most unfavourable to the reception of moisture, and by employing cylinders, or rather filaments of small diameter, so that but little could be received upon their surfaces, he was enabled to reduce the dispersive action almost entirely to the second source of loss mentioned. The following are his general conclusions:
1. That in a given state of the atmosphere (according to barometric, thermometric, and hygrometric indications,) the dissipation in any given short time, varied directly as the repulsive intensity of the charge.
2. Hence, by ascertaining upon any day the rate of dissipation for any given intensity, the dissipation for any other intensity may be calculated from the above law.
3. Hence also, having given the initial intensity, and the law of dissipation ascertained by experiment, the repulsion, after any time elapsed, may be determined.

(67.) To this point Coulomb had arrived, employing balls of the same substance, and of the same magnitude for his experiments. He then proceeds to prove that the law is general for balls of different substances, pitch, copper, and wax, whatever be their magnitudes. An inquiry here obviously suggested itself, connected with the very different natures of these bodies. Does an insulated and electrified globe of wax, or any non-conductor, retain its electricity...
Electricity; that by which a copper ball, or one from among the conducting class, retains its electricity? Experiments seem to prove the contrary, and the inference which may be drawn from them is, that the air alone, by its pressure and non-conducting property, performs a very principal part at least in restraining the electric fluid from expanding itself in space and leaving the excited body.

From spherical bodies we are next led to consider the loss of electricity from substances of any regular or irregular figure; and it appears that all such cases are subject to laws identical with those already described. In making these experiments, however, there are some circumstances to be taken into the account, to which we have already adverted in speaking of the effect of points in dissipating electricity; for this reason it is necessary that in these experiments, electrical charges of very low intensity should be communicated to bodies with angular points or projecting surfaces.

A curious experiment connected with this part of our subject has been made by M. Biot. He wished to ascertain whether the dissipation was the same, with whichever of the electrical bodies the ball of the electrometer was charged; and he found that there was so little difference in the effect produced, as to lead him to infer, that with perfect accuracy of experiments, the loss would have been equal in each case.

(68.) In the next place, considering the law of dispersion ascertained for perfect insulators, it was easy to separate and determine the loss arising from imperfect insulation. It appeared that a ball, highly charged with electricity, and suspended by a silken thread, suffered a much more rapid dissipation than could be due to the effect of the air alone; but that the electricity arrived at length at a certain point of diminished intensity, such that the silk now insulated as perfectly as the gum-lac had before done, and the gradual loss became precisely such as might be accounted for, from the action of the air alone. It was proved, moreover, that the greater was the loss from the state of the atmosphere, the greater also was the increase of the loss from the imperfection of the insulation.

(69.) Of the ordinary atmospheric changes; those which have the most intimate connection with the presence of moisture, seem, as might have been expected, to produce the most material effects upon the dissipation of electricity; but Coulomb's most careful investigations did not lead him to place confidence in even the united indications afforded by the barometer, thermometer, and hygrometer, for producing a law of electrical dissipation, which could be accurately expressed in terms of these elements. It appeared, in fact, that some time must always elapse, before these instruments exhibited the true state of the air with reference to the power of electrical dissipation. Hence, on different days, when these three instruments seemed to indicate the same state of the atmosphere, the quantities of electricity lost in a given time would not be the same. It appeared that on a sudden change of weather, by which the hygrometer indicated increased dryness in the atmosphere, the quantity of electricity lost in a given time was not diminished so much as, from calculation, it ought to have been. M. Coulomb attempted to account for this on the supposition that there is an adhesion between the air and the vapour, which interferes with the operation of the hygrometer; so that the material by which in this instrument the indications are obtained, can only be affected by that portion of moisture which is entirely free from the aerial particles, and that as these are only gradually separated, the dissipation of electricity being the more subtle agent, is assisted by certain particles of aqueous vapour remaining in combination with the air, but of which the hygrometer is not sensible.

§ III. Distribution, or local arrangement, of electricity.

(70.) Does electricity reside only at the surface of conducting bodies, or is it expanded throughout the whole of their substance? This important question did not escape the penetration of some of the early experimentalists upon the subject before us. Watson showed that the electric fluid did not pass along the exterior surface of a metallic rod; for he found that an entire coating of wax did not in the least impede the transmission of any charge, large or small, through the conductor. Experiments to the same purpose were made about the same time (1746) by M. le Monnier. By considering the equal division of electricity, which takes place between two bodies of equal surface and similar form, whatsoever be their nature, as proved by an experiment of Coulomb, and that the same takes place if one body be a solid, and the other the thinnest possible shell of matter, we may justly be led to suppose, that all the electricity which any excited body is capable of retaining, resides somewhere in the region of the exterior surface of the body. Thus far, however, M. Achard had arrived in 1780. (Mém. Acad. Berl.)

(71.) The following experiment contains an elegant practical demonstration of this truth. Let S, in fig. 46, represent any spheroid of conducting matter, suspended by a thread of some perfectly insulating substance. Let EE be two caps formed of gilt-paper, tin-foil, or any conductor, and such that when united they accurately fit the surface of the spheroid. An insulating handle of gum-lac is also affixed to each of the caps. Now let there be communicated to the ball S any degree of electricity, and then carefully apply to its surface the two caps, holding them by their cylinders of gum-lac. Upon the removal of the caps, it will be found that every particle of electricity has been abstracted from the spheroid, so that it will no longer affect the most delicate electrometer; whilst the two caps will be found, upon accurate trial, to have acquired precisely the same quantity of electricity which formerly resided upon the body S.

(72.) A proof of the same position, by M. Coulomb, is, however, more general, insomuch as it is applicable to bodies of every possible form. The general outline of the experiment is as follows: By means of the torsion electrometer, and the proof plane which we have already cursorily described, Coulomb was able to measure the quantity or intensity of the electricity conveyed away by the proof plane from any point in an electrified body; and the quantity thus removed was proportioned to the quantity of fluid distributed to the point at which the contact had taken place. Having prepared the substance upon which he proposed to examine the distribution of the fluid, by perforating it with several holes, reaching to
ELECTRICITY.

Practical different depths, and being able by means of the proof plane to convey away charges of fluid from the bottom or sides of these holes, if any there existed, he found that the whole charge of electricity was arranged round the outer surface of the body, and that not a particle of electricity was to be discovered at the bottom or sides of any of these holes.

(73.) We borrow from M. Biot the following very elegant experiment, exhibiting the effect of increasing the surface over which a given quantity of electricity is distributed. A B, fig. 47, is an insulated cylinder, movable round an horizontal axis, and capable of being turned by an insulating handle M. Around the cylinder is coiled a thin lamina of any metal R, the end of which is semicircular, and has attached to it a silk thread F. The metal and cylinder communicate with an electroscope formed of two linen threads f f, to the extremities of which two pith balls are attached. On communicating to the metallic riband a charge of electricity, the balls and the threads diverge. Upon taking hold of the silk thread, and unrolling the metallic riband from the cylinder, the pith balls gradually collapse, and thus indicate a diminution in the intensity of electrical repulsion; and if the riband be sufficiently long, the electrical charge may be spread over so great an extent of surface, as to allow the balls entirely to collapse; but on winding up the riband again, the intensity is restored and the balls diverge to the same extent as before, allowing only for the small dissipation of electricity which may have been produced by the contact of the air during the experiment.

(74.) On the whole, then, it appears that electricity does not reside upon the exterior surface of an excited conductor, but that it is in reality within the substance of the body, but extending to a depth so slight, as to be inappreciable by any known methods of experiment.

(75.) The next point to be ascertained, relates to the intensity of electricity disposed around the surfaces of bodies of different forms; or supposing (if not in reality, at least for the sake of illustration,) that the fluid is disposed as a stratum of some material substance, to find the relative thickness of that bed at different points. In the case of an electrified and insulated sphere, the intensity is found to be the same at every part of the surface. But in a cylinder, or bar, the electrical intensity is much greater at the ends than at the middle, and the ratio of this inequality of distribution increases very rapidly in proportion to the dimension of the diameter of a bar of given length.

(76.) A few other cases of electrical distribution may here be mentioned as facts, the rationale and demonstration of which it must be left for our theory to explain. Two spheres of conducting matter being placed in contact, and charged with either electricity, the fluid will be distributed between them, and repose at their surfaces in the following manner: At their point of contact there will be no free electricity, but the bed of fluid will increase in thickness from this point over each of their surfaces according to a law, depending upon the ratios of their respective diameters, and will arrive at its maximum thickness on each sphere at the point diametrically opposite to that of contact. The maximum thickness of the bed upon the smaller sphere, will be greater than the maximum thickness of the bed upon the larger sphere. After the distant separation of the spheres, each will retain the electricity it possessed during the contact, and the quantity retained by each, and therefore the electrical charge which each will now have uniformly distributed over its surface, will be determinable also by the ratio existing between the radii of the spheres. The smaller will evidently retain a charge of greater intensity; because the actual quantity upon its whole superficies, though less than the quantity upon the superficies of the larger globe, is disposed over a much smaller surface.

The facts which have now been recited concerning the distribution of electricity upon two spheres which have been in contact, are true only when they are removed to such a distance from each other, as to preclude all mutual influence, a subject which we shall not be able to investigate, until a further acquaintance with the principles of electrical induction.

Upon a comparison of the quantitative distribution of electricity between an excited globe and a circular disc placed in contact, M. Coulomb found that this distribution was in the direct ratio of the entire surfaces of the two bodies.

(77.) It follows from these observations, that we may represent the arrangement of electricity upon an insulated metal sphere by the diagram fig. 48. In this case the figure is in one respect designedly incorrect, because the dotted line which is supposed to represent the exterior surface of the stratum of fluid, is without the sphere, when, in fact, to produce a true representation of the case, it ought to coincide with the surface; but we shall find this a necessary evil in order to make the electrical distribution and tension, which is produced in bodies of other forms, the more intelligible. We suppose then a line p, perpendicular to the surface of the sphere at any point, to measure the thickness of the bed of fluid, and therefore to be, according to some ratio, a representation of the electrical intensity at that point. In a similar manner, fig. 49, may be taken as a representation of the quantitative distribution of electricity at different parts of the insulated and electrified bar A B. The series of ordinates drawn from the bar to the points m n o p q, may be supposed to represent the thickness of the electrical stratum at these points respectively; and from a series of such ordinates, we may obtain the dotted line m n o p q, to give a general representation of the distribution of the electricity upon the bar.

Now it has been proved that the pressure exerted by electricity, which we may term the electrical reaction, against the air, varies as the square of the thickness of the electrical stratum; and therefore the squares of all these ordinates may represent the electric tension at these points respectively. By an application of this reasoning to the action of a point, we shall readily account for the powerful dispersion of electricity which we have before mentioned as taking place from all bodies of that form. In fig. 50, let C be the extremity of the electrified prime conductor of a machine; D a metallic point communicating with the conductor. On the principles we have laid down, the dotted line n o p, will give some idea of the distribution of the fluid; and the perpendicular line P p may be supposed to represent the thickness of the stratum of fluid accumulated at the extreme point P. Supposing this point P perfectly acute, the form
of the curve $n o p$, will depend principally upon the general form of the conductor, and the quantity of electricity communicated to it. Now the resistance of the air which is the force opposing the dispersion of electricity from conducting surfaces of all kinds, varies with its density, its hygrometric state, and probably its temperature. Hence for every degree of atmospheric resistance, there is some intensity of electrical repulsion proportioned to the square of the line $F p$, by which this resistance may be overcome, and the electricity may disperse itself into the surrounding atmosphere. And it is found by experience, that in the ordinary state of the atmosphere, it does not require any very great quantity of electricity to be imparted to a conductor for the production of this effect with a point of moderate acuteness.

The following experiments, in addition to some that have been adduced under the head of electrical light, are illustrative of this species of action.

(76.) Exp. Affix to the prime conductor of a machine, a pair of pith balls suspended by a fine silver wire, as described in art. 16, and let the conductor be charged with either electricity, the pith balls manifest the presence of this electricity by their divergence. If now we hold a pointed metal rod in the hand, presenting the point near to the conducting cylinder, but without touching it, the electrical charge is rapidly withdrawn, and the balls collapse. This experiment is rendered more striking, by repeating it with a rod having a large ball at the end, instead of the point, taking care that no spark pass from the conductor to the ball. In this case the divergence of the wires continues for a much longer time; therefore the metal ball has not absorbed the electricity with the rapidity that the points produced in the conductor to the ball. In this case the divergency of the wires continues for a much longer time; there the metal ball has not absorbed the electricity, and the electricity may disperse itself into the surrounding atmosphere. Hence in all cases, points and angular bodies absorb and emit the electric fluid, with much greater rapidity than those bodies which have obtuse or plane surfaces.

(78.) Exp. Let two cross wires $A B$, $C D$, fig. 51, be supported by means of a cap $H$ upon a fine point at the top of an insulating stand, and made to communicate by a chain with the electrified conductor of a machine. Let each of the four arms terminate in a point bent in a similar direction with regard to the axis, as the figure represents. Each of these points will give off a current of electricity, which from the reaction of the resisting medium the air, will cause the system of points to revolve backwards with considerable rapidity.

(82.) Exp. Fig. 53 is a representation of an elegant electrical little experiment depending upon the same principle. Two wires $A B$, $C D$ are stretched in the direction of a plane slightly inclined to the horizon, between four insulating pillars. Across these wires another wire is made to rest, having a cross wire at right angles to it with two bent points, as in the former experiment. This system is electrified by forming a communication with the prime conductor by means of a chain, as seen at $A$; and by the revolution of the bars, dependant upon the dispersion of electricity from the points, the transverse wire is made to roll up the inclined plane.

(80.) Exp. Fig. 52 is a representation of an elegant electrical experiment concave surface of which rests upon a fine point 0tery. From the sphere $A$, an arm is extended, which carries upon a point at its extremity a smaller ball $B$, with a wire passing through it, which wire bears at one end another small fixed globe, and at the opposite end a bent point. There is also affixed to the arm passing from $A$ to $B$, a point $D$ extended in the plane of the horizon. Let electricity be communicated to this system by a chain as before. The dispersion of electricity from the point $D$, will cause the ball $B$ to revolve round $A$; while at the same time the dispersion from the point, at the extremity of the rod $C B$, causes the ball $C$ to revolve round $B$. This then, supposing $A$ to represent the sun, $B$ the earth, and $C$ the moon, is called the electrical orery.

CHAPTER IV.

As far as we have hitherto proceeded in investigating the principles of the science before us, we have spoken of electricity developed by mechanical friction, and have given a pledge, that we will hereafter lay before our readers the other known sources of electrical excitation; but as a considerable proportion of important electrical apparatus depends upon the excitement caused by induction or influence, we devote the present chapter to an examination of this most interesting branch of our subject.

(81.) Exp. In fig. 53 $A$ is a metal sphere, the interior concave surface of which rests upon a fine point orery. A cross these wires another wire is made to rest, having a cross wire at right angles to it with two bent points, as in the former experiment. This system is electrified by forming a communication with the prime conductor by means of a chain as before. The dispersion of electricity from the points, the transverse wire is made to roll up the inclined plane.

(82.) Exp. Fig. 53 is a representation of an elegant electrical little experiment depending upon the same principle. Two wires $A B$, $C D$ are stretched in the direction of a plane slightly inclined to the horizon, between four insulating pillars. Across these wires another wire is made to rest, having a cross wire at right angles to it with two bent points, as in the former experiment. This system is electrified by forming a communication with the prime conductor by means of a chain, as seen at $A$; and by the revolution of the bars, dependant upon the dispersion of electricity from the points, the transverse wire is made to roll up the inclined plane.

(80.) Exp. Fig. 52 is a representation of an elegant electrical experiment concave surface of which rests upon a fine point 0tery. From the sphere $A$, an arm is extended, which carries upon a point at its extremity a smaller ball $B$, with a wire passing through it, which wire bears at one end another small fixed globe, and at the opposite end a bent point. There is also affixed to the arm passing from $A$ to $B$, a point $D$ extended in the plane of the horizon. Let electricity be communicated to this system by a chain as before. The dispersion of electricity from the point $D$, will cause the ball $B$ to revolve round $A$; while at the same time the dispersion from the point, at the extremity of the rod $C B$, causes the ball $C$ to revolve round $B$. This then, supposing $A$ to represent the sun, $B$ the earth, and $C$ the moon, is called the electrical orery.

See also Cavallo's and Singer's Electricity; Coulomb, Mém. Acad. Paris, 1784, 1785, 1786, 1787, and 1788; Biot, Physique; Libes, Physique; Fischer, Physique.
different parts of its length, the ball will be attracted in all positions, the neutral point before mentioned alone excepted.

5. But if the pith ball be previously electrified, it will be attracted by one end of the cylinder, and repelled by the other end, showing that the two extremities of the conductor are charged with the opposite electricity.

6. In fact, if we touch the two extremities of the cylinder, successively, with a small insulated conducting body, such as the proof plane, and examine the nature of the electricity which is removed at each contact, we shall find that at the extremity of the conductor nearest to the electrified body A, the electricity is of the kind opposite to that of A, while that at the other end of the conductor is identical with it.

7. If the cylinder be removed to a distance from the electrified body A, or if we remove the electricity of this body by touching it, all signs of excitement in the conductor immediately cease.

8. In this experiment, as far as the first six results are concerned, the body A, primarily electrified, loses nothing by the influence which it exerts. No part of its own electricity is transmitted to the cylinder, for if (by Coulomb's method) the intensity of its electrical excitement be measured, before and after the experiment, it will be found to have undergone no diminution, save that which is necessarily occasioned by the ordinary dissipation due to the contact of the air.

9. This uniformity of condition exists only when the body A is free from the influence of the insulated cylinder; for as long as the cylinder is near to the electrified body (this body being of conducting matter) the electrical intensity upon its surface is different, as may be proved by experiment.

10. If, without touching the electrified body, we remove the conducting cylinder to a distance, and again bring it back several times alternately, the phenomena described appear and disappear without undergoing any alteration.

(83.) From the enunciation of these results, the following consequences are deducible.

1. Since the cylinder abstracts nothing from the electrified body, it follows that the two electrical principles are contained within its own substance, and are developed by the influence of the excited body.

2. Since the two electricity disappear as soon as the influence of the foreign body ceases, although these electricity are prevented by the insulation from escaping to the earth; it follows that their respective proportions are such that when left to themselves, they produce mutual saturation. 3. Lastly, that saturation is effected without their absolute destruction, because they reappear as often as the cylinder is subjected to the influence of the foreign electrified body.

Thus are we led to the recognition of this fact, that the principles of the two electricity exist naturally in all conducting bodies, in such a state of combination as to produce mutual neutralization. This then is what we call the natural state of bodies.

8. We perceive that friction which appears a method of calling the electricity into existence, is only a process by which they are disengaged from their state of natural combination, the presence of either one then being rendered apparent upon the absorption of the other. Hence it is, doubtless, that we constantly observe that the substance rubbing, and the substance rubbed, manifest the opposite electrical states. In short, since the mere influence of an electrified body, presented at a distance, compels these two electricity to separate from each other, and to distribute themselves so that those of a dissimilar nature should be nearest to each other, and those of the same nature removed furthest from each other; to enunciate this fact, we must admit that the electricity of the opposite kind attract each other, and the electricity of the same kind repel each other, according to some certain laws which it is the province of the experimentalist to investigate.

There is, however, one phenomenon which may require further consideration. We remarked in the experiment last recited, that the electrical intensity of the body A underwent some change, which change was permanent only so long as the cylinder was presented to it. Now as the free electricity at the surface of any body acts at a distance upon the latent electricity of any other body, and destroys in part, at least, their combination, it is evident that these once set free, ought in their turn, to act upon the body which has set them free, and change the electrical intensity of all points in its surface, either by constraining the free electricity which is found there to assume some new distribution, or by adding to this electricity that which the body may furnish from the decomposition of its natural latent electricity, or, lastly, by producing both these effects simultaneously.

Further, the decomposition of the combined electricity in this case, is indispensably necessary to the production of attraction, for the attraction is diminished in proportion to the difficulty of this decomposition; and if the one be impossible, the other will cease altogether. To be convinced of this fact, take two silken threads of equal length, and affix to them two small spheres of equal magnitude, the one of pure gum-lac, and the other of a body coated by a surface of gold-leaf. Let these two suspended balls be placed side by side and near to each other, and bring near to them an excited glass tube or stick of wax. It will be seen that the ball having a metallic surface, upon which the decomposition of the combined electricity is easily effected, will be much more readily and forcibly attracted than the other. Upon the ball of pure gum-lac the effects only commence after a certain time, by the decomposition produced at its surface, and its electrificated state continues even after the excited body has been removed. The first ball, although the ball neuter, contracts also, by this process, a slight degree of permanent electricity, because the resin of which it is composed, becomes impregnated with that electricity which was developed at its surface; and both balls are assisted in this process by the action of the air, which tends to deprive them of that one of their combined electricity which is repelled from the primarily excited body, the action of the air being less upon the other electricity, which is, in a great measure, rendered latent by the presence of the extraneous fluid, which, by its approach, effected the decomposition. Hence it is a general remark, that insulated bodies which have been exposed for some time to the influence of
an excited body, finally possess an excess of electricity, opposite in kind to that of the body, and this effect becomes apparent immediately upon the removal of the electrified mass.

(84.) As the results at which we have now arrived will form the constant subject of future application, it may be convenient to reduce them to a sort of theorem, under the following enunciation.

When an insulated conducting body B, fig. 55, in its natural state, is brought near to another insulated and electrified body A, the electricity distributed upon the surface of A, acts by induction upon the two latent and combined electricities of B, decomposing a certain quantity of them, proportional to the intensity of its action, and educing by this resolution the two constituent principles. Of these two electricities thus set free, it repels that of the same kind, and attracts that which is opposite in kind. The former is impelled to that part of the surface of B which is most distant from A, and the latter is brought to the side nearest to A. These two electricities, thus liberated, react upon the free electricity of A, and also upon its combined electricity, producing a further decomposition, especially if A be formed of conducting matter. This new separation brings with it a further decomposition of the combined electricity of B, and so on until the quantities of each elementary principle liberated upon the two bodies, shall be in equilibrium by the just balance of all the attractive and repulsive forces which they exert upon each other, by virtue of their identical or opposite natures. To calculate the law of distribution which will fulfill these conditions, will be the business of the second or mathematical part of this article.

For the present let us suppose this equilibrium established, and that we may continue our observations upon the resulting phenomena, let us return to the same arrangement of our apparatus represented in fig. 55. Further, in order to abridge the enunciation of facts, let us suppose that the electricity primarily imparted to A is vitreous. Then, if the conductor B have a resistance which tends to obstruct any further communication of the vitreous electricity of A relieved from its combined electricity of the earth, all the vitreous electricity accumulated at that extremity is shared with the immense mass of the globe, and its electrical reaction becomes insensible; or, as may also be said, it decomposes the combined electricity of the earth, attracts resinous electricity by which it is neutralized, and repels the corresponding vitreous electricity which becomes distributed over the surface of the terrestrial sphere. In whatsoever manner we may conceive the matter, there is no longer any free vitreous electricity at V; therefore the vitreous electricity of A relieved from the influence of B, and so on until the attraction of A for R shall be completely satisfied. These decompositions, however, which in our reasoning we have supposed to take place in succession, that their progress might be more apparent, are produced instantaneously in metallic bodies, which may be considered as endowed with perfect conducting power, and it is from this cause that a single contact is sufficient to produce the complete effect. From what has been already said, we may readily comprehend why B, when removed beyond the influence of A, manifests a superabundance of resinous electricity, and why that excess is greater in the present than in the preceding case.

The experiments hitherto recited have all tended to demonstrate the action of the body A upon the conductor B; but the reaction of B upon A may also be made the subject of experiment, and with perfect confirmation of the results already obtained. The experiments upon B may also be varied by communicating to it at first a feeble charge of resinous electricity, and a series of actions will be manifested by
For the purpose of giving a definite form and name are united to each other by their force of combination. For the purpose of giving a definite form and name are united to each other by their force of combination. For the purpose of giving a definite form and name are united to each other by their force of combination. For the purpose of giving a definite form and name are united to each other by their force of combination. For the purpose of giving a definite form and name are united to each other by their force of combination.

Suspended balls, and allow of a short contact between act as well upon it through the substance of the glass.

That the one plate has received a vitreous and the other nish also, and the suspended ball gradually lowers itseh forwards itself to the vertical line, and at last, when the faces are in contact, the system of discs acts only upon the ball, as any other body in a natural state does; but by again separating the discs, the ball may be made to elevate itself again as before. These two electricities, thus neutralized by their mutual contact (or at least very great proximity,) represent to us precisely the state of the combined electricities; with this difference only, that in conducting bodies they are united to each other by their force of combination alone, and may be set at liberty by the distant influence of either free electricity; instead of which, in the discs before us, each electricity is detained by the non-conducting power which the glass opposes to the freedom of its motion. For this reason the experiment now described will succeed equally with discs of gum-lac, or of sealing-wax, or even with one disc of such a substance, and one disc of metal; but it cannot succeed with two metallic discs, because in this case no resistance is offered to the motions of the electricities which are disengaged by friction, and consequently they reunite again as fast as the friction produces their momentary separation.

The following is an experimental proof of this proposition: Take two discs of smooth glass with plane surfaces; fragments of a glass mirror are well adapted to the purpose. Let A B, C D, fig. 56, represent these discs, each being four inches in diameter, and both affixed to insulating glass handles M and N; let there be also a pith ball suspended by a filament of untwisted silk. Rub the discs against each other, holding them by their insulating handles, and, without separating them, present them together to the suspended ball, no attraction is produced; but separate the plates from each other, and each, when presented to the ball, will now attract it. They have then both become electrified by the friction, and by presenting each in turn to another suspended ball charged with either known electricity, it will be found that the one plate has received a vitreous and the other a resinous charge. These electricities, however, do not manifest themselves when the discs are in contact, because as they reside upon the two surfaces which touch each other, the distance of all their points, from the electrical pendulum, is absolutely the same; and thus the opposite actions which they exert, tending to separate the combined electricities of the small ball are equal, so that the total result of their action is nothing. We may even modify the experiment so that this compensation shall be exhibited in its progressive state. For this purpose, after having separated the discs, we present the surface that has been rubbed, belonging to either of the planes, to the suspended ball, and allow of a short contact between the bodies. As soon as the ball has absorbed that small quantity of electricity which suffices for its volume, it becomes repelled and separates. Continue it in this state of repulsion by presenting it to the opposite face of the disc, fig. 57; for the electricity will act as well upon it through the substance of the glass.

Next, let the second disc gradually approach the former, so as to place their electrified surfaces again in contact. In proportion as the distance between the faces diminishes, the repulsive force is found to diminish also, and the suspended ball gradually lowers itself towards the vertical line, and at last, when the faces are in contact, the system of discs acts only upon the ball, as any other body in a natural state does; but by again separating the discs, the ball may be made to elevate itself again as before. These two electricities, thus neutralized by their mutual contact (or at least very great proximity,) represent to us precisely the state of the combined electricities; with this difference only, that in conducting bodies they are united to each other by their force of combination alone, and may be set at liberty by the distant influence of either free electricity; instead of which, in the discs before us, each electricity is detained by the non-conducting power which the glass opposes to the freedom of its motion. For this reason the experiment now described will succeed equally with discs of gum-lac, or of sealing-wax, or even with one disc of such a substance, and one disc of metal; but it cannot succeed with two metallic discs, because in this case no resistance is offered to the motions of the electricities which are disengaged by friction, and consequently they reunite again as fast as the friction produces their momentary separation.

The following is an experimental proof of this proposition: Take two discs of smooth glass with plane surfaces; fragments of a glass mirror are well adapted to the purpose. Let A B, C D, fig. 56, represent these discs, each being four inches in diameter, and both affixed to insulating glass handles M and N; let there be also a pith ball suspended by a filament of untwisted silk. Rub the discs against each other, holding them by their insulating handles, and, without separating them, present them together to the suspended ball, no attraction is produced; but separate the plates from each other, and each, when presented to the ball, will now attract it. They have then both become electrified by the friction, and by presenting each in turn to another suspended ball charged with either known electricity, it will be found that the one plate has received a vitreous and the other a resinous charge. These electricities, however, do not manifest themselves when the discs are in contact, because as they reside upon the two surfaces which touch each other, the distance of all their points, from the electrical pendulum, is absolutely the same; and thus the opposite actions which they exert, tending to separate the combined electricities of the small ball are equal, so that the total result of their action is nothing. We may even modify the experiment so that this compensation shall be exhibited in its progressive state. For this purpose, after having separated the discs, we present the surface that has been rubbed, belonging to either of the planes, to the suspended ball, and allow of a short contact between the bodies. As soon as the ball has absorbed that small quantity of electricity which suffices for its volume, it becomes repelled and separates. Continue it in this state of repulsion by presenting it to the opposite face of the disc, fig. 57; for the electricity will act as well upon it through the substance of the glass.
attractions and repulsions, is that of the inverse square of the distance. The mutual actions of the two fluids has also been strongly exemplified in the recent paragraphs of our article, wherein all the phenomena of influenced or induced electricity are laid open.

Our general proposition may then be thus enunciated. Each of the two electrical principles has the properties of a fluid; the molecules of which enjoy perfect mobility, are mutually repulsive of each other, and attractive of those of the other fluid, with forces varying according to the inverse square of the distance. And at equal distances the attractive and repulsive forces are equal to each other.

It is not contended that the experiments hitherto advanced, will prove the whole of these propositions with perfect accuracy, but it is necessary thus to collect and arrange the conclusions to which these experiments justly lead; in order that we may have some definite system, upon which our future explanations may be founded; and it is but by a slight anticipation that we have taken in the whole of these essential elements of our law, since in a future division of this treatise, devoted to theory alone, every branch of our proposition, which yet requires such support, will be brought forward with rigid mathematical demonstration.

Our general proposition may then be thus enunciated. Each of the two electrical principles has the properties of a fluid; the molecules of which enjoy perfect mobility, are mutually repulsive of each other, and attractive of those of the other fluid, with forces varying according to the inverse square of the distance. And at equal distances the attractive and repulsive forces are equal to each other.

It is not contended that the experiments hitherto advanced, will prove the whole of these propositions with perfect accuracy, but it is necessary thus to collect and arrange the conclusions to which these experiments justly lead; in order that we may have some definite system, upon which our future explanations may be founded; and it is but by a slight anticipation that we have taken in the whole of these essential elements of our law, since in a future division of this treatise, devoted to theory alone, every branch of our proposition, which yet requires such support, will be brought forward with rigid mathematical demonstration.

The hypothesis of two fluid has now, doubtless, the greater number of partisans; but in justice to those who have embraced, and who still adhere to the views of Franklin, we will endeavour to present a short abstract of his theory.

The hypothesis of two fluids has now, doubtless, the greater number of partisans; but in justice to those who have embraced, and who still adhere to the views of Franklin, we will endeavour to present a short abstract of his theory.

(87.) For the sake of consistency, we have throughout this article adhered to a system of explanation founded upon the hypothesis of Symmer, respecting the nature and action of the two fluids originally discovered by Du Fay, enriched and confirmed as this theory has been by the researches and discoveries of later years. In the historical introduction prefixed to this article, we have stated our reasons for assigning the merit of this hypothesis to Mr. Symmer; and although in an article like the present, which can only be considered an outline of electrical science, we feel bound not to become warm partisans of any particular hypothesis, because our limits will scarcely permit us to examine those difficulties which attend every view of the subject; yet we must confess that between the theory of one fluid proposed by Franklin, and the supposition of two coexistent fluids as advanced by Symmer, the advantage appears to us greatly on the side of the latter.

The hypothesis of two fluids has now, doubtless, the greater number of partisans; but in justice to those who have embraced, and who still adhere to the views of Franklin, we will endeavour to present a short abstract of his theory.

(88.) In this theory only one electric fluid is supposed to exist. It is considered to be material and to possess the properties of an elastic fluid. It is also supposed to attract and to be attracted by all other matter.

The attractions of different substances, for the electric fluid are different, as also those of the same substance in different states, and under different circumstances; so that the quantity of electricity naturally existing in given quantities of different substances may be unequal; and the same body may, under the circumstances of its combination with other matter, attract more or less than when alone; but its original attraction will be restored by destroying the artificial combination.

When the attraction of any substance for electricity is equal to the quantity of electric fluid it contains, that substance exhibits none of the phenomena of excitation; but these are immediately produced when there is either more or less electric fluid than is adequate to the saturation of the existing attraction. If there be more, the electrical signs will be positive, (vitreous,) if less they will be negative, (resinous.)

"Electrical excitation may then be thus effected: the bodies employed have each a certain quantity of the electrical fluid, proportionate to their natural attraction for it, this they retain, and appear unelectrified, so long as they remain in their natural state. Now if two such bodies are brought in contact, their natural attractions are altered, one of them attracts more than in its separate state, and the other less; the electrical fluid diffuses itself amongst them in quantities proportionate to their relative attractions, and they consequently appear unelectrified. But if they are suddenly separated, the new distribution of the electrical fluid remains, whilst the original attractions are restored, and as these are not equal to each other, the bodies will appear electrical: that whose natural attraction was increased by contact, having received an addition to its quantity of electric fluid, will be positively electrified; and that whose attraction was lessened, having lost a portion, will be negative.

"Take, as an instance, the electrical machine: let the attraction of the cushion for the electric fluid be represented by 20, and that of a similar surface of glass by 30, the sum is 50. Bring the bodies in contact, their attractions alter; that of the glass becomes 40, and that of the cushion is reduced to 10, the sum of these is still 50; the natural electricity therefore, though unequally distributed, is still equal to the sum of the attractions, and does not appear; for the cause of its unequal distribution, (the contact,) is still active. Separate the glass from the cushion, its original attraction of 30 will now only operate, but it has acquired 40 of electricity by contact with the cushion; the glass is therefore positive with a force equal to 10. The cushion will now also have its original attraction of 20, but its electricity amounts only to 10; it is, therefore, negative with a force equal to 10. And here is seen the reason why positive and negative bodies act more powerfully on each other than on indifferent matter, for their mutual difference is often twice as great as their individual; since if the latter be 10, the former may be 20.

"The effects now described continually recur during the revolutions of the cylinder, every part of which is successively brought in contact with the cushion, and passes forward with the electricity it thus progressively acquires. The silk flap may be considered as a continuation of the rubber, which, by partially maintaining the altered attraction of the glass, counteracts the tendency of the acquired electricity to pass back into the cushion. The surface of the glass where it passes from beneath the silk flap has not this compensation; hence the acquired electricity is there uncombined, and has a tendency to diffuse itself amongst the surrounding bodies: the conductor, with its row of points, is the nearest reservoir, and into this it passes, and the conductor becomes thereby positively electrified. During this process the cushion and its attached conductor constantly furnish electricity to the glass, and they are consequently negative in the same degree; but they have only a limited surface, and a certain quantity of natural electricity, and,
ELECTRICITY.

Practical if perfectly insulated, can furnish only a definite positive conclusion; but if they are connected with the ground, whose surface is comparatively unlimited, they operate upon an extensive store, to the supply of which there appears no assignable bound. It is for this reason that the electricity of either conductor separately, is more apparent when the opposite one is uninsulated.

Singer, Electricity, p. 61.

The above outline of the hypothesis of Franklin is not precisely in the state in which it was left by its illustrious proposer; neither can we be certain that all those who contend for the existence of but one electric fluid would subscribe to every part of the doctrine thus laid down, but we have considered that it would be the fairest course, and one in which we should be least liable to the accusation of partiality, to bring forward these passages as the most recent explanation with which we are acquainted of the opinions of an author on this side of the question. As far as the hypothesis is required to explain all the common phenomena of electricity, such as the attractions of bodies, and the charges communicated to jars and batteries, either of these two celebrated theories will be found sufficient; but we confess it does not appear to us that Franklin's hypothesis is adequate to the satisfactory explanation of several of the phenomena of influential or induced electricity.

The following, whatever they may prove, are experiments of great beauty, and therefore claim a place in that which was positive rendered negative, the electricity of which was before negative shall become positive, and whose surface is comparatively unlimited, they operate

Electricity. The following, whatever they may prove, are experiments of great beauty, and therefore claim a place in that which was positive rendered negative, the electricity of which was before negative shall become positive, and

upon each other, sensible at great distances, like the heavenly bodies, and thus the supposition of any such repulsion is contrary to the ordinary phenomena of nature. It is true that in the hands of Franklin his principle was sufficient to account for all the experimental phenomena known in his time; but when Æpinus had undertaken an accurate mathematical investigation of all the phenomena in ques-

Experimental proofs.

...
Applica-

tion, he perceived the necessity of calling in the aid of this supposed repulsive force, to make his demonstra-
tions accord with the facts he intended them to elucidate.

Opposed as this condition is to the acknowledged nature of things, if we were to admit it solely for the sake of connecting together electrical phenomena, we might arrive at a conception of their dependence, and even be enabled to foretell their appearances; not indeed in quantities and numbers, but under those general conditions which depend upon a displacement of the one electricity. Thus, for example, we might explain the attractions, the repulsions, of electrified bodies; and even the development of electrical properties from bodies in their natural state by the distant influence of another electrified body. But it does not appear that it would be possible to explain in the same manner why, conducting bodies acting by attraction upon the molecules of the electric fluid, the electricity should divide itself between their surfaces according to certain ratios, entirely independent of their chemical composition, and determined only by their dimensions as we find to be the case; nor yet why the negative state, which is accord-
ing to this system only a privation, an absence of electricity, should ever be developed alone at the sur-
face of these bodies, and establish itself at each point of that surface, according to the rigorous hydrostatic laws which a real fluid would follow, if all its mole-
cules were mutually repulsive of each other, accord-
ing to the inverse square of their distances. Still less could we, upon this hypothesis, foresee or explain why, when two unequal spheres of conducting matter are removed from contact, there should be developed around the point of contact, and always upon the smaller, signs of an electrical state contrary to that of the total mass, be it positive or negative; while, on the other hand, the necessity for this development, its limits, and its constancy upon the smaller sphere may be foreseen with the greatest ease, upon the theory of two fluids; nay, may even be calculated in all its most minute particulars with a surprising degree of exactness. (See part ii. of this Treatise.)

(93.) Let us now proceed to apply this hypothesis of two fluids, in explanation of those effects which our experiments already laid before us. As it is found possible to obtain electricity in some way or other, from all bodies that can be properly submitted to experiment, we are led to infer that it is an universal property of matter. We suppose that in every particle of matter a portion of each electricity naturally resides. That in the ordinary state of that particle there is an equal quantity of each fluid present, produ-
cing mutual saturation; and that therefore when we say no electricity is present in a body, we mean that there is no free electricity that can be recognised by its effects or properties. Suppose now that we can by some means effect the decomposition of this natural electricity, and that we can remove one of the kinds from the particle, it is evident then that the remaining electricity being no longer saturated, is called into a state of activity, and exerts the proper-
ties that are natural to it.

In the ordinary electrical machine we may at any instant suppose the development of electricity to take place by the mutual friction of the rubber, and an equal surface of the cylinder, or plate. The vitreous electricity will be carried forward with the cylinder, to the surface of which it is confined by the oil silk, and if there were no conductor to receive it, a part would be dissipated in the surrounding air, and a part would return again upon the glass to the cushion. At the same time the rubber receives or retains the resinous electricity set free by the decomposition, and if insulated soon acquires such a charge of this electricity that its repulsive intensity either prevents further decomposition, or drives off a quantity suffi-
cient in a great measure to again combine with and neutralize that vitreous electricity which is produced by the continued action of the machine. But if the rubber communicate with the earth, this excess of resinous electricity is shared with that body, and the effects on this side of the machine continue to go on as at the first instant of its action. A similar accumu-
lation of electricity upon the insulated prime con-
ductor, when it has become charged to its utmost possible extent, will on similar principles produce a similar diminution of the charge, or rather of the repulsive intensity of the electricity. Hence we arrive at the full explanation of the necessity for allowing the rubber to communicate freely with the

ground, when a considerable quantity or a constant supply of vitreous electricity is required at the prime con-
ductor; and vice versa.

(94.) The action of the prime conductor itself will also require some portion of our attention in applying the principles of the chapter before us. It is not to be considered as merely a receptacle or channel through which certain electricity which enters at the points is to proceed; but it, together with its system of points, may claim the merit of a more active species of service. At the edge of the silk flap we have clearly shown that there must be a torrent of electricity ready to escape to the nearest conductor which its own repulsive intensity will enable it to reach. This portion will then naturally make for the points, and be conveyed by direct transmission to the prime con-
ductor. But the accumulation of this electric mass at the edge of the silk cannot take place without also acting by induction upon the natural electricities of the conductor and its points; the electricity of which we now speak being vitreous, will attract towards the points of the prime conductor a portion of resinous electricity dependent in quantity upon the intensity of the action of the machine, and this intensity at so small a distance is very considerable, and the points are of all others the form most favourable for the emission of electricity, a portion of resinous electricity is constantly issuing from the conductor to com-
bine with the vitreous electricity arriving at the edge of the silk. The appearances presented by the points of an electrical machine in a darkened room, will afford a beautiful illustration of this system of effects.

(95.) In art. 51, we described the process for commu-

nicating either electricity to Hauy's electroscope, by employing the principles of induced electricity, and it is obvious that in a similar manner we may, with any excited body, communicate to any electro-
scope a charge consisting of either electricity at pleasure. Either we may impart by direct contact some portion of the electricity from the excited body, in which case the charge is similar; or we may by the distant influence of the excited body decompose the natural electricity of the electroscope; and having removed the similar electricity which is acted upon

ELECTRICITY.

Practical
Electricity.

(96.) It may almost be considered a superfluous

Electrical task to enter upon the subject of what the early

atmospheres; experimentalists termed electrical atmospheres; but as

the principles we have so recently brought forward

may almost be considered a superfluous effort to enter upon the subject of what the early experimentalists termed electrical atmospheres; but as the principles we have so recently brought forward will afford a ready explanation of this phenomenon, and as the subject does not appear to have been well understood, even in some recent treatises of great merit on electricity, we feel it incumbent upon us to devote a few lines to the elucidation of this subject.

The idea of the electric effluvium forming an atmosphere around an excited body, is perhaps to be traced among the theoretical views of the earliest practical electricians. The writings of Otto Guericke clearly contain a supposition of this kind, and the Florentine academicians attempted to submit the arrangement of this atmosphere to ocular inspection, by bringing a piece of excited amber near to a volume of smoke, so that the visible particles which constituted the smoke were attracted by the amber, and formed a stratum around the excited body, so long as its electrified state continued permanent.

Dr. Franklin improved upon this method, by placing heated iron plates under electrified conductors, and then scattering upon the plates small fragments of resin. The smoke as it rose from the plates arranged itself in visible strata around the electrified surfaces, presenting numerous beautiful appearances. These researches of Franklin were followed up by MM. Wilcke and Æpinus; and it is but due to this latter most acute electrician to remark, that as far as the explanation of all these phenomena depends upon electrical induction, he arrived at a just theory of the matter. Beccaria and Canton also published several curious memoirs on this subject. It was maintained by some that there actually existed an atmosphere of electricity surrounding the excited body; but Æpinus justly contended that the effects which appeared to indicate the presence of such an atmosphere were to be ascribed to electrical influence; and that the supposed extent of such an atmosphere was in fact only the sphere of action of the electricity arranged upon the excited body; but at the same time he made a correct view of some portion of error in supposing that the air is electrified throughout this sphere of influence, when in fact it is much more simple to leave the air (in this sense) out of the question, and to consider the particles of smoke only as so many small bodies, possessed of freedom of motion, and therefore attracted towards an electrified surface.

It would be an unprofitable task to enter upon a minute examination of M. Canton's views, which were in principle deduced from the explanations of Æpinus, but which contain also some erroneous opinions respecting the part performed by the air in the production of these phenomena. Canton found that two unelectrified pith balls placed within a small distance of an excited body, such as either a glass tube or a stick of wax, diverged, from having become charged with an electricity opposite to that of the excited body. And generally that any unelectrified substance placed within the electric atmosphere (sphere of action) of any excited body, obtained a charge of the dissimilar electricity. These facts admit of a ready explanation, upon the principles of electrical induction, and in taking leave of this subject we have only to remark that the views of M. Æpinus appear to have been much more philosophical and accurate than those of the preceding or contemporary experimentalists, in this field of research.

(97.) In considering the arrangement or distribution of the electric fluid upon conducting bodies in contact, (art. 76,) we were unwilling to pursue those investigations further at that time, from their intimate connection with the new distribution which takes place the instant that contact is destroyed; and it was impossible to enter upon that part of our task without a previous acquaintance with the phenomena of induced electricity. The faint outline which we propose now to give of these arrangements is imperiously called for by the numerous consequences deducible from them, and which must all be taken into account by the accurate practical electrician.

We are therefore for the present again confined to the enunciation of certain facts presented to us by experiment, which will require all the ingenuity of the most refined theory fully to account for.

If two spheres of equal magnitude, composed of conducting matter, be electrified and placed in contact, the free electricity will be equally divided between them; and it may be proved by delicate experiment that no free electricity resides at the point of contact; this also is conformable to theory. If now the two spheres be separated beyond the limit of the sensible influence of each other, the free electricity will be found of equal intensity upon each; or, in other words, the two spheres have during their contact divided the electricity equally between them. In the case of unequal spheres, it may also be proved by experiment, and accounted for by theory, that after their contact the total quantity of electricity carried off by the smaller sphere, is less than that which remains with the larger sphere; but according to a law depending upon the ratio of their diameters, such that the stratum of fluid retained upon the smaller sphere is of greater thickness than that upon the larger sphere.

Thus far we speak of the ultimate arrangement of the fluid, when the two bodies shall have been removed beyond the sphere of their mutual influence upon each other; but let us now take into account the effect of induction, and trace the progress of effects upon the spheres during their gradual recession from each other.

Let there be two unequal spheres, both vitreously electrified, of which fig. 60 may represent a vertical section. The bodies being so arranged that their centres may move along the same horizontal line; when the points A, a, are in contact the electricity is unequally divided between them, and arranged at their surfaces, but is absolutely nothing at this point of contact. At the instant of their separation, however, this arrangement is destroyed, a part of the combined electricity of the smaller sphere is decomposed, and the resinous portion thereof, being the contrary to that of the larger sphere, is attracted to the point a, by which the spheres formerly were in contact. By gradually increasing the distance of the spheres, this effect is diminished, and at length a position may be found, at which the resinous electricity of the smaller sphere developed by induction, and collected at the point a, is equal to the vitreous electricity at the same point,
according to the state of its distribution over the sphere, and thus a second time the point a is found without a single molecule of free electricity. The distance at which this effect takes place, depends upon the ratio of the radii of the spheres, and the quantity of electricity at first communicated to the system. By all further separation beyond this limit, the electricity remains of the same nature, throughout the whole surface of the smaller sphere, being the same which it possessed at the moment of contact. These phenomena are peculiar to the smaller of the two spheres, whatever be the quantity of electricity communicated to the system. Upon the larger sphere, and upon every part of it, the electricity is at all times of the same kind as during the contact of the bodies.

(See part ii. for the mathematical investigation of these properties.)

The laws by which these effects may be foreseen and calculated, have even been extended to the same problem in its most general form, where the spheres are not first brought into contact, but are charged with any known quantities of the same or opposite electricities.

Discharge or spark.

(98.) Under whatsoever conditions the experiment is commenced, if there does not exist upon the two spheres that exact ratio between the two electricities in quantity and kind, which contact would have established, according as they gradually approach each other, the thickness of the electric strata at the points nearest to each other upon the two surfaces becomes greater, and increases as their distance diminishes. The same effect takes place with regard to the pressure exerted by the electricity against the lamina of air interposed between the two bodies. Finally then, this pressure will overcome the resistance of the air, and the fluid escaping under the form of a spark or otherwise, ought to pass before the contact from one surface to the other. The fluid thus accumulated previously to the discharge is of opposite kinds, and of nearly equal intensities upon each of the spheres.

If at the first opposite electricities be communicated to the two spheres, the charge which arranges itself upon each to form the spark, continues to consist of portions of these opposite electricities. But suppose both spheres to have received the same kind of electricity, vitreous for example, then during their approach a decomposition of the combined electricity takes place upon that sphere which contains less of the vitreous fluid than it ought to have during contact; the residuary electricity resulting from this decomposition is determined towards the point where the spark is preparing; and at the same time the other sphere, which has already more vitreous electricity than it ought to have after contact, remains vitreous throughout.

Other and more complicated cases of electrical action dependent upon these principles, and connected with this series of illustrations, have been devised as trials of the theory; but as that is not our present object, we limit ourselves to an explanation of such cases only as occur in experimental electricity.

(99.) Perhaps it may be thought that we have even carried these apparently intricate details further than was absolutely necessary for our practical purposes; but it is only at this part of our progress that we find ourselves in possession of sufficient acquaintance with the phenomena of electricity, to explain a result which we could not avoid meeting with in the outset of our compilation. Why did not the ball mentioned in art. 2, as soon as it had received a portion of the same electricity which had been developed upon the glass tube, manifest a spontaneous repulsion? To answer this question, we must minutely consider all the circumstances of the case. The excited glass tube may be supposed to be studded with molecules of vitreous electricity, fixed immovably upon the particles of its surface. Upon presenting this excited tube to the suspended pith ball, its natural electricity is decomposed, and as we have shown, in art. 17, attraction must take place, the ball then comes in contact with the tube. During this process, the side of the ball next to the tube is charged with resinous electricity, and as it is formed of conducting matter, a sufficient quantity of the resinous fluid is immediately supplied to neutralize the one or more molecules of vitreous electricity found upon the glass exactly at the point of contact. When this neutralization is completed, there still remains the attraction of all the more distant molecules of vitreous electricity disposed upon the surface of the glass, where they are fixed, and therefore cannot proceed to the ball for the purpose of neutralizing the stratum of resinous electricity which they have attracted to its proximate surface. Hence, then, it is necessary either to let the ball move along the surface of the glass, so as to pick up, as it were, a sufficient number of molecules of vitreous fluid to saturate all its induced resinous fluid, and to produce an actual and immediate repulsion between the two bodies; or else by shaking off the ball from the tube, and then gradually approximating the bodies, there may be a distance found at which the repulsive force exerted between the fluid upon the tube, and the fluid imparted to the ball is manifest; at least, if the disparity of excitement be not too great, a circumstance that ought to be guarded against.

(100.) After these ample, and as we trust satisfactory details, it scarcely can be necessary to enter minutely into the same analysis of all the effects produced in the cases of balls of conducting matter mentioned in art. 17. We there asserted that the effects produced by electrical induction would tend to aid the forces under examination, and such, upon a just review of the matter, will be found to be strictly the case.

For several of the illustrations in this chapter we are indebted to the admirable Traité de Physique of M. Biot, vol. ii.
CHAPTER V.

Application of the principles of induction to the artificial increase, or quantitative accumulation of electricity.

In the first three chapters of this treatise, electrical phenomena have been described and reasoned upon under the hypothetical assumption of two fluids, ever resident in all bodies; and these chapters were devoted to an examination of the effects produced by the motions of the identical communicated or transmitted molecules of these fluids. The subsequent chapter brought before us the agency of a given quantity or intensity of electricity, in enabling us by its influence to develop in other insulated conducting bodies a certain portion of free electricity, dependent upon known laws arising from the magnitude, form, and relative position of the bodies. In the chapter now before us, we proceed to show in what manner, by a practical application of these principles, we may be enabled, by having at command a sort of reservoir capable of retaining a given quantity of either free electricity, to obtain from the earth and to insulate an equal quantity of the dissimilar fluid, which is the principle of the electrophorus, or by similar means to determine towards any given part of an insulated system of bodies a greater proportion of electricity than that part would otherwise acquire, which is the effect both of the condenser and the electrical jar or battery. The following then will form the principal matters contained in the three sections of this chapter.

§ I. The electrophorus.

§ II. The condenser, and its applications.

§ III. The electrical jar, and battery.

I. The electrophorus.

(101.) The electrophorus was invented by the celebrated Volta, about the year 1774, and from the principles of its action we trust we shall be enabled fully to establish its claim to a place in this part of our treatise. To be as explanatory as possible, let us analyze certain effects depending upon the properties of induced electricity, before we proceed to an examination of the instrument itself.

It has been shown, that if we bring any insulated conducting body near to an electrified and insulated conductor, and then suddenly remove the former body, and remove it beyond the sphere of action of the electrified conductor, we shall find that it has acquired a charge of free electricity. If a disc of metal, furnished with an insulating handle, be brought near to the electrified conductor of a machine, (taking care that no spark pass between the bodies,) and then again removed, it will be found upon trial to remain in its natural unexcited state; but if at the same time that the disc is near the conductor, it be touched with the finger, so as to form a communication with the earth, and then withdrawn from the presence of the electrified conductor, it will be found to have acquired a charge of free electricity dissimilar in nature to that of the conductor.

Next, let a metal disc A, fig. 61, supported upon an insulating stand, receive a spark from the prime conductor of an electrical machine; it may then be employed to electrify another similar disc B, without contact or spark, by the means pointed out in the two former experiments; and as the second disc is electrified by induction, without abstracting one particle from the electricity of the first disc, the experiment may be repeated an indefinite number of times; or, at least, so long as the disc A is able to retain its electricity. The only obstacle to this being the dispersion which is continually going on from the contact of the air.

To analyze the process that takes place in these discs, let the lower disc A be made to communicate by a wire with an insulated pith-ball electrometer, as seen in the figure. On the communication of electricity by the spark the balls will diverge, but in proportion as we bring near the uninsulated disc B, the divergency of the balls and wires will diminish, until at last the electricity which before rendered them mutually repulsive seems to be destroyed. But it is in fact only rendered latent, for as soon as the disc which communicates with the earth is again removed, the divergency of the wires is reproduced to an extent as great as before. In this case the decomposition of the natural fluid contained in the upper plate increases as the plate approaches towards the electrified body, and consequently its electrical charge augments in proportion as the distance between the two discs decreases, and would arrive at a maximum at the instant of that distance becoming nothing. The obtaining this maximum effect is however prevented by the passage of a spark between the bodies, for which reason it is necessary to interpose a thin lamina, of some substance not readily permeable to the electric fluid, such as a plate of glass, or a stratum of resin.

By the application of this method, we arrive at the construction of the electrophorus. Let the lower plate be supported by an insulating stand as before; upon its upper surface place a thin plate of glass, and let the upper plate of metal also be furnished with an insulating handle. If then electricity be communicated to the lower plate by a spark, we may at will place the upper plate upon the glass, touch it for an instant with the finger, and then having raised it by the insulating handle, it will be found charged with an electricity the opposite to that of the lower plate. This process may be repeated indefinitely.

Retaining these principles in view, we may construct an electrophorus, such that the thickness of the insulating plate may be indefinitely small, by forming the lower disc of glass or resin, either of which substances may be excited by friction, and retain their electricity so forcibly, that the upper metallic disc may be placed immediately upon the surface of the excited disc, without receiving by communication any sensible quantity of electricity, while at the same time, from the proximity of the metal which is to be electrified by induction, to the electricity resident upon the glass or resin, the most powerful effects are produced.
Practical Electricity. Let B B, fig. 62, be the upper surface of a plate of resin rubbed with a cat-skin, by means of which resinosous electricity is developed. Let a metal disc A A, suspended by an insulating handle, be gradually brought near to the resinosous plate, and let a wire pass from the upper part of the metal plate to an insulated pith-ball electroscope. In this case the balls will be found to diverge with resinosous electricity. By employing a plate of glass instead of resin, the converse effect is of course produced. Hence, generally the electricity of the upper surface of the metallic plate, as manifested by the pith balls, is of the same nature with that of the lower plate excited by friction.

If the upper disc be placed in contact with the excited plate, and again removed, as all the effects that can be produced arise from the decomposition of its natural electricity, and as from the insulation neither electricity can escape, upon again withdrawing the disc, those electricities recombine, and the metal returns to its natural state. But if a considerable time elapse before this removal and recomposition take place, some portion of that electricity which has been repelled towards the pith-ball electroscope, will be dissipated by the contact of the air, and an exact spontaneous saturation cannot again take place.

From the preceding analysis of effect, it is evident that in order to give to the metal disc the utmost charge of which it is susceptible, we must open a channel for the escape of the resinosous electricity which is repelled; and this is done by touching the disc for a moment with the finger, and thus connecting it with the ground.

As yet we have considered the surface which has been submitted to friction, as if it alone existed in a state of perfect insulation in free space; but in reality the resinosous cake of the electrophorus is a plate of appreciable thickness, and hence a new series of phenomena will arise. The electricity developed at the surface which has been rubbed must act by influence upon the natural electricity of the second surface also, and of all other contiguous bodies, in the same manner as it acts upon the movable plate of metal; and this complicated action will modify the absolute quantity of electricity which is to be rendered latent during the contact.

Let us then consider the electrophorus of Volta as it is actually constructed. Let B B, fig. 63, be the resinosous cake, which is usual to have cast in a mould of tin D D, so that in fact all the points of the under surface of the plate have an immediate communication with each other. Previously to exciting it by friction, let the apparatus be placed upon an insulating stand, and let the tin case communicate with the balls of an electroscope. Beat the upper surface of the resinosous plate with a piece of dry fur, and the balls of the electroscope will diverge with resinosous electricity. Evidently then this effect has been produced by the electricity developed at the upper surface, which has decomposed the natural electricity of the case, and attracted the vitreous portion, at the same time that it repelled the corresponding resinosous portion to the electroscope. Next touch the case, the resinosous electricity is abstracted, and the vitreous remaining latent, undergoes no diminution, but in consequence of the escape of the resinosous portion, the threads collapse. If now we gradually bring near the superior metal disc, touching it at the same time with the finger, so that it may communicate with the earth, the free electricity of the resin acting upon the natural combined electricity of the metal plate, repels its resinosous electricity to the earth, and attracts its vitreous portion towards that surface which is nearest to the remaining resinosous disc. This vitreous electricity, acting in its turn, by attraction upon the resinosous electricity of the surface rubbed, and also by repulsion upon the vitreous electricity collected upon the tin case, evidently tends both ways to diminish the force by which this vitreous electricity is rendered latent, and some will therefore be set free, causing the balls again to diverge, but with vitreous electricity, and this divergence will increase in proportion as the metal disc approaches more and more nearly to the resinosous plate. But since this vitreous electricity of the case tends to repel the vitreous electricity with which the upper plate is to be charged, we must make the tin case communicate with the earth, by which means it is reduced to its natural state, and the electricity of the upper surface of the resin renders latent the maximum quantity of vitreous electricity upon the metal disc A A, just as if the tin case did not exist at all.

In repeating all these experiments with rigid accuracy, the influence of the air in producing a gradual dissipation of those electricities which are not rendered latent must be taken into the account; but if we consider an electrophorus left with its plates in contact, we shall see no reason to suppose that its effects will be much if at all diminished by the access of the air; because all the resinosous electricity of the lower plate is rendered latent by a saturating quantity of vitreous fluid, which has been attracted towards the lower surface of the upper plate, by means of its communication with the earth. Hence it is found that a well-constructed electrophorus will retain its electrification in a process of time the two electricities of the plate and the resin do actually enter into combination, and undergo a mutual and permanent saturation.

It is even possible to form an electrophorus such that the resinosous plate may receive and retain a charge of vitreous electricity. For if two resinosous disc be taken of equal magnitude, and one of them be excited by beating and rubbing it with a cat-skin, we know that it will become resinosously electrified, and that consequently it will be capable of developing a charge of vitreous electricity in the movable metal disc of an electrophorus. Having thus charged the movable metal disc, let it be placed upon the un electrified plate of resin, and after having remained some time in this situation, the resinosous disc will have suffered the decomposition of some of its superficial electricity. The resinosous portion will have combined to neutralize, as far as it may be able, the free vitreous electricity of the metal; and upon the removal of the upper disc, the resinosous plate retains a charge of vitreous electricity. Thus we obtain an electrophorus, the effects of which are directly contrary to those of the original one, which has so long occupied our attention.

The best composition for the resinosous plate Composition for the resinous plate is found to consist of equal weights of shell-lac, resin, and Venice turpentine, melted together. These
Principle of condenser.

(106.) From the laws of electrical distribution which have been already investigated, it appears that one conductor, charged with a given quantity of electricity, will communicate by contact to another unelectric and insulated conductor, a certain quantity of the same free electricity with which the former conductor is endowed. Throughout the case now enunciated, the two conductors are supposed to be placed in free space, or at least to have all other bodies situated beyond the sphere of influence of the fluid distributed to them.

Let us now proceed to show that the quantity of electricity communicated to the second conductor may vary greatly if the last condition specified be not strictly complied with. In fig. 64, A is a metal disc, having a strong wire and knob affixed to its upper surface. By bending the wire, a loop is formed through which a glass rod B, which serves as an insulating handle. If now the knob be allowed to touch the excited prime conductor of a machine, the wire and plate A will receive a certain charge of electricity, which may be roughly measured by touching the ball of the electrometer, fig. 32, with the plate A. That this experiment may succeed well, it is necessary that the charge of the prime conductor should be but slight, and consequently the divergence of the gold leaves will not be considerable. Now we may conclude that as the conductor is of considerable magnitude when compared with the plate A, the quantity of electricity carried off by one contact is not great; and that therefore by another similar contact of the plate A, we shall be able to obtain a nearly equal quantity of free electricity. Let this contact however be made with some variation of circumstance; for at the same time that the knob touches the prime conductor let another metal disc C, having also a metal stand, which is to be held in the hand, be brought near to A; so that the planes of the two plates may be parallel to each other, but not so near that any spark may pass from one to the other. While they are in this relative position, let this system of bodies be withdrawn from the prime conductor, and then also remove the plate C, and apply the plate A to the electrometer as before. It will then be found that the leaves will diverge much more widely than before, and consequently the plate A has carried off a quantity of electricity much greater than during the former contact.

By a recurrence to the principles of induced electricity we shall obtain a ready explanation of these effects. The body A receives in the first case its ordinary charge of communicated electricity, but in the second case, upon the approach of the plate C, the natural electricity of C is decomposed by the influence of the electricity, (be it of what kind it may,) that is disposed upon the plate A. Of the two electricities developed in C by this decomposition, the one that is of the same kind with that upon A is repelled to the earth, and the opposite kind is attracted towards the upper surface of the plate C. In this position it is able to attract to the under surface of the plate A a further quantity of the free electricity of the conductor, and this upon its arrival will produce a further decomposition upon the disc C. Thus will these effects take place in fact simultaneously, (although, for the sake of illustration, they have been traced in a consecutive order,) until an equilibrium is established between the quantity of free electricity which the conductor can afford to A, and the quantity of the opposite electricity which the attractive force of this electricity can draw to the disc C from the great reservoir the earth.

As long as the plates A and C are near to each other, a great portion of these electricities are rendered latent by their mutual influence, but upon the separation of A and C beyond their sphere of influence, both the electricities again resume their free state; the redundant fluid of C returns to the earth, and the redundant fluid of A having no channel by which it may escape, is capable of affecting the electrometer to a degree much greater than if the disc C had not been employed in the experiment.

(107.) We shall now be enabled to proceed to a description of the Condenser; an instrument frequently employed for the purpose of obtaining a considerable quantity of electricity from a feebly excited substance, in order that this electricity may be transferred to the electroscope for further examination.

In fig. 65, B is a metal disc, supported by a stand of the same nature. A is a similar disc fitting upon the upper surface of B, and having an insulating handle proceeding from its centre, and also a small metal pin and knob affixed to its circumference. The under surface of the plate A, and the upper surface of the plate B, are coated respectively with a film of any non-conducting resinous varnish. If now we wish to condense the charge of electricity which may be obtained from some feebly excited body, the metal pin from the plate A is placed in contact with the body, at the same time that by retaining the stand B in one hand it is allowed to communicate freely with the earth. It is obvious that by this process the charge which the plate A is capable of receiving is considerably increased, the electricity is condensed, and in a great measure rendered latent, so long as A and B retain their relative positions. Next, Vol. IV.
ELECTRICITY.

Practical Electricity.

Let the contact between the pin and the excited body be destroyed, and then, by means of the insulating handle, raise the disc A from the stand, and apply the pin to the cap of a delicate electroscope; a great portion of the electricity of A, which the presence of B had rendered latent, will be set free, and the electroscope will be sensibly affected. The object of the varnish upon the surfaces of the plates is to prevent the immediate communication of electricity by contact; and it is plain, from theory, that the thinner this interrupting stratum can be made the better. A plate of glass might serve to separate the two discs, but is exceedingly liable to the condensation of moisture upon its surfaces, by which the insulating property is greatly impaired; and it is also found, that when a disc of glass is employed as the interposed plate, a very considerable portion of the induced fluid remains affixed to the upper surface of the glass, after the insulated metal plate has been removed, by which the effect upon the electroscope is sensibly deteriorated.

Such is the condenser of Volta, with whose name the instrument is usually associated, although Æpinus had before constructed a similar apparatus. There are also many other instruments in which the same principle is employed under various modifications, according to the peculiar views or purposes of the inventors, who have given to them the names of condensers, doublers, or multipliers. From these we shall select such as appear most worthy of description, from their real utility to the practical electrician; and as it is obvious that the principal use of the condenser is to render sensible the presence of minute quantities of electricity, we shall be prepared to find it an important addition to our electroscopic apparatus.

Cuthbertson's condenser.

(108.) Cuthbertson's condenser consists of two circular brass plates, fig. 66. The one A, which is called the receiving plate, is supported by a glass pillar, while the other B, which is called the condensing plate, rests upon a pillar of brass, or some conductor, jointed at the bottom so that it may fall back into the position represented by the dotted lines of the figure. If the plate A be made to communicate by the hook at the back of its ball with any feebly excited body, the presence of the plate B which communicates with the earth will condense upon A a greater quantity of electricity than it could otherwise receive. Let the communication between the plate A and the electrified body be destroyed, and then withdraw the plate B. By this process the electricity upon A will remain no longer latent, and may be communicated by contact to the cap of an electroscope for examination.

Condensing electroscope.

(109.) By the combination of this apparatus with Bennet's gold-leaf electroscope, we arrive at the most convenient and delicate instrument of this species. In fig. 67, A is the receiving plate affixed to the cap of the electroscope, and communicating with the ground by means of its conducting pillar C, and capable of being withdrawn by turning upon its movable joint. The practical application of this instrument is sufficiently obvious from the explanations already given.

Condensing electroscope of Volta.

(110.) Fig. 68 represents an instrument precisely similar in principle, but differing slightly in its construction. This instrument, the condensing electrometer of Volta, has justly some claim to attention, from having been employed by that celebrated experimentalist in examining the weak electrifications of the galvanic pile. It is in fact the discs of the condenser, in combination with the small electroscope, which we have already sufficiently described.

(111.) Cavallo's multiplier.—This ingenious instrument is represented by fig. 69. It consists principally of four circular brass discs, ABCD. A is supported by an insulating glass stem H, firmly fixed into the wooden base of the instrument Q R S; B is a similar disc, having its insulating support I affixed to a lever L K, moving upon a pivot at K. C is a similar disc, which like A is supported by an insulating rod G, fixed into the board Q R. The fourth disc D, is not insulated, being supported by a metal rod. When the lever K L is placed as the plate represents, the plane of the disc B is parallel to the plane of the disc A, and distant \( \frac{1}{\sqrt{2}} \)th of an inch. The plane of the disc D is also parallel to the plane of the disc C, and capable of any variation of distance by means of the slider FP, into which its supporting rod is affixed. O m is a small wire fixed to the plate B, which when B is as near as possible to A, touches a strong vertical wire N, for the purpose of forming a communication with the earth.

Let us now suppose the plate A to be connected with any very feebly electrified body, and for the sake of illustration let the electricity developed be vitreous. The lever being placed in the position represented by the plate, the disc B is in communication with the earth, and will therefore have attracted towards it a portion of resinous electricity, by which means also it will enable A to receive a greater portion of the vitreous electricity of the excited body. Upon removing the lever for the purpose of bringing it to the position represented by the dotted lines, O m ceases to touch the wire N, and the plate B becomes insulated. The resinous electricity which had been latent during its proximity to the vitreous electricity of the disc A is set free, and finally by the small wire O m coming in contact with the plate C, the free electricity of B is shared between the two discs B and C; but in consequence of the presence of the plate D, which communicates with the earth, C is enabled to receive a much greater portion of fluid than is left upon the movable disc B. By successive motions of the lever, any number of repetitions of these effects may be produced, until a very considerable charge of resinous electricity has accumulated and become latent upon the disc C. By withdrawing the slider FP, the plate D is removed from the presence of the disc C, and as there is no longer any power capable of rendering latent the resinous electricity upon C, it will be found to have acquired a charge capable of affecting the electroscope. It is obvious that there is a limit beyond which the multiplication of electricity by this instrument cannot take place; because after a certain time the electricity upon C will have accumulated to such an extent, that upon withdrawing the disc B from contact with C, it will carry back as much electricity as the charge upon the disc A can enable B to retain when in a state of communication with the earth.

Nicholson's spinning condenser.—Fig. 70 and Nicholson's 71 are designed to convey some idea of this singular instrument. Fig. 70 represents in outline a condenser.
ELECTRICITY.

Practical Electricity. "A is a metallic vase having a long steel axis which passes through a hole in the stand H at K, and rests on its pointed end in an adjustable socket at C. The use of the vase is by its weight to preserve for a considerable time the motion of spinning, which is given by the finger and thumb, applied at the top of the instrument. The dark parts D and E represent two circular plates of glass, nearly one inch and a half in diameter. The upper plate is fixed to the vase, and revolves with it; the lower is fixed to the stand. In the lower plate are inserted two metallic hooks F and G, diametrically opposite to each other. They are cemented into holes drilled into the edge of the glass which is nearly \( \frac{1}{2} \) ths of an inch thick. In the upper plate are inserted in the same manner two small tongues of the fine flatted wire used in making silver lace. These tongues are bent down so as to strike the hooks at each revolution; but in all other positions they remain freely in the air without touching any part of the apparatus.

At C is a screw, which by raising or lowering the vase, keeps the faces of the glass planes at any required distance from each other. The contiguous faces of the glass planes are coated with segments of tin-foil, as represented in fig. 71. Each of the tongues from the upper disc communicates with one segment of tin-foil upon the same disc; the hook F also communicates with that coating of the lower plate which is the nearest to it, but the hook G is entirely insulated from the whole apparatus, and is intended to communicate only with the electrified body, or an atmospheric conductor. The lower coating nearest to G is made to communicate permanently with the stand H, and consequently with the earth.

"In this situation suppose the motion of spinning to be given to the apparatus, one of the tongues will strike the hook G, by which means the upper coating annexed to that tongue will assume the electric state of the body with which G communicates; and the electric charge thus received will be the greater in comparison of the proximity of the lower uninsulated plate, to which at the instant it is directed opposite. The tongue G with its plate or coating proceeds onward, and after half a revolution, arrives at the situation to touch the hook F. The upper coating with its tongue, the lower coating on the side of F, and the hook F itself must then constitute one jointly insulated metallic mass, throughout which the charge of free electricity received at G is dispersed. Of this electricity the greater part will be determined towards the hook F," (according to the principles laid down in our third chapter.) "The motion being continued at the coating and its tongue instantly pass on, leaving F electrified, and proceed to bring another charge from G, which is to be deposited at F, as before. The electroscopic balls at F will therefore very speedily be made to diverge." (Nicholson's Journal, April, 1797.)

(113.) The following general observations, by the late Professor Robinson, on the various methods for ascertaining minute degrees of electricity are so excellent that we feel no hesitation in presenting them to our readers.

1. "If the absolute quantity of electricity be small, and pretty much condensed, as that produced by a smallourseline when heated, or by a hair when rubbed, the only effectual method of manifesting its presence, and ascertaining its quality, is to communicate it to a very delicate electrometer; i.e. one that is very light, and has no great extent of conducting surface." The electroscopes of Haüy or of Coulomb are best adapted to this purpose.

2. "When we wish to ascertain the presence of a considerable quantity of electricity which is dispersed or expanded into a great space, and is little condensed, such as the constant electricity of the atmosphere in clear weather, or such as the electricity which remains in a large Leyden jar after the first or second discharge, this may be best ascertained by means of Cavallo's collector, or multiplier, or by the condenser.

3. "When the electricity to be ascertained is neither very considerable in quantity, nor much condensed, such as the electricity of the hair of certain animals, of the surface of chocolate when cooling, &c. In this case, the best method is to apply a metallic plate furnished with an insulating handle, such as one of the plates of the doubler, to the electrified body, and to touch the plate with a finger while it remains sometimes in this situation, which done, the plate is to be removed, and brought near to a sensible electro-scope; or its electricity may be communicated to the plate of a small condenser, by which it will be rendered more apparent. In this operation, care must be taken not to bring the plate too near the body whose electricity is to be examined, lest the friction likely to happen between the plate and the body should produce some electricity, the origin of which might be attributed to some other causes."

(114.) It may be thought by some that we have described but few of those ingenious instruments which have been constructed for the purpose of rendering sensible minute degrees of electrical excitation, but in fact the extreme delicacy of Coulomb's electro-scope precludes all necessity for the more complicated apparatus of spinners, doublers, multipliers, &c. These instruments may however be sometimes required for certain peculiar purposes of investigation, and therefore we subjoin the necessary references for all the most important instruments of this description.

§ III. The electrical jar, and battery.

(115.) In our historical sketch we have adverted to the discovery of the Leyden jar for the accumulation of electricity, either by Kleist or Muschenbroek; and in the present section we propose to describe this important instrument, both in its simplest forms, and in the more complex construction of the electrical battery.

Fig. 72 is a plain glass jar; the shaded part represents a coating of tin-foil, affixed by paste or gum.
Practical Electricity.

Having thus described the construction of the Leyden jar, it may be advisable, before we proceed to examine the rationale of its action, to refer to certain experiments which will point out the precise circumstances upon which its effects seem to depend.

For these researches we are indebted to the labours of Dr. Franklin. His first efforts were directed to the ascertaining the relative states of the exterior and interior coating of the jar. By suspending an electrified pith ball from a silken thread, he found that it would invariably be attracted by the one coating, and repelled by the other. Hence it was evident that the two coatings were oppositely electrified. When the interior communicated with the prime conductor of a machine, it received a charge of vitreous electricity, and the exterior coating became equally charged with the resinous electricity. By reversing the communication, connecting the outside of the jar with the conductor, and the inside with the earth, the converse effects were produced, and the jar became charged to a degree of intensity as great as before.

(116.) Let the jar, thus prepared, be placed upon a plate of glass, or some insulating support, with its ball nearly in contact with the prime conductor of an electrical machine. Upon setting the machine in motion, a feeble spark will pass from the conductor to the ball; and on removing the jar with one hand, at the same time touching the ball with the other hand, scarcely any effect will be perceived. The jar, in short, will be found to have received no charge of electricity. If now, instead of placing the jar so that the exterior coating remains insulated, we touch the outside of the jar with the hand or any conducting body, or affix a chain communicating freely with the earth; upon again putting the machine in motion, an abundant succession of sparks will pass from the conductor to the ball. Remove the jar, holding it by its exterior coating in one hand, and then touch the knob with the other hand, or with any conducting substance; a strong spark will be perceived, and a sort of convulsive shock will be experienced in the joints or muscles, which, to most persons, is extremely disagreeable. It is easy to perceive when the jar has received its full charge by the feebleness, or entire cessation of the sparks, passing from the conductor to the knob of the jar. If it be required to communicate the shock to more than one person, let all the party form a chain by joining hands, and let the person at one extremity of this chain touch the outside of the jar, while the person at the other extremity, completes the circuit by touching the brass knob. All will feel the shock, and the intensity of effect produced upon each will not be much less than it would have been, if he alone had completed the circuit between the two surfaces of the jar.

Franklin's experiments.

(117.) Having thus described the construction of the Leyden jar, it may be advisable, before we proceed to examine the rationale of its action, to refer to certain experiments which will point out the precise circumstances upon which its effects seem to depend.

For these researches we are indebted to the labours of Dr. Franklin. His first efforts were directed to the ascertaining the relative states of the exterior and interior coating of the jar. By suspending an electrified pith ball from a silken thread, he found that it would invariably be attracted by the one coating, and repelled by the other. Hence it was evident that the two coatings were oppositely electrified. When the interior communicated with the prime conductor of a machine, it received a charge of vitreous electricity, and the exterior coating became equally charged with the resinous electricity. By reversing the communication, connecting the outside of the jar with the conductor, and the inside with the earth, the converse effects were produced, and the jar became charged to a degree of intensity as great as before.

(118.) Having arranged two jars, so as that the knob of each should receive electricity from the prime conductor, it is plain that both the jars would become similarly charged with vitreous electricity. On sus-

pending an insulated pith ball near to the two knobs, it would be attracted by either until it had received a charge of free electricity, by contact, and then was repelled by both the knobs equally. But if of the two jars, the one were charged by its knob, that is, with vitreous electricity on the inside, and the other were charged by having its exterior coating in contact with the conductor, so that the interior would be resinously electrified; the pith ball being then suspended between the two knobs vibrated backward and forward from one knob to the other until both the jars were discharged.

(119.) Again, if the interior coating were made to communicate with the conductor, and the exterior with the rubber of the electrical machine, but at the same time having no communication with the earth, by any conducting body, the jar became fully charged as before.

(120.) It has already been remarked, that no charge could be communicated to the jar, unless the exterior coating communicated with the earth; and this, together with the last experiment, points out some important change to be performed upon the exterior of the jar, while the interior is receiving its charge. The oscillation of the small pith ball between the knobs of the two oppositely charged equal jars, having produced their mutual discharge, suggested, that in charging or discharging a jar, one coating gained as much electricity of the one kind, as the other did of the opposite kind. The process of withdrawing the electricity from a charged jar, was thus analyzed by Franklin. Having placed the jar upon an insulating stand, he suspended a linen conducting thread near to the exterior coating. By repeatedly touching the knob, which communicated with the interior, he was enabled, gradually, to discharge the jar; and in so doing, he found that, at every successive contact, a portion of the electricity on the outside became free, and the linen thread sprang to the exterior coating, in order that it might receive and remove the superfluous fluid.

(121.) The converse of this proposition applying to the case of a coated jar or disc receiving electricity, was thus elegantly investigated by Professor Richman. Two discs of tin-foil were applied as coating to the plate of glass, so as to leave a clear interval between the tin-foil and the edge of the pane. The glass was then placed in a vertical position, and to each the upper and opposite edges a thread was affixed, so that the two might hang parallel to each other on opposite sides of the glass. By communicating a charge of electricity to one of these coatings, the adjoining thread was repelled, and raised itself so as to form a certain angle with the surface of the glass, and at the same time an equal angle was formed by the other thread next to the tin-foil on the opposite side of the pane.

Fig. 73 represents a section of this apparatus, in which the strong dark lines mark the coated part of the plate. If any conducting body were brought near to one side of the plate, the thread on that side would sink, and form a less angle with the coated surface; but the thread on the opposite side would receive an additional elevation, equal in quantity to that which the former had lost. If one side were touched by the finger, the thread on that side would immediately and entirely collapse; but the angle of elevation of the
other thread would be doubled. Hence it is evident that the angle intercepted between the two threads, is a constant quantity, dependant upon the charge, communicated to the plate in the first instance.

(128.) To return again to the researches of Franklin, we find him endeavouring to ascertain in what the efficacy of the coating, applied to a jar, consisted. What function does it perform? Does the accumulated electricity reside in the coatings, or upon the glass?

By charging a jar and placing it upon an insulating stand, he found, that after the lid of the jar and the knobbed wire were removed, the charge still remained, and that by connecting the interior and exterior coatings, the jar was discharged as usual. In the next place, having charged a jar, of which the inner coating consisted solely of a quantity of water, he poured out the water into a clean jar, and as he could obtain no shock from the water thus removed, he concluded that he had not abstracted the electricity from the interior of the jar. He then filled the first jar again with fresh water, and proved that the electricity had remained all the time in the jar, by obtaining from it a shock as usual. Thus was he led to the true explanation of this phenomenon, which may also be readily obtained by any one from the following experiment.

(129.) Exp. Let a large tumbling glass, fig. 74, of a conical form, have an exterior and interior coating of tin-foil, fitted nicely, but not cemented to the surfaces. Charge this jar as usual, place it upon a glass plate for insulation, and holding it by the uncovered part, lift out the inner coating of tin-foil, and then raise the glass from its outer coating also. By touching the outside and inside of the glass simultaneously, no perceptible shock will be obtained, neither is there any effect produced by touching either, or both the coatings; but let these coatings be again carefully adjusted to their places, on the opposite sides of the glass, and a shock may be obtained in the ordinary manner. Hence it is evident, that in the Leyden jar the electricity is accumulated upon the glass, and not in the coating substances, and that the latter are only necessary for the formation of a complete communication between every point on the exterior and every point on the interior, at the instant of the discharge.

(130.) A very slight degree of consideration will show, that in fact the coated jars and coated discs are but peculiar forms of the condenser, which we have already so fully described. In this instrument there are two metallic surfaces, separated by a non-conducting body, and these may be removed to variable distances from each other, in which respect alone the instrument differs from a coated jar, which consists also of two metallic surfaces, with an interposed non-conductor. If similarly employed, the effects also of the apparatus are the same; for if we communicate a considerable charge of electricity to the upper plate of a large condenser, while the lower disc has a free communication with the earth; and then having touched the lower plate with the fingers, and apply the thumb to the upper disc, a complete discharge will be produced, and a shock will be obtained similar to that from a jar having a coated surface of equal extent.

Perhaps it would be difficult to adduce a more striking proof of the similarity or identity of the two cases, than that which is afforded by the discharge of a jar, or a condenser by alternate sparks from the two coated surfaces.

(135.) Exp. Let a charged jar be placed upon an insulating stand, and a condenser also be fully charged, by allowing the lower disc to be connected freely with the earth, and after the charge has been obtained, let this communication be destroyed, so that the lower plate becomes insulated like the outer coating of the jar. The inner coating of the jar and the upper disc of the condenser, are then similarly electrified; as also the outer coating of the jar and the lower disc of the condenser. Upon presenting a finger to the outer coating of the jar, or to the lower of the two discs, no effect will be produced; because all their electricity is rendered latent by the presence of that resident upon the opposite coated surfaces. Next, let the finger be presented to the ball communicating with the inner coating; and to the upper disc of the condenser. In both these cases a small spark will be obtained, but a considerable portion of the electric charge will remain, being rendered latent by the electricity of the opposed surfaces. Again, approach the outer coating, and the lower disc, and from each a feeble spark may now be obtained. By these alternate contacts, the two oppositely charged surfaces, both of the jar and the discs, may be entirely discharged; because at each repetition of the process a portion of electricity is set free by the removal of the small excess on the side of the surface touched.

(136.) Hence it is very evident that the complete explanation of the effects produced by the Leyden jar, is to be deduced from the principles of electrical induction; because it is the power of accumulating the opposite electricity upon the exterior of the jar which allows of the successive accumulation of that on the inside, by their two opposite powers of rendering each other latent as they arrive at the positions occupied by each respectively.

Let us, however, proceed to a more minute analysis of these effects, by which the action of the Leyden jar will, it is hoped, receive a very satisfactory explanation.

Place an uncharged jar upon an insulating stand, (fig. 75,) and let its exterior surface communicate with the pith-ball electroscope already so frequently referred to. Impart two or three sparks to the brass ball of the jar, and immediately the pith balls will diverge with vitreous electricity. The exterior coating of the jar has, therefore, suffered the decomposition of its natural electricity.

While things are in this state, touch the electroscope, and the wires will again fall into their natural vertical position. By this contact the escape of the vitreous electricity, which caused their divergence, has been facilitated; and it has become impossible to remove from the interior surface all the vitreous electricity which has been communicated to it. A part has become latent, and this can only have been effected by the influence of a resinous electricity. In fact, if we now touch the ball for the purpose of removing the portion of vitreous electricity which remains free, the electroscope, communicating with the exterior surface, will again diverge, but with resinous electricity.

The same arrangement of our apparatus being retained, we charge the prime conductor of a machine with a certain quantity of electricity, and then form a
electricity. After the free electricity has become distributed between the conductor and the interior of the jar, the electroscope, communicating with the exterior, will diverge as before with vitreous electricity. If by touching the electroscope, we allow this electricity to escape, the repulsive force which it exerted upon that on the Interior of the bottle, ceases to exist, and the ball again placed in communication with the conductor of the machine, will show itself capable of receiving an additional charge of electricity. The electroscope will then again begin to diverge, and always with vitreous electricity. If a passage be offered for the escape of this electricity, the ball becomes again capable of receiving a further quantity of electricity from the conductor. The electroscope again diverges, and so on in succession. This phenomenon is repeated continually, in the same manner, until the portion of vitreous electricity, which remains in a state of freedom upon the interior surface, shall have arrived at such a degree of accumulation, as to hinder, by its repulsive force, the introduction of any additional quantity of electricity of the same nature, arriving from the surface of the conductor. The jar has then become fully charged, and its discharge may be effected by any of the ordinary processes for that purpose.

(128.) A very cursory inspection of these principles, will prove to us that a given quantity of electricity to be abstracted from the prime conductor of a machine, may be employed for the charging of two or more jars, almost as powerfully as if the whole were communicated to one only. For this purpose, let the jars be placed consecutively as represented in fig. 76. A chain or wire serves to convey the electricity from the prime conductor to the ball of the first jar. The ball of the second jar is similarly connected with the coating of the first, and another chain forms a communication between the coating of the second jar and the earth.

Upon the influx of electricity to the ball and interior coating of the first jar, the natural electricity of the exterior coating undergoes decomposition; the resinous part is rendered latent by the influence of the vitreous electricity within the jar, and the vitreous part is repelled to the interior of the second jar, where it performs the same office as the similar electricity did when primarily communicated to the first jar. The vitreous fluid developed at the exterior of the second jar is repelled to the earth, and any required portion of resinous fluid is conveyed to the exterior coating of the same jar, in order by its influence to render latent the vitreous electricity which arrives at the interior of the jar. Let all the connections now be interrupted, and the two jars will have received their full charge, and it is evident that whatever upon these principles of explanation can be proved true of two jars, may be extended to any number of jars arranged consecutively, and properly connected for the purpose.

(129.) Hitherto we have spoken of the Leyden jar in its most simple form, but it may be desirable now to describe the best construction at present known for this important instrument of electrical research. A B, fig. 77 is a glass jar, having a mouth sufficiently wide for the convenient application of the tin-foil to the interior surface. C is a hollow brass cap, cemented into a glass tube, which reaches to the bottom of the jar, and is fastened into the wooden disc that closes its mouth. This wooden disc or plate should be well dried by baking, varnished on both sides, and cemented into the jar. D is the knob of a small brass wire, which forms the communication between the cap C and the inner coating of the jar. This wire, passing loosely through a small hole in the cap C, may be removed at pleasure, for the purpose of cutting off all communication between the cap and the interior coating. In consequence of this wire not reaching quite to the bottom of the jar, the lower part of the tube is provided with a coating of tin-foil, which joins to the inner coating of the vessel. Enough has already been said of the layer of tin-foil which is to be pasted on the outside, to correspond with the foil within; and neither ought to extend too near to the top of the jar. It is also an improvement to spread a delicate film of some resinous varnish, both on the inside and on the outside, over those parts of the glass which are not occupied by the foil. At the bottom of the jar there is a hook affixed, to which a chain may be conveniently suspended, for the purpose of communication with the earth, or any appropriate conductor.

It is obvious, that when a jar of this construction has received its charge of electricity, the wire may be carefully withdrawn, or suffered to fall out by reversing the jar; and that then no discharge can possibly take place until the wire be restored; neither is there any loss of electricity, even if the jar be carried in the pocket.

(129.) In the construction of the Leyden jar, the Thickness of the glass is an important consideration; for as it has been proved that the power of accumulation, by which the charge is obtained, depends upon the mutual attraction of the molecules of two fluids, according to a force varying with the inverse square of the distance; it is evident that the intensity of charge which may be communicated to any contended non-conductor of given superficial extent, will increase rapidly as the thickness of the non-conducting body decreases; and hence the thinner the glass, the greater will be the charge. Such, at least, will be the case, provided this law undergoes no modification in consequence of the attractive and repulsive forces being exerted through a non-conducting body, instead of through the air or free space. On this subject there is little of conclusive experiment to guide our determinations: some researches of Mr. Cavendish led him to conclude that the charges which might be imparted to jars of given superficial extent, varied inversely as the thickness of the glass.

In practice, however, it is found impossible to diminish the substance of the non-conducting body interposed between two oppositely charged surfaces, beyond a certain extent. Thus, at some degree of intensity, a spark will force a passage through the plate of air between the two discs of the condenser. At some point of accumulation upon the opposite surfaces of a charged jar, although the electricity, being latent, have no action upon other bodies, yet they tend towards each other with such violence as to force a passage through the substance of the glass. To obviate this danger, a sufficient thickness must be allowed for the jars employed in experiments of this nature, and it is found that the common glass jars, to be purchased at the glass-houses, are as thin as can with
A very elegant jar is mentioned by some authors as having been constructed by the same able electrician, in the following manner: A long-necked phial was made of sheet-tin, and then coated entirely on the outside with sealing-wax, 3/4ths of an inch thick. The sealing-wax was then coated with tin-foil, all but the neck; the tin plate corresponded with the inner coating and wire, and the tin-foil with the outer coating, while the wax acted the part of the glass in a common jar.

Jar of coated wax.

An ingenious little instrument, called Cavallo’s self-charging jar, is thus constructed. Take a glass tube eighteen inches long, and an inch and a half in diameter. Coat one end with tin-foil and close the surface of the coated end with a cork through which a wire passes, touching the inner coating, and terminating in a ball on the outside. By holding the uncoated part in one hand, and rubbing the outside of the coated part with the other hand, touching at intervals the knob with the rubbing hand, the inside coating gradually receives a charge. If now the outside of the coated part be held in one hand, and the ball be touched with the other hand, a shock will be obtained.

Coated plates.

It will now be evident to our readers, that a plate of glass, or any non-conductor may be coated in a manner similar to the jar, and that its effects will be the same. Dr. Bevis appears first to have proposed this change, and Dr. Franklin made considerable use of coated plates in his experiments; but at present the jar is the form under which the instrument is almost universally employed. Beccaria constructed a plate consisting of a resinous mixture, containing equal quantities of pure colophony and pulverized marble. By spreading this about the thickness of one-tenth of an inch with a hot iron; and then coating the surfaces with tin-foil, he considered that he had obtained an instrument capable of a greater charge than a glass plate of equal extent; with the advantage of being much less endangered by the effects of a spontaneous discharge.

A plate of mica has also been employed for the formation of a coated pane, as its strength enables it to resist an electrical charge of considerable intensity.

The electrical battery.

Gralath, who published a work on electricity in 1747, first proposed to combine together the effects of several jars, so as to construct what is now very appropriately termed an electrical battery. Fig. 79 is a representation of this piece of apparatus, in which every essential part is so clearly expressed by the plate, as to require scarcely any specific description. The interior of the wooden box, in which the jars are arranged, or at least the bottom upon which they are placed, is coated with tin-foil, for the purpose of ensuring a direct communication between all their exterior surfaces; and from this conducting substance, a chain or wire communicates with a ring seen at the front of the case, by which, in charging the battery, a connection is formed with the earth, and which, of course, must be also employed for completing the circuit, between the exterior and interior coating, in order to effect a discharge.

In charging an electrical battery, we have only, as in the case of a jar, to form a connection between the rods which communicate with the interior surfaces, and the prime conductor of a machine in action; at the same time allowing the exterior surfaces to communicate with the earth, by means of the ring before mentioned; and it may, in general terms, be asserted that the quantity of electricity, of given intensity, contained by different batteries, varies directly as the extent of coated surface. The degree of intensity to which any given extent of coated surface may be charged by the successive accumulation of electricity, as we have before seen, will vary according to some inverse ratio of the thickness of the glass, of which the jars are made, and of course the thinner the glass the greater would be the charge of which the battery is capable; but in practice, it is found that the jars cannot, with safety, be made thinner than they are usually obtained at the glass-house for other purposes.

If it be required to charge a large battery from the action of a small machine, we may resort to an artifice founded upon the experiment described in art. 127. In fig. 81, four jars are arranged, without the frame or case, for greater clearness in illustration; and it is essential that each jar or section of the battery to be charged by this method, should occupy a separate insulating stand. A, B, C, D, are the balls communicating with the interior surfaces. A wire is passed from the coating of the first jar to the knob of the second; another wire from the coating of the second to the ball of the third, and so on; while the exterior coating of the last jar is allowed to communicate freely with the earth. Suppose vitreous electricity be conveyed from the prime conductor of the machine to the first ball A, the whole of the vitreous electricity that can be furnished by decomposition from the exterior coating of the jar A, is put in requisition to render latent the vitreous electricity at the interior of the same jar; while the vitreous electricity resulting from this decomposition is repelled to the jar B, which thus becomes charged, and a similar series of effects is transferred in succession from one jar to another, so that all become charged.

The interior surfaces of all the jars have accumulated vitreous, and the exterior surfaces resinous electricity. A moderate degree of caution in preserving the insulation, will enable us to derange all the former system.
Effect of humidity.

(134.) The increased effect, as to its capability of receiving a charge, which is produced in a jar by a slight degree of moisture upon the surface, was accidentally noticed by Mr. Brooke, and an analogous phenomenon was remarked by Mr. Cuthbertson in 1792. He found that a recently coated jar, which had not become perfectly dry, received a greater charge than could afterwards be communicated to it, when it had been deprived of all moisture. He then took a dry jar, and having breathed into it, he found that the power it had then acquired, when compared with that which it before possessed, bore the increased ratio of twelve to five. Resuming this subject in 1796, he found that on a dry day in March, a battery of fifteen jars, containing seventeen square feet of coated surface, would ignite eighteen inches of wire, but by breathing into each jar through a glass tube, the battery acquired a power of receiving a charge which would ignite sixty inches of the same wire. This is certainly a very singular circumstance, and one which it is important for the practical electrician to bear in mind.

Lateral explosion.

(135.) There is one phenomenon connected with the communication of an electrical charge to a jar or battery, which may fairly claim our attention in this part of our treatise.

It was, we believe, first remarked by Mr. Henley, that when a jar is discharged by means of a bent metallic wire, not having a glass insulating handle, some degree of shock is experienced by the hand which grasps the wire, especially if the quantity of electricity to be discharged be considerable. Also, if one end of a chain be placed in contact with the exterior coating of a charged jar, and the remaining part of the chain be loosely laid upon a table, it is found, that on the discharge of the jar, in a darkened room, the chain, though it forms no part of the circuit, becomes luminous by the passage of sparks from one link to another, and therefore has, in some manner or other, been affected by the discharge. The same effect may be produced when the chain is not quite in contact with the exterior coating of the jar, in which case a spark also passes from the jar to the chain whenever the general discharge takes place.

This phenomenon, which is known by the name of the lateral explosion, is, however, better illustrated by the following experiment of Dr. Priestley. "When a jar is charged, and stands upon the table as usual, insulate a thick metallic rod, and place it so that one of its ends may be contiguous to the outside coating of the jar, and within about half an inch of its other end, place a body of about six or seven feet in length, and a few inches in breadth; then put a chain upon the table, so that one of its ends may be about one inch and an half distant from the coating of the jar. To the other end of the chain apply one knob of the discharging rod, and bring the other knob to the wire of the jar, in order to make the explosion. On making the discharge in this manner, a strong spark will be seen between the insulated rod, which communicates with the coating of the jar, and the body near its extremity, which spark does not alter the state of that body in respect to electricity; hence it is imagined, that this lateral spark flies from the coating of the jar, and returns to it at the same instant, allowing no perceptible space of time, in which an electrometer can be affected. Whether this lateral explosion is received on flat and smooth surfaces, or upon sharp points, the spark is always equally long and vivid." Cavallo's *Electricity*, vol. i. p. 283.

Now in all these experiments, we think that we may again recognise the effects of electrical induction; and that from this principle we shall be able to deduce a more satisfactory explanation of the phenomenon, than that proposed by Mr. Cavallo. Let us consider the last mentioned as the most clear case, and, as it is evident, that the laws which are applicable to the one, may also be brought to bear upon all the other cases recorded, the insulated metallic rod being in contact with the exterior coating of the jar, will be affected by the charge which that coating receives. Suppose the jar to receive internally a charge of vitreous electricity, the exterior coating will become resinously electrified, and the rod will either partake of this resinous state throughout, or will become vitreously electrified at that extremity which is farthest from the jar and nearest to the long insulated body. In whichever way the rod becomes electrified, as it has no connection with the other body, and yet is very near to it, the effects of induction must take place. The natural electricity of the long insulated body will be decomposed, one of its elementary principles will be attracted towards the end which is presented to the rod, and the rendered latent, and therefore protected from dissipation. The opposite electricity will be repelled to the other end of the insulated body, and from the very form of the conductor upon which it resides, it is in the most favourable circumstances for being dispersed into the surrounding atmosphere. Let us now suppose, that after a short time the jar is discharged, its exterior coating, and the rod connected with it, will immediately return to their natural state; the electricity which had been collected, and rendered latent at the nearest extremity of the long conductor, will be again set at liberty, and in dispersing itself over the body upon which it resides, it again unites with the opposite electricity, which had been repelled to its most distant extremity. But some portion of this electricity has been dissipated, and therefore the two principles will not be found in their just quantity required for mutual saturation; that electricity which had been latent will be found in excess; and the conductor is, in fact, possessed of a charge of free electricity. The electrical charge will, upon the principles of arrangement already explained, assume a state of great comparative intensity at the two ends of the conductor, and as one of these ends is near to the rod which touches the exterior coating of the jar, which communicates with the earth, a spark must pass between the bodies to enable the conductor to return to its natural state.

All those circumstances, so minutely specified by Priestley as tending to the success of the experiment, seem to confirm our explanation of the phenomenon, that the conductor should be very long and very slender. The better, therefore, we say for the separation of the two electricities, and the dispersion of
Practical Electricity.

one of them, that the long conductor should not approach near to the exterior coating of the jar, but should be acted upon through the intervention of a sort of thin conductor projecting from the jar. Because, to us it appears that the form of this intermediate conductor, is most proper for affecting the longer one, and because the charge of electricity, immediately upon the outer coating of the jar, would not act so strongly upon the long conductor, from being rendered latent by the presence of the vitreous electricity within the jar. At the same time, the un-electrified state in which the long bar is found, after the passage of the spark which was quite inexplicable before, seems a necessary consequence, resulting from those principles upon which our explanation has been founded.

At the same time it may be just to state that, to the best of our recollection, the lateral explosion has been explained in a different manner, and supposed to depend upon the interruption of the circuit through which the discharge takes place. Thus, Mr. Cavallo states, "the cause of this phenomenon to be the interruption of the circuit made by introducing bad conductors into it; for as this interruption is greater or less, the lateral explosion is more or less sensible." Even upon our view of the matter, this imperfect or interrupted circuit may not be without its effect; but we feel convinced that a few judicious experiments, made with a thorough understanding of the principles and peculiarities of induced electricity, would remove all the difficulty with which this phenomenon is at present encumbered.

(136.) In communicating an electrical charge to a jar or battery, we have shown that the two electivities, distributed at its opposite coated surfaces, are rendered latent by the effects of their mutual attraction, so that the jar may be highly charged, and yet, from having no free electricity, neither coating may produce any effect upon the gold-leaf electrometer, and hence the quadrant electrometer of Henley, depending upon the same principle, gives no just indication of the extent to which a battery is charged.

But although the two electivities thus circumstanced, have no effect upon other bodies, every molecule present upon each of the surfaces, exerts its due attractive force upon all the molecules of the other fluid upon the opposed surface; and also, its repulsive force upon all the molecules of its own mass of fluid of which it forms a part. Hence we may arrive at a knowledge of the limit, beyond which any given extent of surface cannot be charged. Suppose a current of electricity from the prime conductor of a machine, to be determined toward the interior coating of a jar; we know that its momentum will depend upon the form of the conductor, and the quantity communicated to it by the machine in a given time; and therefore, all other circumstances being favourable, we conclude that the fluid will continue to accumulate within the jar, and to become latent by the effect of the opposite electricity, which it will bring to the exterior coating, until the repulsive force of the molecules of electricity within the jar, is sufficiently great to counteract the momentum of the approaching current of electricity from the prime conductor; when, of course, no further accumulation can take place.

At this period the prime conductor will, by its points, if from no other part, dissipate electricity as fast as the machine can supply it. A jar then, during the process of charging, and as soon as the charge has arrived at its maximum, will have some portion of free electricity, shared between its interior coating and the prime conductor of the machine. The obstacles, therefore, to our obtaining a charge of indefinite magnitude upon a given extent of coated surface are these: The imperfection of the air and glass, as barriers to the progress of electricity, and the limited decomposing, generating, or determining power of the machine. If glass were a perfect non-conductor, and had perfect strength to resist the passage of the mutually attractive fluids, however accumulated, we then must have a plate of thickness indefinitely small, in order that the two fluids might be precisely equal to each other in quantity and intensity. But it is found by experiment, that if the glass of a jar have not considerable thickness, the fluid forces a passage through, and the glass is fractured.

Again, if the air were a perfect non-conductor, (which perhaps in a pure state it really is,) and had at the same time a perfect power of resistance, so that every portion of the fluid could pass through it, (which property it certainly has not,) there would be no necessity for such considerable spaces, as we are compelled to leave, between the extremities of the two coatings of a jar; and it is frequently found, that if we attempt to charge a jar or battery beyond a certain point, the electivities acquire a sufficient intensity of attractive force to burst their way through the air, and pass from one coating to the other, so that a spontaneous discharge takes place.

An electrical charge, which the air at some given density is capable of retaining in its place upon the two coated surfaces of a jar, will escape, if that density be sufficiently diminished. Of this mode of action we obtain an elegant illustration, by placing a charged jar under the receiver of an air pump, in a darkened room. As soon as a sufficient degree of exhaustion is produced by working the air pump, the fluid is seen to pass over the edge of the jar in a luminous torrent, from the vitreous to the resinous side; and thus, a mutual saturation again gradually takes place.

(137.) With any given battery, the point at which dissipation from the conductor becomes equal to reception from the cylinder or plate, will depend upon the activity or power of the machine, measured by the quantity of electricity which it furnishes in a given time. And if the producing power of the machine be given, we may consider the electrical charge of which any jar or battery is capable, to vary in the direct ratio of the superficial extent of the coated part, and in some inverse ratio of the thickness of the glass; yet in practice it is found impossible to judge of the intensity of the charge communicated to the jars or batteries, other than by the effects produced upon their discharge. For obtaining an estimate of this species, Mr. Cuthbertson proposed to measure the length of a wire of some given metal, and of given diameter, which the discharge of the battery is capable of igniting. This is, however, evidently a method not susceptible of great delicacy or accuracy. All those electrometers, described in chap. ii. which depend upon the repulsion of any two parts of the same system of bodies communicating freely, and
Lane's discharging electrometer.

Practical Electricity.

charged with the same electricity, are inadequate to our purpose; because they measure only the repulsive energy of the free electricity, and render no account of that which has become latent.

(138.) Before we enter upon the task of describing those instruments which have been contrived for the purpose of measuring the charges of jars and batteries, we would wish to introduce to our readers, whom we are bound to consider as inexperienced electricians, an instrument of perpetual use for discharging jars without partaking of the shock, which would frequently be unpleasant, and even, in some cases, attended with danger. Fig. 82 represents this instrument, called a jointed discharger. A B is a handle of glass; B C, B D, are brass wires terminate by brass ball at C and D. At B, is a joint which, allowing a freedom of motion to the two arms, enables the experimenter to place the two balls at any convenient distance from each other. With this instrument it is easy to discharge a jar or battery, by bringing one ball in contact with the exterior, and the other in contact with some part of the interior system of arrangement; while the glass handle forms a protection from all the effects which take place in the restoration of electrical equilibrium.

(139.) The greater part of the instruments described in our second chapter for indicating and measuring free electricity, depended, primarily for their action, upon the repulsive forces exerted by molecules of the same electricity upon each other. It has, however, been proved, that the electric fluids which reside upon the opposite coated surfaces of a charged jar, have the power of mutually depriving each other of this repulsive property, which, in fact, accounts for their assuming what we have termed the latent state; and hence it follows, that neither the presence, nor the quantity of an electric charge, can be ascertained by any of the instruments already enumerated. But although the mutual repulsion between the molecules of the same fluid is in that case destroyed, or veiled, the attractive force between the respect of molecules of the dissimilar fluids is unchanged, and appears to be in reality the probable cause of the temporary extinction of the self-expansive property.

That the repulsive power is thus destroyed, is easily proved by the fact, that if we touch either coating of the jar, the other coating remaining insulated, we are unable to remove the electricity which the former coating may be in contact with. That the attractive powers of the dissimilar fluids are not destroyed, is manifest from the fractures of the jars which sometimes take place by the spontaneous union of the two electricities, which thus force for themselves a passage through the substance of the glass.

There are, however, some other principles, which have been resorted to for obtaining measures of the electrical charge accumulated in a jar or battery.

Lane's discharging electrometer.

(140.) Of these we propose first to describe Lane's discharging electrometer. Fig. 83 is a representation of this useful instrument. A B is a strong bent glass rod, having at one end a brass cap and conical point C, by which it fits into the ball of a jar, or into a hole in the prime conductor of an electrical machine. At the other end of the glass rod is a ball D, perforated for the admission of a brass bar, having a ball at each end, and so constructed as to slide backwards and forwards through the ball D. If the instrument be fixed by its point C to a conductor, or to a jar, while the outer ball communicates with the other side of the jar, no discharge can take place, except between the body to which C is affixed, and the inner ball of the discharger. Hence, by sliding the bar along, the distance which the shock or spark has to traverse may be regulated. It is obvious that this instrument attempts to estimate the accumulated charge of a jar by measuring the distance in air which the discharge is capable of traversing. This will be subject to some variation from the changes to which the atmosphere is subject; and in the case of sparks at least, other changes may be produced by altering the form of the balls, or the conductor to which the instrument is affixed.

(141.) Henley's universal discharger is an instrument something similar in its principle, but is universal chiefly employed for the deflagration of electrical discharges, and is extremely convenient in many galvanic experiments. As a measure it is little employed, except by placing different lengths of wire between its forceps, to be fused or ignited by the electrical discharge. A and B, fig. 84, are glass pillars cemented into a wooden stand. At the top of each of these pillars is a brass cap, so jointed as to move both vertically and horizontally. Through a spring tube at the top of this joint, the handle D or C passes, and is capable of being moved backwards or forwards by sliding it through the spring tube E. These handles are each composed of a strong brass wire, terminated by a ball, or point, or pair of forceps; and have at the other extremity a solid glass rod, to serve as an insulating handle. F is a small wooden table, having a slip of ivory glued longitudinally into its upper surface, and capable of being elevated or depressed by means of a screw G. In using this instrument, the two sides of the jar or battery are connected by chains or wires, with the two brass caps at the tops of the pillars. The substance through which the discharge is to be passed, is placed upon the top of the stand F, or in any other way between the balls or forceps; and, by means of the insulating handles, the distance may be regulated so as best to suit the purpose of any required experiment.

(142.) Several different kinds of electrometer Cuthbertson's discharging electro-meter have been invented upon the principle of measuring the intensity of the electrical charge, by the weight which the electrical forces might be able to overcome. The best of these, and we believe the only one now employed, is Cuthbertson's discharging electrometer. In fig. 85, A and B are glass insulating rods, supported by a wooden frame. At the summit of the rod A is a large ball C, through which the brass rod D C passes, having a ball at each end. This rod is capable of moving in a vertical circle, being delicately balanced upon knife-edges within the ball C; F is another ball supported by a brass wire fixed into C. G is another brass ball communicating by a chain, with one side of the jar or battery, while C communicates with the opposite side by means of the chain H. K is a small slider which moves along the graduated arm C E, and measures the weight in grains, which, if placed at E, will cause the arm and ball E to descend to G. When the chain H communicates with one side of a jar, and the chain from G with the other side, it is obvious that no discharge
can take place until the ball B shall descend upon the ball G; and therefore, by the adjustment of the slider K, the charge may be compelled to continue to increase, until the force exerted shall be equal to any required number of grains upon the scale of the instrument.

As far as experiments have hitherto proceeded, it would appear that this instrument is a tolerably accurate measure of the intensity of electrical charge upon two coated surfaces of given extent, and having a non-conductor of given thickness interposed between them. The following results are cited by Mr. Singer in proof of this supposition. Two inches of steel wire, employed for making the hair spring of a watch, were fused, by being placed in the circuit, through which the discharge of a jar passed with the beam of Cuthbertson's electrometer, loaded to fifteen grains. The same jar was capable of fusing eight inches of the same wire, with the charge which it acquired by loading the beam with thirty grains. If, instead of increasing the weight beyond fifteen grains, two such jars be employed, the eight inches of wire are fused as in the last case. Hence it would appear, that it is the same thing, whether the intensity of the electricity be doubled, or the extent of the coated surface.

CHAPTER VI.

Effects of electricity upon organic and inorganic matter, and also upon the other imponderable physical agents.

In arranging the subordinate divisions of this chapter, considerable difficulties must be encountered, arising from the imperfection of our knowledge, both of our effective agent, and of the subjects upon which we suppose its action to take place. We are frequently unable to distinguish accurately between cause and effect. If we pass a powerful electrical charge through a small metallic wire, the metal may be heated to redness, or whiteness, or may be fused, or even volatilized. Heat then is produced; but from whence? Did it exist originally in the metal, and was it forced out by the violent mechanical action of a material fluid passing through the wire? or is it the electric fluid, again appearing under some new modification of form? Arguments might be found in favour of each of these views, but this is not the place for their appearance. When an electrical machine is in powerful action, there is a peculiar smell something similar to that which is produced by the friction of two pieces of quartz upon each other; but how electricity should thus affect our sense of smelling, we are unable to tell. Amidst difficulties such as these, which meet us at every step we take in physical inquiry, we propose to arrange the subjects of this chapter under the following sections.

§ I. Effects of electricity upon inorganic matter, comprising those which are purely mechanical.

§ II. Effects of electricity upon vegetable life.

§ III. Effects of electricity upon animal life.

§ IV. Effects of electricity in the production of chemical composition and decomposition.

§ V. Effects of electricity in the development of light from phosphorescent bodies.

§ VI. Effects of electricity in the evolution of heat.

§ VII. Effects of electricity upon magnetic bodies.

§ VIII. Effects of electricity upon inorganic matter, comprising those which are purely mechanical.

(143.) To be enabled to give a specific account of those electrical effects which are purely mechanical, we ought in the first place to know whether electricity be a material fluid or not; and as we have acknowledged our inability to satisfy the inquirer upon this point, we can only venture to class together a few phenomena which seem to be most easily explained upon the supposition of material and mechanical agency.

The power of an electrical discharge to heat substances of considerable conducting power in its passage through them will be examined hereafter; but it would seem that in all such cases there is either a great and permanent expansion, or which perhaps amounts to the same thing, a separation of the particles of the body through which the discharge takes place. Thus, it was observed by Dr. Priestley that a chain through which an electrical discharge had passed, had suffered a diminution in its length. Upon a more accurate trial, he found that a chain twenty-eight inches long, lost a quarter of an inch of its length by the passage of a charge through it from 64 square feet of coated surface. Mr. Nairne passed the charge from 26 square feet of coated surface repeatedly through a piece of hard drawn iron wire 10 inches long and \( \frac{1}{4} \) th of an inch in diameter. The wire was examined after the sixth, ninth, and fifteenth discharges, and it was found to have lost about \( \frac{1}{4} \) ths of an inch of its length by each shock. The total contraction was fully one inch and \( \frac{1}{4} \) th. No perceptible loss of weight could be discovered, but the increase of thickness seemed to be in proportion to the longitudinal contraction the wire had undergone. It appeared also, that a copper wire plated with silver, and of the same dimensions as the iron wire before employed, underwent a diminution of length only \( \frac{3}{4} \) ds as great as that had been suffered by the former wire.

Mr. Brooke passed the charge from 16 square feet of coated surface, nine times successively through a steel wire 12 inches in length and \( \frac{1}{4} \) th of an inch in thickness, and thus produced a longitudinal contraction of one inch and a half.

(144.) It may easily be conceived that whenever the electrical discharge takes place through more imperfect conductors, its progress will be marked by still greater violence of effect; and it appears that even the most perfect conductors with which we are acquainted, if they have not sufficient magnitude for the free transmission of the discharge, suffer from the passage of the fluid, in a manner similar to imperfect conductors of greater volume. For the convenience of
100

ELECTRICITY.

Practical Electricity. 

the young electrician, the following illustrations of this species of action are arranged in a series of experiments, which it will not be found difficult to repeat. 

(145.) Exp. Let a capillary tube, such as is employed for the stem of a thermometer, be filled with mercury, and let this mercurial thread form part of the circuit in an electrical discharge. In this case although the conductor is excellent, it will undergo so great an expansion as to burst the glass tube in which it is contained.

(146.) Exp. If a substance of inferior conducting power be employed, its volume may be considerably increased, and the same effect will still be produced. Thus, insert two wires through corks in the opposite ends of a small glass tube, let the distance of the ends of the wires be half an inch; fill the tube with water, and pass a moderate charge through it; the tube will be broken and the water dispersed. Singer.

The expansion of fluids by electricity is indeed very remarkable and productive of some singular results. When the charge is strong, no glass vessel can resist the sudden impulse. Beccaria inserted a drop of water between two wires in the centre of a solid glass ball of two inches diameter; on passing a shock through the drop of water, the ball was shattered with great violence. Mr. Morgan succeeded by the same means in breaking green glass bottles filled with water, when the distance between the wires that conveyed the spark and the sides of the glass exceeded two inches. (Singer.) The same author states that, with but a moderate charge he has in that way broken glass tubes the thickness of half an inch in the sides, and having a bore of the same diameter.

(147.) Exp. "Drill two holes in the opposite ends of a piece of wood which is half an inch long and a quarter of an inch thick; insert two wires in the holes, so that their ends within the wood may be rather less than a quarter of an inch distant from each other; pass a strong charge through the wires, and the wood will be split with violence. Loaf sugar, stones, and many other brittle non-conductors may be broken in the same way, if a sufficiently powerful charge be employed."

(148.) Exp. Introduce two wires into a soft piece of pipe-clay, and pass a strong shock through them: the clay will be curiously expanded in the interval between the wires. This experiment will not be successful if the clay be either too moist or too dry.

(149.) Exp. Place a piece of plate glass about an inch square and half an inch thick, flat upon the small table of the universal discharger, and press it by a weight. Set the points of the sliding wires opposite to each other, and against the under edge of the glass, so that the spark may pass beneath it: the charge of a large jar transmitted in this way rarely fails to break the glass.

(150.) Exp. Let a spherical cavity be turned in a piece of ivory, capable of receiving the half of a light wooden ball; a small conical cell is to be made at the bottom of the spherical cavity, and two wires inserted through the sides of the mortar into it: if a drop of water, oil, alcohol, or ether be put between the wires, and the ball placed over them in its cavity, a charge sent through the drop of fluid will convert part of it into vapour, and expel the ball with considerable force. Beccaria; Lullin.

(151.) If an electrical discharge be passed over the surface of a piece of dough, its course will be marked by an irregular line or indentation. If over ice, the surface is sometimes marked with spots, as if a hot needle had been laid upon it. If over snow, a channel is furrowed out upon its surface. If through a piece of paper, or a green leaf, the substance is rent in the direction of the discharge.

(152.) Several experiments have at different periods been brought forward as evidence of the materiality of the electric fluid, or as affording proof of the existence of one fluid by showing in what direction motion is produced at the instant of a discharge. A light ball has been made to move along a groove, between the two balls of a discharger, or a wheel has been made to revolve, by presenting the extremities of its radii to an electrified point, but we feel little inclined to occupy our pages with experiments of this nature, as we are convinced that all these cases are easily explained by taking into consideration the ordinary effects produced by attraction in our atmosphere.

(153.) There are however some singular appearances presented by substances through which electrical discharges have proceeded, which it will be accordant with our plan to introduce under the present section.

If a considerable electrical discharge from a Leyden jar be passed through a card or a quire of paper, there will appear a sort of bur or some expulsive effect which had taken place, or some body had passed from the centre towards the two external surfaces of the plane; but it is said, that the larger protrusion will be found upon the resinous side of the plane, which fact has been brought forward as a proof that there is but one fluid which at the instant of the discharge, passes from the positive to the negative surface of the jar. Mr. Symmer upon a careful examination of these appearances, was convinced of the existence of two currents which had passed in opposite directions through the quire of paper, and had left a hole such as would have been produced by drawing two threads through, in opposite directions. (Phil. Trans. 1759.) To the same gentleman we are indebted for the following variation in this experiment: Let a slip of tin-foil be placed in the midst of a quire of paper; and within another quire of paper let there be two slips of tin-foil, separated by the two middle leaves of the quire. By passing a strong shock through each of these quires, different effects will be produced. In the former, the tin-foil will have received two indentations in opposite directions, and the leaves of paper will be rent in such a manner that on both sides of the tin-foil the bur shall point toward the outsides of the quire; but the indentations upon the foil, and the burs in the paper will be in opposite directions. In the other quire, all the leaves will be perforated, excepting the two between the tin-foil, and these two will have received indentations in opposite directions.

(154.) Even if we were to admit that the effects thus produced upon paper, pasteboard, or soap, do prove the passage of the discharge to proceed from the positive to the negative side of the jar or battery, there does not appear any absurdity in supposing that the vitreous electricity should have the power of proceeding under certain circumstances, with the greater velocity to form a union with the resinous fluid. It appears in fact that these motions are influenced in some way or other by the state of atmospheric pressure; for let a varnished card be suspended by silk,
in such a manner that two blunt wires proceeding from the opposite sides of a battery may be in contact with the opposite surfaces of the card; but so that the points although in contact with the card are half an inch distant from each other. When the discharge of the battery has taken place, the card will be found perforated, but always at the point where the resinous wire touches it, even if a hole be previously made against the point of the wire from the vitreous side of the battery. Clearly then, in this case, the fluid passes from the vitreous to the resinous conductor.

In the next place let all conditions remain the same, and let the experiment be performed under the receiver of an air-pump. It will be found that in proportion as the pressure of the air is removed, the perforation will be made nearer to the vitreous conductor. Hence it would appear that in rarefied air the negative electricity is capable of advancing to meet the vitreous electricity, and that in general the air exerts a greater coercive force upon the former than upon the latter fluid. Tremery, *Journal de Physique*, liv. p. 357.

This passage of the charge from the vitreous to the resinous surface is easily perceived in a darkened room, and some instances of this kind have already been noticed, (89.) and (90.) M. Charles rendered this motion very apparent, by covering long pieces of black cloth with metallic spangles or filings, so that the interruption of continuity in the circuit, made the time and therefore the direction of the discharge very perceptible.

(155.) From the instances which we have already brought forward of powerful mechanical effects produced by the passage of an electrical discharge through an imperfect conductor, we are in some degree compelled to recognize electricity as a material fluid; but if so, how extraordinary must be the velocity of its movements. Its weight is to us inappreciable, and yet by its momentum it can rend and disperse the densest metals, and from this circumstance alone, reasoning upon the universal laws of mechanical force, the velocity must be immense.

(156.) Exp. Let a strip of gold or silver leaf, or Dutch metal be gummed to the surface of a piece of paper, and so arranged between the forceps of the universal discharger that an electrical charge may be passed through it. No portion of metal will afterwards be found; part is seen to be dispersed in a sort of vapour, or perhaps very minute powder, and part remains in a state of oxidation upon the paper, which thus receives a greenish brown colour.

(157.) Exp. "Take three pieces of window-glass, each an inch wide and three inches long, place them together with two narrow strips of gold-leaf between them, so that the middle piece of glass has a strip of gold on each of its sides; the extremities of the gold strips should project a little beyond the ends of the glass: pass the charge of a large jar through the gold strips, they will be melted and driven into the surfaces of the glass. The outer plates of glass are usually broken, but that in the middle frequently remains entire, and is marked with an indelible metallic stain on each of its surfaces."

At the same time that these violent dispersive effects are produced, the development of heat and chemical coagulation also takes place. Of these we shall speak hereafter, but this dispersion of so heavy a metal as gold leads to the following singular speculation: Gold is about nineteen times specifically heavier than water, and the volume of water in the state of vapour, is 1600 as great as in its liquid state. Let us suppose it necessary that the vapour of gold shall be compelled to assume the same density as the vapour of water. In this case the filament of gold-leaf in the process of volatilization, must undergo an expansion of volume equal to nineteen times 1600, or become 30,400 as great in its solid state.

Some recent experiments seem to prove that the two electricities exert opposite actions upon the molecules of matter, under circumstances favourable to crystallization, and that this process is assisted by the presence of resinous electricity. As these researches have been made with the voltaic pile, we must reserve a more specific account of them for their appropriate situation under the article devoted to that modification of electrical action.

When an electrical discharge takes place in the air, whether it be a spark or from the more abundant accumulation of a shock, a report is heard; and this report has we think been satisfactorily explained on a common mechanical principle. "The sound is produced by the sudden collapse of the air which has been displaced by the passage of the electric fluid; and it is consequently greater in proportion to the quantity and intensity of the charge. Hence when different sized jars have been charged to the same degree, (of intensity,) and then successively discharged, the explosions produced will be louder in proportion as the jars are larger; and the effect afforded by a battery of extensive surface will be that of a comparatively violent effort." Singer, p. 147.

(158.) There is an elegant illustration of electrical attraction, for which we are indebted to Professor Lichtenberg of Göttingen, which has also been considerably modified and improved by more recent electricians.

Exp. Take a smooth disc of resin, or the lower plate of an electrophorus, and trace any lines over its surface with the knob of a jar charged with vitreous electricity; and then repeat the same with a jar charged with the opposite fluid. By means of one of the old-fashioned powder puffs or some similar contrivance, project over the surface of the disc a mixture of finely powdered sulphur and red lead, triturated together in a mortar. By the friction thus produced, the sulphur will have acquired vitreous, and the minium, resinous electricity; and each substance when projected upon the disc will attach itself to the oppositely electrified lines, forming a series of red and yellow outlines. These are the figures of Lichtenberg, produced in the most simple manner; but other and far more complicated varieties of the experiment may be found by the following references. Lichtenberg, *Nov. Com. Gottingen*, 1777, vol. viii. p. 168; Benet, *New Experiments in Electricity*, 8vo. Lond. 1789.

§ II. Effects of electricity upon vegetable life.

(159.) The first experiments upon the application of electricity to living vegetables, were made by Mr. Mainbray of Edinburgh, in October 1746. It appeared that two myrtle trees which had been subjected to gentle electrical action during the month of October, put forth leaves in the subsequent spring, earlier than some similar trees which had not been electrified.

The Abbé Nollet supposed that he had fully verified these results, and his experiments were repeated and varied by MM. Jallabert, Boze, the Abbé Menon, Dr. Carmoy, the Abbé D’Ormoy, and the Abbé Bertholon, who all conceived that they had found electricity to produce beneficial effects upon the growth of living vegetables. Of these experimentalists, the Abbé Bertholon was by far the most sanguine, and appears to have been most erroneous in his conclusions. It would be a waste of both time and space which we can devote to better purposes, if we should here attempt to describe the extensive system of electrical horticulture proposed by this author. The whole depended upon the elevation of pointed conductors to a considerable height in the air, by which means a supply of electricity was to be obtained, and again dispersed from a series of points over the growing produce of the garden.

A very elaborate series of experiments by Dr. Ingenhouz, in which the processes of preceding writers were repeated and examined, appeared in 1778, and entirely changed the current of opinions upon this subject; and Mr. Cavallo, who appears to have made similar experiments, expresses his complete conviction of the inefficacy of electricity as a stimulus to vegetable life.

Van Marum wished to ascertain whether the sensible perspiration of vegetables were increased by electricity. He therefore insulated the vegetables growing in flower pots, and brought them in contact with vitreously electrified conductors. After being thus exposed to electricity for a quarter of an hour, the loss of weight by evaporation was found to be in some 1/4th and in others 1/4 more than in the unelectrified state. It is possible that even the leaves, which are more delicate, may have suffered some deception; for as every pointed electric conductor propels itself a current of air, so must the points of the leaves of plants; and the constant succession of fresh portions of air by means of this current must tend to increase the quantity of evaporation.

Dr. Van Marum also examined the influence of electricity upon the sensitive plants. He first exposed the Mimosa Pudica to the sun, in order that its leaves might be fully expanded, and then brought it successively within two feet of a vitreously electrified conductor, and of one resinously electrified. By neither of these methods was any effect produced. The plant being placed upon the conductor, the small leaves raised themselves up a little and expanded, when no sparks were drawn from the conductor; but as soon as sparks were taken from the conductor, the small leaves again fell nearly in the same manner as the pendulum electrometer. After a few such changes they at length began to approach each other, to close themselves, and became totally shut. This result took place also in consequence of other kinds of concussions, and therefore must not be ascribed exclusively to electricity. In other respects the plants underwent no change.

In experiments of the same kind made with the Chap. VI. Hedysarum Gyrana, the electricity produced neither acceleration nor retardation in the movements of the small leaves.

(160.) Such is the information we possess upon the effect of feeble electricity applied for a long time to growing plants, or only applied for a short time to plants which seem to possess great nervous irritability. If however the electricity be applied with greater violence to living vegetables, very decided destructive effects are produced.

Mr. Nairne, in the year 1773, made some experi-ments of this sort upon different plants, particularly shocks. Myrtles and laurels. Van Marum, who has most recently examined this subject, made choice of much more vigorous trees, such, for example, as the young stems of the common willow, and in the middle of April, a period at which the young branches usually shoot forth. Through two of these, eight feet in length, he conveyed shocks; to the first, through a space of 15 inches in length; and in two others, through their tops only. After the passage of these shocks the trees were planted; but the parts through which the shocks had been conveyed sent forth no branches. The upper parts through which the shocks had passed, sent forth a few shoots for some days, but very slowly, and these shoots shortly withered and died. Those parts not electrified sent out branches, like the other trees planted near them.

Mr. Cavallo also mentions the very easy manner in which the "Balsam (Impatiens) is killed by means of electricity. The plants of that genus are not remarkably delicate, they grow easily, their stocks and branches are thick in proportion to the size of the plant, and they bear the inclemency of the weather tolerably well; yet a very small shock sent through the stem of a balsam is sufficient to deprive it of life. A few minutes after the passage of the shock, the plant will droop, the leaves and branches become flaccid, and, in short, its vegetation is quite destroyed. I have, indeed, known some plants of that species which have revived in a day or two, but that effect seldom takes place. A small Leyden phial, such as may contain six or eight square inches of coated surface, is sufficient for this purpose; and it may even be effected by means of strong sparks from the prime conductor of a large electrical machine.

"In this experiment neither the internal vessels, nor any other part of the plant, appears to be injured, and indeed the size of the plant, and the inconsiderable strength of the shock which is used, are such as not to indicate the possibility of the vessels being burst, or of the vegetable organization suffering any material derangement; it would, therefore, be useless to investigate the immediate cause which occasions the death of the plant.

"Having subjected several other plants to the action of electric sparks and shocks, I have not found any that can be so materially hurt by an electric power, so small in proportion to its size, as that which is sufficient to destroy the vegetation of a balsam." Cavallo, vol. iii. p. 249.

On the whole, thea, as far as experiments at present warrant our decision, feeble electricity exerts no perceptible influence upon vegetable life; but its more violent effects are similar in their destructive nature to those produced by lightning.
Practical Electricity.

§ III. Effects of electricity upon animal life.

The facts to be brought forward in the present section, will form an abstract of the best authenticated electrical experiments upon living animals, both in the states of health and disease, and will therefore slightly touch upon that branch of the science which is termed medical electricity.

Sparks and shocks.

(161.) The sensation produced by receiving a spark upon any part of the body; and the more powerful one experienced when we form part of the circuit through which the charge from the two sides of a coated jar returns to the state of electrical equilibrium, must be familiar to every one; and the latter is, with good reason, called the electrical shock.

We are not sufficiently acquainted with the nature of that subtle agent, upon which we now treat, to give a satisfactory reason for this singular and violent effect upon all bodies through which the discharge passes. We know not whether in the human frame, the concussion and involuntary muscular motion, be produced merely by an influence upon the nervous system, or by the passage of a subtle, but material fluid through the substance of our bodies; or by the sudden decomposition of the natural electricity of our frame, for the purpose of neutralizing the accumulated masses of the opposite fluids disposed upon the two coated surfaces.

Mr. Morgan states, that if the discharge from two square feet of coated surface be made to pass through the region of the diaphragm, a sudden convulsive action of the lungs produces a loud shout; but that, if the charge be much smaller, it produces a violent fit of laughter, even in the graviest persons. A very strong charge passed through the diaphragm, produces involuntary sighing and tears, and sometimes brings on a fainting fit.

There appears to be some difference in the effects produced by shocks of the same actual intensity, if received by different persons; and it seems that persons of great nervous irritability are affected more violently than those of a more phlegmatic temperament. Mr. Cavendish proved experimentally what our theory would lead us to suppose; that the sensation produced by a shock depends upon the quantity of the electricity, rather than upon its intensity. That a given extent of coated surface, charged to a certain degree of intensity, gave a perceptibly greater shock, than half that extent, charged to a degree of intensity, double of that in the former case. Dr. Robinson, however, states, that a charge of low intensity, received from a large extent of coating, is less disagreeable than one of very high intensity, from a much smaller surface. In this case, however, there is no estimate of the relative quantity of electricity in each case; and it does not seem at all improbable that where the same quantity of electricity is disposed upon the coatings of two jars, the one small, and the other large, the increased intensity of the electricity upon the smaller jar, will cause the discharge to take place with greater rapidity, and consequently with greater perceptible violence of action.

(162.) In our historical introduction, we have related the splendid discovery of Franklin, by which he identified the electricity of the experimentalist with the lightning of the atmosphere. Among other proofs of that identity, history afforded numerous instances of persons who had been killed, during thunder storms, by a stroke analogous to the discharge of an electrical battery; and the death of the unfortunate Richman by a discharge of electricity which he had conducted from the clouds to his own apartment, was a confirmation, (had any such been necessary,) and at the same time a warning to all subsequent electricians. The same system of action which produces the sensible shock, seems, if carried to excess, to be instantly destructive of animal life; and the fact of a pigeon, having lost its sight from the passage of a shock through the head, lends a degree of probability to the supposition, that the destruction of nervous irritability is the immediate cause of the death of the animals.

In attempting to investigate the nature of this destructive action, Dr. Van Marum made several experiments. "For this purpose he employed eels, which, as is well known, even when cut into three, four, or six parts, and when deprived of the head, still retain signs of irritability. These eels were a foot and a half in length, and the shock was conveyed through the whole body. By these means they were instantly killed, and never moved afterwards. They were immediately skinned, and trial was made by pinching, pricking, &c. whether any irritability remained; but no traces of any were perceptible, even when pretty large sparks were drawn from these parts. The strongest salts were attended with as little effect.

"When the shock was made to pass through individual parts, for example the head, these alone lost their irritability, while the rest retained it. When the head was kept free from the shock, the remaining parts only were paralysed. The same experiments were several times repeated on eels 3½ feet in length, and with the same results. When the shock was made to pass through the upper and fore part of the head of large eels, the under jaw, as well as the muscles of the neck and belly, and even the lower part of the body, retained their irritability, while it was completely destroyed in the parts through which the shock had passed. The same effects were produced in warm-blooded animals, for example rabbits, with much smaller batteries." Niebholson's Jour. viii. p. 319.

(163.) It had been remarked that whenever animals had been killed by lightning, the process of spontaneous putrefaction ensued with unwoeated rapidity. This circumstance has been examined by M. Achard, of Berlin. The following is an abstract of his Paper upon the subject.
Electricity.

It is a well-known observation, that after a storm, flesh, either raw or boiled, acquires a putrid smell, which in the latter is particularly acid. It is known, also, that grain suffered to ferment for the purposes of brewing or distilling, undergoes, during stormy weather, very sudden and perceptible changes. On such occasions it is often extremely difficult to observe where the first degree of fermentation ceases, as it passes so speedily; and the second degree, or the acetous fermentation, takes place before one is aware. To ascertain, therefore, whether the electric matter, which during stormy weather is so abundant in the atmosphere, has any share in these phenomena, the following experiments were made.

A piece of raw beef was cut into three parts. One of these parts was electrified positively for ten hours without any shock; a second was electrified negatively for a similar time; and the third was not electrified at all. The three pieces were left in the same apartment, exposed to the same degree of heat. When examined next day, both the pieces which had been electrified appeared to be tender, but were free from the least bad smell. On the fourth day the electrified flesh had an intolerably putrid smell, and that which had not been electrified began to smell a little.

M. Achard repeated these experiments with boiled veal. That which was electrified had, the next day, an acid smell, and an unpleasant taste; but that which had not been electrified, continued sweet for three days, and only on the fourth day began to have an acid smell.

Several birds were killed by electric shocks, and others were deprived of life by sticking a needle through their heads, and then placing them all in the same temperature; they were covered with glass receivers in order to preserve them from insects. Observing the gradual progress of corruption in both sets, M. Achard plainly perceived that it took place much sooner, and advanced more rapidly in those killed by electric shocks, than in those deprived of life by the needle. In those also, to which a stronger shock had been given, the degree of corruption was far greater than in the others; and the cause in all probability was, (according to M. Achard's opinion,) "that in this case the vessels containing the animal fluids were suddenly destroyed, by which means these fluids had diffused themselves through the particles of the body, and might thus accelerate putridity.

It clearly follows from these experiments, that electricity accelerates corruption, and that the putrefaction of flesh after a storm, must be ascribed solely to the more abundant accumulation of the electric matter at that time. M. Achard saw that this was the case in regard to several persons killed by lightning. The body of a farmer, who lost his life in this manner, between five and six o'clock in the evening, emitted next morning a very perceptibly festid smell, which in the evening was totally insupportable." (164.) We have already, in the historical introduction to this article, made sufficient mention of the fraudulent or mistaken attempts made by Pivati to exalt electricity to the rank of a sovereign remedy for all disorders. Philosophers had before them an agent of subtlety almost unexampled, and which traversed the human frame with unmeasured and irresistible rapidity, which affected the nervous and muscular system in a manner which it was beyond the power of volition to control; and it was neither absurd nor unreasonable to suppose that such an agent might, under some modification, produce a salutary effect upon the diseases to which mortality is liable.

They who first proposed the medical application of electricity seem to have entertained mistaken notions of the mode of its action; and consequently, to have erred in their calculation of the effects which it was expected to produce. They conceived that it was to operate as instantaneously upon disease, as it did upon the sensations or muscular powers of the animal frame; forgetting that there are very few cases in which a system of depraved vital action can instantaneously be changed into a healthy discharge of the functions of life. The pretended results of Pivati were refuted by Bianchini and Nollet, and the errors of Winkler were conveyed to them for some others. Several years after these events, the Abbé Bertholon published a work in two volumes, De l'Electricité du corps humain dans l'état de Santé et de Maladie. (1785.) This treatise is fanciful in the highest degree, and ascribes considerable influence to the electric fluid of the atmosphere, in regulating the number of births, deaths, and sicknesses which prevail among mankind.

Approaching, however, to a more respectable era in the history of medical electricity, we find careful experiment the only allowed guide in applying electricity to the relief or cure of disease. Mr. Trembley had communicated to the Royal Society, that many persons had found that while they were electrified, the rapidity of the arterial pulse was increased. The same position was maintained by M. Boze; and the Abbé Nollet, whose candour and abilities as an experimentalist have never been impeached, applied himself to diligent researches connected with this part of our subject. Reasoning upon the increased rapidity with which water escaped through a capillary tube, when in an electrified state, he considered that animal and vegetable bodies were made up of capillary tubes, through which the nutritive fluids were conveyed, and thence inferred that electricity would increase the rate of the circulation and promote perspiration. His experiments, however, led him to the following conclusions: That the constant communication of electricity to a living animal for a considerable time, did increase the quantity of perspiration. These results were obtained from birds, cats, and the human subject. In all cases, pairs of the animals were selected and carefully weighed; after a current of electricity had been conveyed to them for some hours, they were again weighed, and all loss was attributed to perspiration: The electrified animal was always found lighter than the one which had not been so acted upon. No inconvenience whatever was felt by the persons who submitted to these experiments. They only found themselves a little exhausted and had gained an appetite. None of them found themselves sensibly warmer, neither could the Abbé perceive that their pulse was increased.

The comparatively recent experiments of Dr. Van Marum are, however, considered more conclusive on this point. With regard to the effect of electricity upon the pulse. Eleven persons were selected, and the experiment was repeated four times.
Electricity. These persons were placed in a room which was at least from eighteen inches to two feet, if it is such a distance from the machine that they could not hear the noise it made in turning; they were insulated, and the pulse of each was felt when the machine was in motion, as well as when it was at rest, (which last circumstance was unknown to them,) and the beats were counted by a good observer, provided with an excellent watch. In some cases a few beats more were observed, but, on the whole, there was no important acceleration. In general, however, there was great irregularity in the pulse, both during the time the persons were electrified, and during the time the machine was at rest.

For the purpose of ascertaining "the increase of insensible perspiration, Van Marum employed a very delicate balance; one scale of which was insulated by means of a silk cord. On this scale he placed a boy, eight years of age, connected with the conductor; and the balance was brought to a state of equilibrium. He then ascertained the loss of weight sustained in half an hour before the boy was electrified, and found it to amount to 260 grains. By a similar experiment on another occasion, the loss of weight, before being electrified, was 330; and after exposure to electricity only 310 grains. A girl of seven years old lost, before being electrified, 180; and when electrified 165 grains. A boy of eight years and an half lost, un-electrified, 430; and when electrified 290 grains. Another of nine years un-electrified lost 70, electrified 94. As the last boy was exceedingly quiet during the experiment, it was thought that the increase was the consequence of electricity; on this account he was several times subjected to the experiment, and the results were: In the un-electrified state 550; in the electrified 390, 330, 270, 550, and 420. In most of these experiments, it appeared that there was rather a decrease.

It has, however, been stated by Mr. Cavallo, that a medical electrician of considerable experience, assured him, "that in a diseased state of the body, an evident acceleration of the pulse is often observed to result from the application of electricity." Mr. Carpe mentions, that having opened a vein from which the blood did not readily flow, he electrified the patient, and the blood then streamed forth freely.

The scientific application of electricity to medicine, has made less progress than the success which has attended it might have been justly expected to produce. It appears from almost every trial of its power hitherto made, that under judicious management its application can do no harm, and that in many of the most distressing disorders, it has frequently been of considerable service. These are powerful recommendations, and when it is added, that it is an external, and by no means painful remedy; and that it may be applied immediately to the affected limb, without interfering with any other part, its advantages must appear to be considerable.

The machine employed for medical purposes should have sufficient power to furnish a constant stream of strong sparks, for in many cases an application of that kind is essential. If it is a plate machine, the diameter of the plate should not be less than from eighteen inches to two feet; if it is a cylinder, the diameter may be from eight to fourteen inches.

The auxiliary apparatus is very simple; the most essential instruments are: 1st, a jar fitted up with Lane's electrometer, fig. 86, by which shocks of any required force may be given; 2d, a pair of directors, fig. 6 and 9. Occasionally one of the brass balls may be unscrewed, and a wooden point substituted for it. When shocks are passed by the aid of these directors, they are applied at the opposite extremities of the part through which the charge is to pass; and being respectively connected by conducting wires, the one with the outside of the jar, and the other with the receiving ball of Lane's electrometer, previously placed at the required distance, the jar may be set to the machine, which is then put in motion, until any required number of shocks has been given.

The insulated director is employed also to give sparks, being held by its glass handle, and its ball previously connected with the conductor by a flexible wire; being brought near the patient, or rubbed lightly over a piece of flannel or woollen cloth laid on the affected part. When the eye or any delicate organ is electrified, the ball of the insulated director is unscrewed, and the wooden point applied at the distance of about half an inch from the part. The stream of electrified air, which passes from the point under such circumstances, produces rather a pleasant sensation. Very excellent flexible conductors for medical purposes, may be made by sewing a thin spiral brass wire, (such as is used for braces,) within a thick silk riband.

The insulating stool employed, should be of sufficient size to receive a chair upon it, with a resting-place in front of the chair for the feet. The patient being placed on the insulated chair, and connected with the conductor of the machine, becomes a part of it, and sparks may be drawn from any part of the body by a person who stands on the ground and presents a brass ball to it. If the ball is held by a wooden handle, the sensation is less painful than when it is held by metal.

The most respectable and most recent collection of cases to which electricity has been applied, is to be found in a very candid little work on the subject, by Mr. Carpe. We feel that we are unable to improve upon the following abstract of its contents made by Mr. Singer, and arranged under the disorders operated upon.

1. Contractions. Those that depend upon the affection of a nerve only; and in many of these it has been employed without effect, whilst in others, of long duration, immediate relief has been obtained.

VOL. IV.
2. Rigidity. Very frequently relieved, but usually requiring some perseverance in the application to complete the cure.

3. Sprains, relaxation, &c. Electricity may be applied in all these cases with good effect, but its application should be deferred until the inflammation has subsided.

4. Indolent Tumours. Strong sparks and slight shocks are often effectual. The most numerous cases are those of scirrhous testes; and there are some instances of the successful dispersion of scirrhous induration of the breast. Ganglions have also been removed from the wrists or feet by the frequent application of sparks.

5. Chilblains. Mr. Carpe states that electricity is a good preventive against chilblains, and mentions two instances in which they were removed by the action of electrical sparks.

6. Epilepsy. In several instances of persevering application, not one successful case occurred.

7. Deafness. Sparks thrown upon the mastoid process, and round the meatus auditorius externus, and drawn from the same parts on the opposite side, usually afford relief; and about one in five are permanently cured.

8. Opacity of the Cornea. This is sometimes cured by the long continued action of electricity thrown for ten minutes a day on the eye by a wooden point. When caused by the small pox it is said to yield most readily. Mr. Singer also mentions an instance in which consideration benefit was received from the application of electricity; but its use could not afterwards be discontinued for more than a week at a time without a return of the disorder.

9. Gutta Serena. The method of electrifying for opacity of the cornea has been successful in some instances of gutta serena; but there are very many unsuccessful cases.

10. Amenorrhoea. Cases of this nature are generally relieved by sparks and slight shocks; but in retention electricity has been tried without success.

11. Knee Cases. In instances of pain and swelling of the knee the application of sparks has been effectual in about one case in ten.

12. Chronic Rheumatism. Very numerous are the instances of success, the usual application is by sparks for ten or fifteen minutes every day. In recent cases a few days sometimes suffice, but in those of long standing very considerable perseverance is often required.

13. Acute Rheumatism. In one case out of six a cure was effected in about a month by the application of the electrified current of air from a point.

14. Paralysis. Moderate shocks, with sparks occasionally, have been successful in about one case of paralysis in every fourteen that have been tried.

15. St. Vitus' Dance has also been frequently relieved by electricity. There is, indeed, scarcely any disease in which some successful instances of its application are not recorded; but we are still in want of a scientific examination of the statements that have been made on this subject. Singer, p. 295.

§ IV. Effects of electricity in the production of chemical composition and decomposition.

The present section will be found by no means so comprehensive as may at first be supposed, for although it is unquestionable that electricity is capable of exerting a very decided influence upon the ultimate molecules of matter, yet this effect is to be traced principally under that modification which the galvanic battery produces. The oxidation of metals by powerful electric explosions, seems to be effected in a great measure by the elevation of temperature, and not immediately by a pure electrical agency. The case at least with respect to metallic wires which are fused, volatilized, and sometimes oxidated by the electric discharge stands thus. It is obvious that the metal becomes intensely heated, and from this cause alone we know that it would be enabled to combine with the oxygen of the atmosphere, and pass to the state of an oxide. Some peculiar predisposing or determining agency may also very possibly accompany the electricity; but as this can only be inferred, and the former source of oxidation is known and apparent, we hold it to be more correct to consider the oxidation thus produced an effect of heat, and therefore to reserve the recorded experiments on this subject for the sixth section of this chapter.

(166.) Dr. Priestley appears to have been almost the Dr. Priestly first person who attempted to apply the power of electricity to chemical purposes. In his experiments upon air he states that Warltie had already fired a mixture of atmospheric air and hydrogen gas by means of the electric spark, and that upon the disappearance of part of the gases a dewy moisture was found adhering to the inner surface of the glass vessel. Priestley contrived to pass a current of electrical sparks from a brass wire through a small quantity of water in a glass tube. The water was coloured blue by litmus, and after sparks had thus passed for two or three minutes, the blue coloured liquor gradually became red, especially at that part which the sparks entered, and the air confined in the
Electricity.

the addition of ammonia, the free acids were saturated, the carbonate of lime was precipitated. The brown colour of the precipitate is supposed to have arisen from the contamination of mercury obtained during the process.

Having confined in the tube some of the same impure oxygen in contact with soap lees, the diminution proceeded rather faster than when lime water had been present; thus it appeared that the greater strength of the alkaline lixivium rendered it more proper than lime water for absorbing and examining the acid produced. Mr. Cavendish then ascertained, that when pure oxygen was employed no absorption was effected, neither was there any when pure azote was enclosed in the tube; but that when five parts by volume of pure oxygen were mixed with three of common air, an absorption almost total took place. Considering common air to contain about one part of oxygen and four parts of azotic gas, it follows that the mixture of five parts of oxygen gas and three of common air was equivalent to seven parts of oxygen gas and three of azotic gas.

Having proceeded thus far, Mr. Cavendish supplied the interior of the tube with a small quantity of the alkaline lees, and then introduced some of the gas mixed in the proportion last mentioned. By a current of sparks diminution of the air kept taking place, and fresh gas was admitted when necessary. At length no further diminution seemed to be produced, and then a little pure oxygen gas, and afterwards a small quantity of common air were added, in order to try whether the cessation of absorption depended upon any failure in the due proportions of the two elements. This not appearing to be the case, the alkaline lixivium was separated from the mercury, and proved to have become perfectly neutral by producing no change in the colour of litmus. By evaporation to dryness a salt was obtained which had the properties of nitre.

Mr. Cavendish subsequently repeated this experiment on a much more extensive scale, and proved incontestably, that the alkaline lixivium was converted into a solution of nitre, that, therefore, nitric acid had been formed during the process, and hence that nitric acid is composed of the oxygen and azotic gases.

(168.) In the order of time it will be necessary for us next to advert to the experiments of Van Marum, Van Troostwyck, &c. made with the great Telnyian machine at Haerlem. For observing the effect produced by transmitting the electric spark through different gases, a cylindrical glass receiver was employed, 6 inches in length and 1½ in diameter. This receiver was inverted, and a ball and wire were affixed by passing the wire through a hole made in the bottom.

By this contrivance a quantity of any gas could be confined over water or mercury; and by bringing the ball near to the prime conductor of the machine a spark would be received, which must escape by passing from the end of the wire within the receiver, through the confined gas, to the mercury or water over which the vessel is supposed to stand. With this instrument it appeared, that oxygen gas obtained from red precipitate underwent a diminution equivalent to ¼th its original volume, and that the properties of the quantity remaining were not altered. On pouring out this air, the peculiar smell which electricity frequently elicits was very perceptible.

Nitrous gas was diminished to less than half its original volume, and being then mixed with atmospheric air, no red fumes appeared, neither was there any condensation. Its usual smell was lost, and it would not support combustion. The surface of the mercury was covered with a sort of powder, containing a new combination formed from that metal.

Hydrogen obtained from the action of dilute sulphuric acid upon iron, underwent no diminution, but communicated a slight redness to tincture of turnsole. This probably arose from a slight degree of impurity from admixture of common air with the hydrogen.

Elefant gas obtained from spirit of wine and sulphuric acid, increased to about three times its original volume, and lost in some degree its inflammability.

Sulphurous acid gas obtained from sulphuric acid and charcoal was diminished a little, and black spots were formed on the inside of the glass receiver. Afterwards it was observed that only 4th of the electrified elastic fluid was absorbed by water. It extinguished a candle and had very little smell.

Muriatic acid gas seemed in a great measure to oppose the passage of the electric fluid, since the sparks would not pass through a greater length than ¾ inches of this air. Considerable diminution was produced, but the remainder was readily absorbed by water.

Carbonic acid gas liberated from chalk by sulphuric acid, was a little increased in volume and rendered less absorbable by water.

Fluoric acid gas was not diminished, nor did it undergo any sensible alteration.

Gaseous ammonia was at first almost doubled in bulk, and then underwent slight diminution. It became unabosrbable by water, and by the contact of flame it exploded, like a mixture of inflammable air with a good deal of common air.

Lastly, common air was tried, and it was found to give a slight redness to the tincture of turnsole, becoming at the same time sensibly deoxigenated. The experiment was repeated thrice at different times, and was examined each time after the electrization, by the admixture of nitrous air in Fontana’s eudiometer, and compared with the same air not electrified, the latter always suffering the greatest diminution. In the first experiment the diminishments were ¼¼ and ¼¼; in the second ¼¼ and ¼¼; and in the last ¼¼ and ¼¼. (Cavallo, vol. i. p. 282.)

In attempting to repeat Mr. Cavendish’s experiment on the production of nitric acid, by electrifying a mixture of the azotic and oxygen gases, Van Marum made use of a glass tube ¼th of an inch in diameter; into the closed end of which an iron wire ¼th of an inch in diameter was affixed; this tube having been filled with mercury was inverted over that fluid and placed in a vertical position, after which the air to be operated upon was introduced. The oxygen gas was obtained from red oxide of mercury, and carefully purified by alkali from any acid vapour with which it might be contaminated. With five parts of this gas three of common air were mixed, and a quantity introduced which occupied three inches in length of the tube. To this there was added ¼th of an inch of alkaline lixivium, such as employed by Mr. Cavendish. By a current of electric sparks transmitted through the tube for fifteen minutes, two inches of the gaseous mixture were absorbed by the lixivium. By further addition of the mixed gas, and continuation of the process, 6¼ inches of air were absorbed. The lixivium proved to
ELECTRICITY.

Practical have become impregnated with nitric acid, but not to Electricity. saturation. With the same lixivium the experiment was resumed, and 14 inches more of air were absorbed; and the rate of diminution did not seem to decrease although the lixivium had now absorbed seventy-seven times its own volume of gas, whereas in Mr. Cavendish's experiment only thirty-eight measures of the air had been taken up.

In a similar experiment made with oxygen gas obtained from muriatic acid, the alkaline liquor was made to absorb 178 times its own volume of gas without seeming to have approached toward the point of saturation. Dr. Van Marum then wrote to Mr. Cavendish on the subject, and was informed that the oxygen gas employed had been obtained from a black powder produced by shaking mercury with lead. On a subsequent application for further information, a misunderstanding arose on the part of Van Marum who supposed that Mr. Cavendish had endeavoured to conceal the process for obtaining this oxygen; and Cavendish to prove that he had made no secret of the matter, published the letter which he had previously sent to Van Marum.

Proceeding with the researches of Van Marum, we learn that oxygen gas obtained from red oxide of mercury, and had been kept a week, underwent a diminution of 4th by the application of electricity for thirty minutes. The surface of the mercury became oxidated, and it would appear that combination took place between the vapour of mercury in the tube and the oxygen; for towards the end of the experiment the glass tube was so coated with oxide as to have ceased to be transparent. By containing some of the same gas over water, and thus acting upon it, a diminution was here also obtained. The cause of this was not satisfactorily investigated, but in all probability it was owing to the absorption of gas by the water.

It does not appear that pure azotic gas electrified alone and then in contact with alkaline lixivium, underwent any permanent alteration.

Nitrous gas confined by lixivium, being electrified during half an hour, lost 4ths of its volume; the lixivium appeared to have absorbed a great quantity of nitric acid; and the gas remaining in the tube did not seem to differ from common azotic gas. Some of the same nitrous gas was confined by lixivium, was, by standing three weeks, diminished to half its volume, and this residuum also proved to be azotic gas.

Hydrogen gas confined by infusion of turpont, was electrified for ten minutes without producing change of colour in the infusion or diminution in the gas.

Three inches of olefiant gas, by fifteen minutes' application of electricity expanded to ten inches. It had then lost its inflammability, and upon the addition of nitrous gas no diminution ensued.

A column of ammoniacal gas three inches in length expanded to six inches in four minutes, but by a continuation of electricity for ten minutes longer, no further increase took place. Water would no longer absorb this air, which had now become slightly inflammable.

The following singular experiment is also described: "two balloons made of the allantoid membrane of a calf, were filled with hydrogen gas, of which each contained about two cubic feet. To each of these was suspended by a silken thread about eight feet long a weight, just sufficient to keep it stationary at a certain height in the air. The balloons were connected, the one with the positive, the other with the negative conductor, by small wires about 30 feet in length; and being kept nearly 90 feet asunder, were placed as far from the machine as the length of the wires would admit. On being electrified these balloons rose up in the air, which was electrified as the wires allowed, then attracted each other, and uniting as it were into one cloud, gently descended."

(169.) M. Achard wishing to ascertain what effect would be produced on air electrified without sparks, filled a Leyden flask with air, (the degree of oxygenation of which he had previously ascertained by an eudiometer,) and electrified it as strongly as possible: he then let it stand a few hours, and examined the air again. Neither contraction nor dilatation had taken place; and the same result was obtained even when he had exposed the jar to abundance of sparks. The quality of the air had not been changed by the mere presence of the electricity.

He then by a careful repetition verified Franklin's experiment, by which it appeared that the quantity of air in a jar was neither increased nor diminished by the introduction of a charge of either positive or negative electricity. The rarefaction of air produced in Kinnerley's air thermometer, (31.) is an expansion solely due to the increase of temperature from the passage of the sparks through a resisting medium.

(170.) The experiments of Priestley on the reduction of the metallic oxides by heating them in hydrogen, are frequently supposed to have led to the knowledge of the compound nature of water. In this, however, as in many similar cases, the general progress of science was such, that this important discovery seems almost to have been made in several places about the same time. About the latter end of 1776, Macquer attempted to ascertain whether any carbonaceous matter were produced in the combustion of hydrogen gas, by holding a china saucer over the flame. He found however only some drops of water upon the surface of the saucer. MM. Bucquet and Lavoisier in September 1777, wishing to learn whether carbonic acid could be produced by the combustion of hydrogen, fired five or six pints of this gas in a wide mouthed bottle, at the same instant pouring in two ounces of lime water. There was no carbonic acid, and the process was such that the water produced escaped unobserved. In 1781, after some attempts made by Mr. Warltire and Dr. Priestley, who fired mixtures of common air and hydrogen in close vessels, and remarked an appearance of dew on the inner surfaces; the complete and satisfactory synthesis of water was performed by Mr. Cavendish, to whom the honour of this discovery is generally and justly ascribed; although it appears that Mr. Watt, who had reasoned upon Priestley's experiments, had arrived at a similar conclusion, which he communicated to Dr. Priestley by letter, dated April 26, 1783. Mr. Cavendish, in 1781, burned 500,000 grain measures of hydrogen, and having collected 135 grains of pure water, ventured upon the bold conclusion, that water was compounded of the two gases, oxygen and hydrogen. The celebrated Lavoisier having had a different opinion in view, though he made many experiments on these substances, did not arrive at the true composition of water, until he was informed by Sir Charles Blagden of Mr. Cavendish's result, which he immediately verified upon a large scale.
ELECTRICITY.

The Journal de Physique for 1789, contains an account of the discovery of the decomposition of water by electricity, made and communicated by three associated Dutch chemists, Messrs. Paets, van Troostwyck, and Dieman. They set out by reasoning upon the theories which then agitated the chemical world respecting the constitution of water, and either inadvertently or disingenuously attribute the knowledge of its synthesis to Lavoisier and the French chemists. They proceed to state that "being employed with Mr. Cuthbertson in an investigation of the effects of electric shocks on different substances, they had the curiosity to observe its effect upon water also. For this purpose they filled a tube of 4th of an inch in diameter, and a foot in length, with distilled water. One extremity of the tube was hermetically sealed, and a gold wire was closed in it, which projected an inch and a half within the tube. The other extremity of the tube was immersed in a small glass vessel full of distilled water, and another wire passed through this aperture and went up into the tube so as to be 4ths of an inch distant from the first mentioned wire. In order to transmit the electric shock, the wire was immersed through the water contained in the tube, between the extremities of the two wires, the closed end of the tube was placed against a copper ball standing insulated at some distance from the prime conductor of the machine; and a communication was made from the extremity of the wire which stood in the vessel full of water, to the outside of a Leyden jar, having one square foot of coated surface, and whose knob communicated with the prime conductor. The electrical machine employed was a very powerful double plate one, on the Teylerian construction, causing the jar described to discharge itself twenty-five times in fifteen revolutions. By a series of shocks with this apparatus, decomposition was effected, and the upper part of the tube was speedily filled with gas. As soon however as the electrical discharge passed through any portion of this gas, a re-union instantly took place, water was formed, and there remained only a small quantity of air which did not entirely disappear; and upon repeated trials it was found that a fresh discharge passed through this residuum would produce further combination, and thus the volume of gas remaining, though never entirely recomposed, become only 4⁄7th of that volume originally produced by the decomposition.

These experimentalists concluded, that the gas produced by the electrical discharges, was a mixture of oxygen and hydrogen from decomposed water;

1st. Because no other gas than oxygen known would instantly disappear on passing an electric spark through it; and 2dly. That the gases obtained must have been oxygen and hydrogen, from the decomposition of the water, because they were in such proportions that their recombination produced water; the small gaseous residuum being probably a portion of air previously held in a state of mechanical admixture with the water.

They found that liquida which were compounded of other elements beside hydrogen and oxygen, such as sulphuric and nitric acids, afforded gas by the action of electric discharges, but such that it did not again disappear upon passing an electric spark through it; but was condensed by the addition of nitrous gas over water. Hence it would appear that oxygen gas had been evolved by the partial deoxidation of the bases of these acids.

The experiments last recited, were carefully repeated by Dr. Pearson. He first states that the decomposition of water by electricity may be effected by what he calls the interrupted explosion, employed by the Dutch chemists, or by the uninterrupted or complete explosion.

For the success of the former process, Dr. Pearson considers it necessary that the machine should be of considerable power, and prefers a plate machine to one made with a cylinder. The jar should have 150 or 160 square inches of coated surface; and the distance between the insulated ball and the prime conductor must always be less than the distance between the extremities of the wires. The distance between the extremities of the upper and under wire, which seemed to answer best with the power already described, was from 3ths to 4ths of an inch. The diameter of the upper wire cannot be too small, and the diameter of the tube should not be more than 4th nor less than 1⁄16th of an inch. The apparatus employed by Dr. Pearson for the other process, is described in his memoir on the subject.

On the whole, his experiments led him to conclude that the mere concussion of the electric discharges, appears to extricate not only the air mechanically combined with water, and separable by boiling and the air pump, but also a further portion upon which these two processes have no effect. The quantity of this air differed greatly in several specimens of water operated upon; but in all cases, though varying in purity at different periods of the process, it seemed to consist of a mixture of oxygen and nitrogen, such as is found to constitute our atmosphere.

After this air, which is supposed to exist unchanged in a state of admixture with the water, has been removed by the first application of the discharges, the true decomposition of the water by the separation of its two gaseous elements commences, and the following are the properties of the mixed gas produced. Immediate condensation by the transmission of an electric spark, with the reproduction of water. The addition of some nitrous gas produced an immediate absorption, probably from the formation and solution of nitric acid.

To the quantity remaining after the oxygen had been saturated by nitrous gas, a fresh portion of oxygen was added, and upon passing an electric spark through a quantity of this mixture well dried, immediate condensation with deposition of moisture was produced. Several other ingenious experiments tendency to confirm the opinions which these admirable researches had induced, will be found by a reference to the paper from which these leading facts are extracted.

(172.) In all these experiments we have seen, that Dr. Wollaston to effect the decomposition of water, it was necessary to employ a succession of discharges from a coated surface, and that a series of sparks as they had hitherto been applied, was from some cause or other incapable of producing a similar effect.

This anomaly, if such it can be considered, was removed by Dr. Wollaston in the year 1801. This most accurate philosopher, who seems to possess a peculiar power of justly estimating the relative magnitudes of cause and effect, and of compelling their mutual adaptation; together with a skill in all manipulations
Electricity, any, gives the following account of his process:

"It has been thought necessary for the decomposition of water to employ powerful machines and large Leyden jars; but when I considered that the decomposition must depend upon duly proportioning the strength of the charge of electricity to the quantity of water, and that the quantity exposed to its action at the surface of communication depends on the extent of that surface, I hoped that by reducing the surface of communication, the decomposition of water might be effected by smaller machines, and with a less powerful excitation, than have hitherto been used for that purpose: and in this hope I have not been disappointed.

"Having procured a small wire of fine gold, and given it as fine a point as I could, I inserted it into a capillary glass tube; and after heating the tube so as to make it adhere to the point and cover it in every part, I gradually ground it down till, with a pocket lens, I could discern that the point of the gold was exposed.

"The success of this method exceeded my expectations. I coated several wires in the same manner, and found that when sparks from the conductors before-mentioned were made to pass through water, by means of a point so guarded, a spark passing to the distance of 1/120th of an inch would decompose water, when the point exposed did not exceed 1/240th of an inch in diameter. With another point, which I estimated at 1/240th of a successions, sparks 1/240th of an inch in length, afforded a current of small bubbles of air.

"I have since found that the same apparatus will decompose water, with a wire 1/240th of an inch diameter coated in the manner before described, if the spark from the prime conductor passes to the distance of 1/240th of an inch of air.

"In order to try how far the strength of the electric spark might be reduced by proportional diminution of the extremity of the wire, I passed a solution of gold through a capillary tube, and by heating the tube expelled the acid. There remained a thin film of gold, lining the inner surface of the tube, which by melting the tube was converted into a very fine thread of gold, through the substance of the glass.

"When the extremity of this thread was made the medium of communication through water, I found that the mere current of electricity would occasion a stream of very small bubbles to rise from the extremity of the gold, although the wire by which it communicated with the positive or negative conductor, was placed in absolute contact with them. Hence it appears that decomposition of water may take place by common electricity, as well as by the electric pile, although no discernible sparks are produced. The appearance of two currents of air may also be imitated, by occasioning the electricity to pass by fine points of communication on both sides of the water; but in fact the resemblance is not complete; for, in every way in which I have tried it, I observed that each wire gave both oxygen and hydrogen gas, instead of their being formed separately, as by the electric pile.

"I am inclined to attribute the difference in this respect, to the greater intensity with which it is necessary to employ common electricity; for, that positive and negative electricity so excited, have each the same chemical power as they are observed to have in the electric pile, may be ascertained by other means." Phil. Trans. 1801, p. 432.

(173.) Before we finally take leave of gaseous composition and decomposition, we shall introduce the following observations and table from Mr. Singer, with slight numerical corrections, such as the knowledge of the present time may afford.

"In these experiments the gases are usually exposed to the action of electricity in a closed tube with two wires passing through its sides near the closed end: the tube is filled with mercury, and inverted in a vessel of the same fluid, and the gas being then introduced until it presses the mercury below the wires, sparks are passed between them until the required change is produced; with mixtures of inflammable gases and oxygen, the first spark usually produces the change, but with other mixtures it is sometimes necessary to continue the current of sparks for hours.

"When figures are prefixed to the gas or to the result in the following table, they indicate the proportional measures employed or produced. The use of different proportions will frequently occasion a variation in the result:

Oxidation and deoxidation.

Practical to its influence, of promoting their union; we might by incidental changes in quantity or temperature. That peculiarity of their physical condition exists in the manifestation a power of disuniting the elements of a compound by means of them through the solution. After 100 turns of the machine, the wire which communicated with what is called the negative conductor, had a precipitate formed upon its surface, which upon beingburnished was evidently copper; but the opposite wire had no such coating. Upon reversing the direction of the current of electricity, the order of the phenomena was of course reversed; the copper being shortly redissolved by assistance of the oxidating power of positive electricity, and a similar precipitate formed upon the opposite wire.

Similar results were obtained from gold wires, and a solution of corrosive sublimate. The machine employed was a cylinder of seven inches diameter, having a conductor on each side 16 inches long and $\frac{3}{4}$ inch in diameter, each furnished with a sliding electrometer to regulate the strength of the spark received from them.

Having brought forward this instance of deoxidation...
by negative electricity, Dr. Wollaston shows by the following experiment upon vegetable colour, the oxidizing power of positive electricity.

“A card being coloured with a strong infusion of litmus, I passed a current of electric sparks along it, by means of two fine gold points, touching it at the distance of an inch from each other. The effect as in other cases depending on the smallness of the quantity of water, was most discernible when the card was nearly dry. In this state, a very few turns of the machine were sufficient to occasion a redness at the positive wire, very manifest to the naked eye. The negative wire being afterwards placed upon the same spot, soon restored it to its original blue colour.”

§ V. Effects of electricity in the development of light from phosphorescent bodies.

(177.) Of that electrical affection of bodies by which light is developed, we have already given some account in the articles from (29.) to (41.) inclusive, and have there introduced that which we conceive to be the most probable explanation of the production of the light which usually accompanies an electric discharge in atmospheric air. Were we acquainted with the true and complete solution of this interesting problem, we should be better able to confine the researches we are about to describe, to that specific branch of our subject, to which we suppose have there introduced that which we conceive to be the nature of light, that we must attribute the difficulty we experience in attempting to draw a plain line of distinction between the subject of the sections already mentioned, and that which we are now entering upon. If we were to suppose with some, that light is a substantial fluid, united by various forces of attraction to bodies, in which it is capable of assuming a latent state, we might consider the former experiments to relate principally to various methods of exciting its sensible properties in any given substance; and in that case the present series may comprehend the action of some one invariable method by the repeated application of which certain effects are produced upon different substances, according to the degrees of power or affinity with which these substances are able to absorb the rays of the luminous principle or fluid.

Why should an electrical spark of the same intensity be of different colours when received from substances dissimilar in their nature? How are some bodies enabled to retain for a time a luminous appearance which they acquire by the passage of an electrical discharge through them, while others do not so? If a flash of light, produced by an electrical discharge in the presence of several substances which form no part of the circuit, communicate to some phosphorescent properties not; and where light is developed the colours are different upon different bodies; where is the theory of light sufficiently extensive to give a complete explanation of all these phenomena?

(178.) To return from these at present useless speculations, which depend rather upon the nature of light, than upon the manner of electrical action, we propose to give a condensed view of the researches of Mr. Skrimshire, which fall within the peculiar province of this section.

It has been proved by Morgan, that there is no fluid, nor solid body, that may not be rendered luminous by the transmission of an electrical discharge through its substance; and that the difficulty of producing this appearance in all bodies increases as the conducting power of the body decreases. Thus, fluids confined in glass tubes into which metallic wires passed through perforated corks, exhibited this appearance by the transmission of a charge between the extremities of the wires placed at a small distance from each other. In consequence of the conducting power of the metals, it was necessary to reduce the dimensions of the channel of communication very greatly before any luminous effects could be produced; of this we have already mentioned an instance. (37.)

In different states of the same body, the ease with which light was developed, increased with every diminution of density; this was proved with the vapour of ether, spirit of wine, and water. The mineral acids, Mr. Morgan considered good conductors; for he found that to obtain a luminous discharge through them, it was necessary to draw a line of the acid upon a plate of glass with a camel’s hair brush. For some other interesting results of a similar nature, we can only refer to the paper published by Mr. Morgan. (Phil. Trans. 1785.)

Mr. Skrimshire’s experiments, to which we have Phosphorescence. before alluded, were performed by placing the substance to be tried, upon a brass plate fixed horizontally upon the ball of a prime conductor; an attempt was then made to obtain a spark from the substance by means of a common discharger. The body was next placed upon a table or wooden stand, and the shock from a Leyden phial first passed over it, about a quarter, or half an inch above its surface; and then, lastly, the discharge was made to traverse its surface, by resting the points of the discharging rods at an inch or more distant from each other upon the stone to be tried. In all these experiments it was found convenient to keep the eyes closed until the sound of the discharge had been heard.

Calcaceous bodies

Are all more or less phosphorescent; and the spark passed along the surface of a piece of rhombic spar was reflected so intensely, as to illuminate the whole table with a brilliant white light.

Common chalk was rendered extremely luminous by passing the shock at some distance above it. The fluid, when passed along the surface, left a vivid zig-zag track of light which continued several minutes.

Ketton stone. Next to chalk in excellence; by passing the shock along the surface, the stone was shattered, and luminous fragments were dispersed in all directions.

Crystal of sulphate of lime produced a vivid greenish light, continuing a few seconds only.

Fresh crystallized nitrate of lime gave sparks of a
Practical ELECTRICITY.

Flame red colour; but did not permanently retain the light.

Muriate of lime rather more phosphorescent than the nitrate.

All the flutes absorbed the light freely; the dark purple spars afforded no spark; but allowed the electric fluid to pass in a purple stream, accompanied with a whizzing noise, whilst a yellowish flour, and another with a greenish tint, which were phosphorescent by heat, afforded very good sparks.

Canton's phosphorus was rendered more luminous by the electric explosion than any substance hitherto tried.

Phosphate of lime. All bones became luminous by the absorption of electric light; the enamel of the teeth still more so. Ivory, very phosphorescent and easily perforated by a discharge.

Phosphuret of lime gave a minute red spark, and was but slightly phosphorescent upon the discharge being made above it. A very small discharge however, if passed through it, was found sufficient to determine the commencement of its combustion.

The testaceae, lithophyta, and all calcareous fossils, imbibed the electric light with facility.

Marbles, lime-stones, stalactites, and spars were phosphorescent; calcined oyster-shells and belemnites beautifully so; and yet quick-lime, fresh from the kiln, ranked among the least phosphorescent of the calcareous genus. Skrimshire, Nicholson's Jour. vol. xvi. p. 281.

Barytic minerals.

Carbonate of barytes afforded no spark; but became for a short time very luminous by the passage of a shock above it.

Sulphate of barytes gave good sparks, but did not become very luminous by the shock. "It is curious that in these two barytic species the facts turn out exactly the reverse of what takes place in the calcareous genus, in which the carbonates give sparks, though they are but slightly luminous compared with the sulphates, which are brilliantly phosphorescent, but give no spark; whereas in the barytic genus, the carbonates are beautifully luminous, but give no sparks; while the sulphates afford good sparks, but are only slightly phosphorescent."

Sulphuret of barytes became only very slightly luminous.

Magnesian minerals.

Pure and carbonated magnesia were both rendered transiently luminous.

Sulphate of magnesia, very luminous through its whole substance.

Sulphuret of magnesia, luminous, but not more so than the carbonate.

Kesefkil of Turkish pipes afforded sparks, but was scarcely luminous, unless the discharge were passed along the surface of the mineral.

Chlorite was rendered luminous by the explosion, and gave singularly coloured sparks.

Steatites, talc, and fibrous amianthus gave sparks, and became slightly luminous by the explosion.

Mica afforded sparks, but did not appear to become luminous by the explosion.

Micaeaceous schistus gave a ramified and coloured spark. Was scarcely phosphorescent, except in the track of the electric fluid.

Argillaceous genus.

Allum, purple spark, luminous by explosion above the surface; shattered by the shock.

Pipe-clay gave sparks; was luminous by the explosion, but not after burning.

Shales and clays generally gave sparks, and became luminous by the explosion.

Slates: all kinds gave sparks, and absorbed light from the explosion.

Hone-stone gave a spark, and became phosphorescent.

Fuller's-earth: a good bright spark, but very feebly luminous.

Reddle: no spark, but rather more luminous than fuller's earth.

Bose: a ramified spark, but not rendered luminous.

Terra sigillata gives a spark, and becomes luminous by the explosion.

Basil gives sparks; but a luminous trace is only to be formed by resting the points of the discharger upon its surface.

Burnt brick afforded small purple sparks; became slightly luminous by the explosion, but afforded a bright track of light between the points of the dischargers when rested upon the surface.

Queen's-ware gave a good spark, but was not phosphorescent.

Glazing of pottery containing a metallic oxide: not phosphorescent, but gives a good spark.

Silicious genus.

Rock crystal: phosphoric by the explosion.

Silicious sand, washed and dried, luminous only where the points of the discharger were in contact with it.

Quartz is phosphoric, gives no spark but a purple stream; and after the explosion it affords the same odour as when two pieces are rubbed together.

Flints afford small purple sparks.

Egyptian pebbles, felspars, agates, caecedonies, and jaspers, gave hissing purple sparks, and became luminous by the explosion.

Porphyries and granite gave a hissing purple spark; were also luminous by the shock which passed along the surface, producing a very bright track of light, which in some specimens continued luminous for several minutes.

Pudding-stones: a hissing spark; the pebbles more luminous than the cement.

Mochas gave good sparks from the arborescent part, but only a hissing stream from the clear part of the stone. Skrimshire, Nicholson's Jour. vol. xvi. p. 107.

Combustible bodies.

Sulphur: roll brimstone: no spark; flowers of sulphur are not phosphorescent.

Phosphorus: inflames both by spark and shock.

Charcoal: some kinds afford sparks, and are phosphorescent; but other specimens had not this property.

Coke gives a good spark, but is not luminous.

Cannel coal and common coal give beautiful sparks. Peat, hard and dry, affords a good spark; but is scarcely luminous.
Metals and their oxides.

Not one of the metals is phosphoric by exposure to the light of an electric explosion, if its surface be clean and bright. Some of their ores and oxides become slightly luminous, while many others have not this property in the smallest degree. In short, throughout all these experiments, not one brilliant appearance of phosphorescence was produced by any metal, ore, or oxide submitted to trial. Skrimshire, Nicholson's Jour. vol. xix. p. 153.

Mr. Singer has described a few experiments analogous to those in his Electricity, p. 201. In addition to the papers already quoted, the reader may consult Gray, Phil. Trans. 1735; Canton's Figures of Sparks, Phil. Trans. 1754; Lane, Phil. Trans. 1767; Crell, Jour. de Phys. 1717; Nicholson, Phil. Trans. 1768; Eandi, Mém. Tur. Par. 1759; Nollet, on the Illumination of Ice, Mém. Acad. Par. 1766; Nairne, Phil. Trans. 1777, p. 614; Morgan, Phil. Trans. 1785, p. 272.

§ VI. Effects of electricity in the evolution of heat.

(179.) By transmitting electrical discharges through small strips of metal, Franklin found that the metal frequently underwent fusion. The method he employed, was to confine the metal between two plates of glass firmly tied together; and then to place this apparatus within the circuit of the electrical discharge from a jar or battery. The glass planes are frequently broken, and sometimes the metal seems to undergo oxidation and vitrification, by which it is enabled to combine with the surface of the glass. Thus a piece of gold-leaf was found by Franklin, either from this process, or simply from having become imbedded in the glass, to resist the action of nitro-muriatic acid, with which he attempted to dissolve it. Experiments upon the fusion of metals may be found in the writings of Franklin, Canton, Priestley, and Beccaria; but it is from the labours of more recent electricians that we must draw the few facts which we hold essential to introduce to our readers.

If the charge from a large jar be passed through a small wire, such a degree of heat is evolved, as to produce the ignition of the wire. In this phenomenon the sudden transit of the electric fluid is the primary cause; but of the specific mode by which such an effect is produced, we are at present entirely ignorant. If that which we term electricity be in reality a substantial fluid, it would be consistent with observed analogies, that when a considerable mass of this eminently expansible fluid is forced through a very small channel, and thereby greatly condensed, heat and light should be evolved. The immense velocity of the motions of electricity, will also account for its possessing a very considerable momentum, even should its specific density as a fluid be exceedingly small; and on this supposition it may, in its passage, produce all the effects of violent impact upon the material particles of the substances through which it passes. Should it not possess any of the characteristics of material substance, and be only a property or affection of matter; still, it is obvious from its expansion and other effects, that it acts upon the particles of all matter, in the same way that tangible substance would do; and therefore the heat which it produces, may be supposed to arise, in part at least, from the mechanical compression undergone by that body in which the heat is developed.

We have already remarked, that by the passage of a strong shock, longitudinally through a metallic wire, the length of the wire is diminished, and its diameter proportionably increased; but if the shock be passed through a similar wire, having a weight suspended by it, so as to produce a considerable degree of tension, the length of the wire becomes increased. This fact, we conceive, will admit of an easy explanation, on the supposition that the temporary increase of heat brings with it a corresponding increase in the freedom of motion among the metallic particles, though it may not amount to fluidity; thus, for a short time, the force of tension exceeds the force of absolute tenacity, and the wire is lengthened.

(180.) Some experiments of Dr. Van Marum were made with a view to ascertain the circumstances under which heat was communicated to bodies by electricity, and the sparks were transmitted through imperfect conductors, in order to increase their energy. For this purpose a wooden rod, one inch in thickness and eleven inches in length, was placed between the ball of the conductor, and the conducting wire. A rod of red fir, after having been electrified for three or four minutes, gave sensible signs of heat; and a thermometer sunk into a hole made in the wood, rose in three minutes from 51 to 84 degrees, and in five minutes to 112 degrees. As the sparks, however, often penetrated under the surface of the rod, it at length split at the end, and continually threw out rays sideways, so as to imitate the effects of lightning.

(181.) A very copious selection of experiments upon the fusion and ignition of metallic wires by electrical discharges, might be made from the papers of Mr. Brooke, Baron Keimayer, Van Marum, Cuthbertson, and Mr. Singer. For this however space cannot now be afforded, and therefore we must content ourselves with abridging the general observations of this last author upon this subject.

"When a powerful electric charge is passed through a slender iron wire, the wire is ignited or dispersed in red hot balls. Very large batteries were formerly considered essential to the production of this effect; but if the wire be sufficiently thin, a single jar, exposing a coated surface of about 100 square inches will suffice. The finest flatted steel wire sold at the watchmakers tool shops, by the name of watch pendulum wire, answers exceedingly well. Cuthbertson's balance electrometer should be employed to regulate the charge; the circuit from the inner to the outer surface of the jar should be short as possible; and the wire intended to be melted placed in a straight line, and confined at the ends by small forceps."
Practical. "The inside of the Leyden jar, and the bent arm of the elecrometer, being connected with the positive conductor of an electrical machine, and two inches of watch pendulum wire placed by means of the forceps, between the lower insulated ball of the elecrometer and the coating of the jar, the slider is to be set on the graduated arm of the elecrometer to 15 grains. The machine is then to be put in motion, and when the intensity of the charge exceeds the resistance of 15 grains, the beam of the elecrometer will descend, and the charge passing through the two inches of wire will render it red hot, and melt it into balls." (Cuthbertson.)

Exp. "If the jar has not a paper ring, it must now be breathed into, and eight inches of pendulum wire being placed in the circuit, the slider of the elecrometer is to be set at 30 grains, and the turning of the machine resumed. When the charge is sufficiently intense, the beam of the elecrometer will descend, and the charge passing through the eight inches of wire, will melt it with the same appearances as the two inches in the last experiment." (Cuthbertson.)

Exp. "Arrange eight inches of wire in the circuit, as in the last experiment; but instead of one jar, charged to 30 grains, employ two jars charged to 15 grains. The wire will be melted precisely in the same manner; so that the effect is equally increased by doubling the extent of coated surface, or the height to which it is charged." (Cuthbertson.)

"From numerous experiments of this kind, it has been concluded by Mr. Brooke and by Mr. Cuthbertson, that the action of electricity on wires, increases in the ratio of the square of the increased power; since two jars, charged to any given degree, will melt four times the length of wire that is fused by one jar; and this will be again quadrupled by doubling the height of the charge." Van Marum had arrived at a different conclusion; for his experiments led him to suppose, that the lengths of wire found by different numbers of jars, varied directly as the extent of coated surface. Mr. Singer, however, contends for the accuracy of Cuthbertson's law; but he reminds us of the caution necessary to be employed in estimating the variations in the powers of different jars, having the same superficial extent of coated surface, if the thicknesses of the jars be unequal. The same author mentions a very large jar in his possession, which, "from the extent of its surface, ought to fuse two or more of the small feet of wire with a charge of 30 grains; but from its limited electrical capacity, in consequence of extreme thickness, it will melt only 18 inches; and this is correspondent to the conclusion drawn by Mr. Cavendish, that the quantities of electricity required to charge different coated jars of the same extent, will be in the inverse proportion of their thickness." Singer, p. 179.

"The effects of gradually increasing the power of the charge, when wires of the same length and diameter are employed, are very remarkable. If the wire be iron or steel, its colour is first changed to yellow, then (by an increased charge) blue, by a further increase it becomes red hot, then red hot and infused into balls; if we continue to increase the charge, it becomes red hot, and drops into balls, then disperses in a shower of globules, and, lastly, disappears with a bright flash, producing an apparent smoke, which, if collected, is a very fine powder, Chap. VI. weighing more than the metal employed, and consisting of it and a portion of the oxygen of the atmosphere with which it has combined."

Van Marum found that in discharging 225 square feet of coated surface through 50 feet of iron wire, \(\frac{1}{4}\)\(\text{th}\) of an inch in diameter, a complete restoration of electrical equilibrium was not effected at once; and that the residuum in the battery, was capable of melting two feet of the same wire. He has given a statement of the lengths of wires of different diameters, and of different metals, which his powerful machine enabled him to fuse upon a splendid scale. Unfortunately, however, these experiments do not present us with any very definitive results, for the fusing points of the metals may be more accurately estimated by other processes; and, supposing such a point in the scale of temperature already known for each metal, the variations in conducting power with regard to heat, and the interference of atmospheric changes, leave us no reasonable hope that the electrical conducting powers of the metals can be ascertained by this process, although it is probable that on the degree of perfection or imperfection of this property, the evolution of heat is dependent.

On the whole, however, he found that with wires of different metals, all drawn to the \(\frac{1}{4}\)\(\text{th}\) of an inch, and with an equal electrical charge, he could fuse of lead wire 120 inches; of tin wire, the same quantity; of iron wire, 5 inches; of gold wire, \(\frac{3}{4}\) inches; and of silver or brass, or copper only, \(\frac{1}{4}\)\(\text{th}\) of an inch. From these experiments he infers that lead is the worst, and copper the best metal for the formation of conductors for defending buildings from lightning. (192.) Mr. Cavallo examined the fusion of grains of native platinum by electricity; the metallic grains were placed in a groove \(\frac{1}{4}\)\(\text{th}\) of an inch deep, made upon the surface of a cake of wax. Through a line of metallic particles thus arranged, it was easy to discharge a battery, and the grains of metal were by these means partially, but evidently fused, so that sometimes two or more of them adhered together.

As the grains of metal, when promiscuously taken, were sometimes large, and at other times small; one might have expected, that the small grains would have been fused easier than the large ones; but this was by no means always the case; some of the small grains were so refractory as not to show any marks of fusion when examined with the microscope, even after having suffered several electric shocks. On the other hand, some of the large grains were frequently agglutinated together by a moderate shock. Upon the whole, it seems that the whiter grains are fused more easily than those of a dark grey colour. Cavallo, iii. p. 352.

These differences in the fusibility of the grains of crude platinum, are strong proofs of the accuracy of Mr. Cavallo's observations; for it will be obvious to every mineralogist, that the more fusible particles were probably the substance which Dr. Wollaston separated by, their appearance, and proved to consist of the alloy of iridium and osmium. Cavallo found that the impure parts of the platinum ore, which were contaminated by particles of gold and iron, were much more easy of fusion; and that filings of pure platinum were more easily melted by this process than the crude grains were. He also remarks, "that
the degree of fusibility of different metallic substances, when exposed to the action of electric shocks, is by no means the same as takes place in chemical furnaces; which shows that the electric fluid is not the same thing as the element of fire; the effects, in general, seeming to be proportionate to the degree of resistance which it meets with in its passage; but with respect to metals, the degree of fusibility which they show in this way, seems to be in the compound proportion of that resistance which each particular metal offers to the passage of the electric fluid, and of its natural degree of fusibility, when exposed to a common fire.

(183.) We now proceed to give some account of those experiments in which the heating power of the electrical discharge has been employed to assist the combination of metallic bodies with oxygen. Of these the earliest, which it may be interesting to examine, were made by Mr. Cuthbertson. This electrician seems to consider that Van Marum and himself were the first to suppose that the oxidation of metals could be produced by electricity; there is, however, much to that purpose in the treatise of Beccaria, dell’Elettricismo Artificiale. Cuthbertson states that, in 1787, he and Van Marum had produced flocculi from different metals, by subjecting them to strong electrical discharges; but that several accidents happened to their apparatus, which was so frequently broken to determine Van Marum (much to the dissatisfaction of Cuthbertson) from all further prosecution of these researches. In 1792, 1793, Mr. Cuthbertson undertook two courses of experiments at Amsterdam upon this subject, which ended, as he says, "with little more information than we before possessed." Subsequently, however, he returned to the same pursuit in London, and with better success. The instrument employed is represented in fig. 90, and may be thus briefly described. A glass cylinder, eight inches long and two and a half in diameter, is closed at its two ends by brass caps. The lower cap is supported by an artificial brass cock, and bears upon its inner surface a small reel. Upon this reel there is wound a fine packthread, along which a metallic wire runs evenly, and is tied to the packthread at every fourth inch. A brass tube about three inches long is screwed into the upper cap, and filled with lard and tow, so that the packthread and wire may be drawn through it from the reel, while the cylinder remains perfectly air-tight. The wire by this means may be submitted to the electric discharge in successive lengths, without opening the cylinder. A is a gage formed of a graduated glass tube, about 10 inches long, which may be screwed upon the end of the stopcock; and by immersing the lower end of the tube in mercury, and opening the stopcock, the air absorbed by any number of discharges is easily ascertainment.

After an explosion made in common air, it is found by examination, that some portion of the oxygen has been abstracted; and if the fusion of the wire be effected, having the cylinder filled with hydrogen or nitrogen, no absorption is produced, neither is there any oxidation of the metal.

The following is a synoptic view of the results obtained by Mr. Cuthbertson, upon a length of 10 inches of different metallic wires, with a battery of fifteen jars, containing about 17 feet of coated surface. The second column contains the diameter of each wire in parts of an inch; the third, the intensity of the charge in grains upon Cuthbertson’s electrometer; and the last, the colour of the resulting oxide.

These experiments may be varied, by exploding the wires when stretched parallel to and at about 4th of an inch distant from the surface of a sheet of paper or glass; in either case a very beautiful figure is impressed, and on glass a part of the metal in an oxidated state appears immediately under the wire; whilst the oxidated portion produces a figure of some width, by which it is encompassed. The colours of the oxides produced in this way, differ from those obtained in receivers, many colours being, in some instances, procured from one metal.

A great variety of results may be seen in Mr. Cuthbertson’s work, p. 197; but as these charges were so high as to risk the fracture of the battery, Mr. Singer used in his experiments finer wires, and of shorter length, with a more moderate charge. The following is a tabular view of his results; the length of wire exploded in each case being five inches.

Singer’s *Electricity*, p. 186.

It must be obvious to any one acquainted with the chemical properties of the metallic bodies, that many of these are only imperfect instances of oxidation; and that in all cases there is probably an admixture of metallic particles and true oxide, which, on analysis, would be found to differ in proportion at each successive trial.

§ VII. Effects of electricity upon magnetic bodies.

(184.) The effects to which this section will be limited, are those only which are developed by the action of the common electrical machine. The discovery of Professor Oersted has, indeed, established, beyond question, the truth of the long-suspected connection between electricity and magnetism. This
distinguished Dane, and those who have pursued the researches to which he pointed out the approach, have proved that in substances of appropriate nature, electricity may always be employed as the source of magnetic excitation. On that branch of electricity, however, which lies within the peculiar province of this article, scarcely any additional information has been obtained. A series of electro-magnetical results has been brought to light, of interest and importance almost unrivalled in the annals of science; but it was from voltaic electricity that these results were obtained, and of these an ample account has already been given under the Magnetical division of these treatises.

In the Philosophical Transactions for 1676, is an account of the effect produced upon the magnetic properties of a compass needle by a violent thunder storm. The thirty-ninth volume of the same work contains two accounts of the communication of magnetism to iron by lightning, which took place at Wakefield, in Yorkshire. Other similar descriptions will be referred to at the close of this section. In one of these instances, which took place on board a ship bound from New York to London, four compasses were totally unfit for service. These, on their arrival, were submitted to the examination of Dr. Gowin Knight, who found that, besides the destruction of magnetism in the needles, several pieces of wire which had been employed in the construction of the cases, had received charges of permanent magnetism.

(185.) Facts such as these could not be overlooked by Dr. Franklin, who, in enumerating the instances of analogous effects produced by lightning and electricity, brings forward the following experiments in confirmation of his surmises of the identity of these two agents.

By transmitting the discharge of four large jars through a common sewing needle, the needle had acquired magnetic properties, and would assume the position of the magnetic meridian, upon being placed so as to float upon the surface of water. If at the time of passing the discharge through it, the needle lay in the plane of the magnetic meridian, that end which then pointed north continued afterwards to assume the same position when freely suspended; and this result underwent no change, whichever way the discharge passed through the needle, whetber from the northward to the southward, or the contrary. But if the needle were first placed, so as to point east and west, that end of the needle at which the vitreous electricity entered, would afterwards point to the north.

It appeared also that the degree of magnetic intensity developed in a needle, by the transmission of a given electrical charge, was greater when the needle had been laid pointing north and south, than it was when the needle had been made to point east and west.

The charge of a large jar or battery, passed through a steel wire placed perpendicular to the plane of the horizon, communicates to it permanent magnetism, and the end which was nearest to the earth at the instant of the discharge, afterwards, in traversing, turns to the north. By replacing the wire in its vertical position, but with the ends reversed, and again transmitting the discharge, the polarity will either be absolutely destroyed, or if not, the poles will be reversed. It is found also, that the polarity of a natural lodestone may be destroyed by the transmission of a powerful electrical discharge.

The experiments of Franklin were verified and extended by Beccaria, who found that lightning always communicated magnetic polarity to bodies containing iron, such even as common bricks. Reasoning upon this principle, he was able, by observing the polarity acquired by such substances, to trace the direction in which the electrical discharge had passed through those bodies that had been struck by lightning. This ingenious philosopher made also some theoretical suppositions respecting the constant circulation of electric matter as a cause of magnetism, and an explanation of polarity; which the discoveries of the present day seem not unlikely to confirm.

Mr. Robins described in the Philosophical Transactions for 1746, the disturbances produced upon the compass needle, simply by a slight friction upon the outside of the glass; but these effects seem to have been due to electrical attraction only, which, for the time that it lasted, was sufficient to overpower the terrestrial magnetism, and derange the natural position of the needle.

A very elaborate series of experiments by Van Marum served only to confirm the accuracy of Franklin's results, and added little of novelty to this branch of our investigations. He found, however, that when a steel bar was placed in the magnetic equator, no electricity was communicated by passing a discharge through the bar longitudinally; but that if the discharge were passed at right angles to the axis of the bar, a considerable degree of magnetic polarity was developed, and that the end which lay towards the east, afterwards became the north pole of the bar.

These experiments were made with a battery of 135 jars, containing 130 square feet of coated surface. Needles of various sizes were operated upon, and steel bars as much as nine inches in length. It was also found that whenever the charge of the battery was so great, with reference to the steel bar, as to produce ignition, no magnetic effect was developed.

CHAPTER VII.

On the various sources of electrical excitation, and on the peculiarities attendant upon its development, from each of these sources.

Introduction.

(186.) It remains only that in this chapter we should give a more complete statement of those processes by which the electrical properties of bodies may be developed. For example's sake, we have hitherto adhered to friction, the most usual, and the most manageable, agent employed in electrical researches. It is however quite immaterial from what source, or by what process, the electricity is evolved; and all that has been said respecting the electricity of friction is true of that produced by every other method, allowance being made for incidental variations in the state of its intensity. In the following sections will be found a review of all the known methods by which electricity may be obtained; arranged for the most part according to that order in which the facts have been successively added to the sum of human knowledge. Mention has already been made of the existence of ten or eleven such processes, (5.); but upon more mature consideration, several of these appear to be only variations of each other, and will be noticed as such, reducing the total number to seven, which number future researches may probably still further diminish.

The contact of metals, as employed in De Luc's column is not here inserted, being reserved for the Galvanic branch of our subject. The order of the succeeding sections is as follows:

§ I. Friction.
§ II. Electricity of animals.
§ III. Change of temperature.
§ IV. The atmosphere.
§ V. Evolution of gaseous matter.
§ VI. Separation of solid particles.
§ VII. Pressure.

§ 1. Friction.

(187.) After that Du Fay had recognised the distinguishing characteristic of the electric fluids as produced from different substances, it became a prevailing error to consider that one electricity or the other was the invariable produce of any given substance, until the researches of Symmer gave a more just description of the phenomenon, and the simultaneous production or evolution of both fluids was under some name or other admitted by all experimentalists.

The following curious case depends probably upon the colouring matter of the riband, rather than upon any peculiarity of surface; and there is no reason to suppose that light, abstractedly considered, has any influence upon the experiment.

"Lay a white riband upon another riband of the same size and fineness but black: then holding them both on one extremity with one hand, draw them swiftly between the first and second finger of the other hand, by which friction they will both be electrified, and on being separated, the black riband will be found negative, and the white positive." (Cavallo.)

(188.) M. de Luc, who published some interesting researches in Nicholson's Journal for January 1811, observes, shall, by the selection of a few extracts, be made to explain his own views upon these subjects. "Friction excited between two bodies has no other effect than that of disturbing the natural equilibrium of the electric fluid, which tends always to be produced among all bodies according to its actual (but in a certain extent local) quantity upon them, and in the ambient air. If both the bodies which exercise friction upon each other are good conductors, this disturbance (the equilibrium being constantly restored) is not perceived; but if one has more disposition than the other to attract the electric fluid thus agitated, with the faculty of transmitting it to its remote parts; when the bodies are separated suddenly, or in general before the equilibrium of the fluid can be restored between them, one is found positive, as having acquired a proportional quantity of electric fluid greater than the ambient air, and the other negative, as having lost that quantity; both being sup-
posed to have previously possessed the same electric state as the ambient air.

"The general effect therefore of friction between two bodies is, that one never becomes positive without the other being negative, (or vice versa.) This evident proof that all the electric phenomena, which we are as yet able to produce at will, namely by friction, proceed from the disturbance of the equilibrium of only one fluid, will be afforded by the experiments which I shall here relate."

"Mr. Cavallo, in his complete Treatise on Electricity, (third edit. vol. i. p. 21,) has given a table, containing the results of his experiments of this kind, wherein is found, that certain bodies become either positive or negative, according to those by which they are rubbed. This circumstance had already shown that negative and positive were not properties belonging to certain bodies, but only different states produced on the same body by different circumstances, and in particular by the difference of those which exercise friction on it; there remained however to be ascertained what effect, in the latter case, was produced on each of the bodies which exercised that friction. This having been one of my objects in these experiments, I kept both bodies between which the friction took place, insulated; at the same time suffering them to communicate with electrosopes. By experiments thus performed, I discovered the general law above expressed; for when any of the bodies, which may be rendered either positive or negative by friction, was brought to one of these states, the body which had exercised it was constantly found in the opposite state: if the former became positive, it had taken some electric fluid from, and if negative it had yielded some electric fluid to the body which had exercised friction upon it. Such are the effects which will be seen in the following experiments."

De Luc then proceeds to describe an electrical machine, so small that it should only equal the effects of a large electrical column, and might be connected with a gold leaf electroscope, without destroying that instrument by the violence of its action. The power of this machine was intended not to exceed that of an electric column containing 600 groups. The cylinder of this minute apparatus was one-fourth of an inch in diameter; and it was necessary that the motion communicated to it should be very slow, or else the excitation became too great for the purposes of comparison. By the friction of brass upon glass, the brass became negative, and the conductor receiving electricity from the glass, showed a positive state of excitation.

When the glass cylinder worked against a small flat piece of glass, the latter not being insulated, the conductor became positive. This experiment is analogous to one which had been some time known to electri
cians, in which, if two pieces of riband of the same kind be rubbed together, the one throughout its whole length, across the other at one place only, the former becomes positive and the latter negative.

By forming the rubber of insulated sealing-wax, a slight charge of positive electricity was developed upon the cylinder; but when the apparatus had been altered, to allow of the sealing-wax repairing its losses by communication with the earth, the electricity evolved, was more copious. A rubber of caoutchouc was affixed; and with this it was found, that on some days the glass became positive, and the caoutchouc negative, while on other days, the contrary effects took place.

The glass cylinder was next coated with sealing-wax, and made to undergo the friction of a brass rubber. This proved an experiment requiring some delicacy of execution; but at length, the electroscope communicating with the waxed cylinder, diverged with negative, and that which communicated with the brass rubber, with positive electricity. De Luc here remarks upon the error of those who had supposed that those bodies which were conductors were themselves incapable of excitation, showing that it was only necessary that the body, if a conductor, should be insulated, in order that its electric excitation might become apparent. A similar series of results was obtained by the Abbé Hauy, at a subsequent period. The last experiment also shows, that brass becomes positive or negative, according to the body with which it is rubbed.

To the same cylinder coated with wax, a rubber of caoutchouc was applied. The excitation was extremely powerful; but invariably the sealing-wax with which a brass rubber had been negative, now became positive; and the Indian rubber was constantly negative.

A red bead, formed of an elastic gum, produced by the inspissation of some vegetable juice, and worn for necklaces, gave a similar variety of results. With a narrow brass rubber, the bead became negative, and the brass positive.

"Such are the constant phenomena observed at the fountain head of all the electric effects which it is in our power to produce; and they depend on friction, respecting which various systems have been fabricated. Now from the whole tenor of these experiments, it may be laid down as a fundamental truth in terrestrial physics, that friction has no other influence in electric phenomena, than that of disturbing the equilibrium of the electric fluid, in such a manner, that one body by acquiring a certain quantity of it, above what it had before, is rendered positive, and that the other is found negative, as having lost that quantity. It is only when its equilibrium is disturbed that the electric fluid is manifest to us: the electroscope is our first test of this disturbance; but if the bodies, either conductors themselves, or associated with conductors, are of a sufficient size, and the electric difference between them has arrived to a certain degree, it is manifested by a spark darting from one to the other, and the equilibrium is thus restored."

(189.) Having thus permitted M. de Luc to plead his own cause, by which we do not pledge ourselves to unite with him in all his views, we may for the present be allowed to leave these and similar speculations, until further experiments shall have rendered us more competent to the task of reasoning upon the subject. The table originally drawn up by Mr. Cavallo, and subsequently improved by Singer and others, may stand as follows:

(191.) Dr. Wollaston is of opinion, that it is the process of oxidation which principally tends to the development of electricity in the common machine. He adduces the following experiments in illustration of his views.

By employing an amalgam of silver, or of platinum, which are metals not liable to be oxidised, he could obtain no electricity. An amalgam of tin, on the contrary, afforded a good degree of excitement. Zinc acts still better; but the best amalgam is made with both tin and zinc, a mixture which is more easily oxidised than either metal separately.

As a further trial whether oxidation assists in the production of electricity, a small cylinder with its cushion and conductor, was arranged in a vessel so contrived that the air contained could be changed at pleasure.

After trying the degree of excitement in common air, carbonic acid gas was substituted, and the excitement was instantly destroyed, but immediately returned upon the readmission of atmospheric air. Phil. Trans., 1601.

The object of Dr. Wollaston in the papers contain...
E L E C T R I C I T Y.

Practical Electricity. By sifting the experimental facts, was to bring a distinct proof of the identity of voltaic and ordinary electricity; and therefore he remarks, that the cushion of the machine, by oxidation of the amalgam which adheres to it, becomes negative; and in the same manner zinc oxidized by the accumulated power of an electric pile, or simply by the action of an acid, is also negative.

(192.) The friction of liquids against solid bodies is also capable of developing electricity. To prove this, let a cylindrical glass receiver be placed upon the plate of an air pump, the top of this receiver is to be formed of a wooden cup, fitted into the receiver by cement, and holding mercury. Upon the exhaustion of the receiver, the mercury pressed by the external air, filters through the pores of the wood, and falls in the form of a delicate shower, striking against the sides of the glass cylinder. If then a small electroscope with a ball suspended by silk be brought near the cylinder, the leaves will be found in the excited state. In order that this experiment may succeed well, some care must be used in making the cylinder perfectly dry, so that it may not lose the electricity produced by the friction of the mercury against its surface, which indeed is never considerable.

By this experiment we are enabled to explain a phenomenon observable in barometers well freed from air. When these are suddenly inclined, so that the column of mercury may rapidly fill all the vacant part of the tube; if the experiment be made in the dark, a phosphoric light is instantly developed, similar to that which is produced by a current of electricity in its passage through a vacuum.

Electrical excitation may also be produced by the friction of a gas against a solid body. If a current of atmospheric air be directed against a plate of glass, by means of a pair of bellows, the glass becomes vitreously electrified. (Wilson.)

(193.) There is yet another mode of electrical excitation, which has been long viewed as possessing some distinct and peculiar character. We are inclined however to refer it also to this section, and to consider it a species of friction, differing only from the instances before recited, in the mode of its application.

After Mr. Bennet had invented the gold-leaf electrometer in 1786, he found that powdered chalk put into a pair of bellows, and blown upon the cap, communicated to the instrument vitreous electricity, when the cap was about six inches from the pipe of the bellows; but the same stream of powdered chalk electrified it resinously at the distance of three feet. The electricity is also changed from vitreous to resinous, by placing a bunch of fine wire, silk, or feathers, in the aperture of the bellows pipe; and is wholly resinous when blown from a pair of bellows without the pipe, so as to come out in a larger stream. This last experiment did not answer in dry weather so well as in wet. "The vitreous electricity of the chalk thus blown, is actually communicated, because part of the powder sticks to the cap; but the resinous is not communicated, the gold leaves collapsing as soon as the cloud of chalk is dispersed."

A piece of chalk drawn over a brush, or powdered chalk put into the brush, and projected upon the cap, electrifies it resinously, but the electricity is not communicated.

Powdered chalk blown with the mouth or bellows from a metal plate placed upon the cap, gives permanent vitreous excitation. Or, if the chalk is blown, the powder may pass over the cap, if not too far off, it is also vitreous. Or, if a brush is placed upon the cap, and a piece of chalk drawn over it, when the hand is withdrawn, the leaves gradually diverge with vitreous electricity as the cloud of chalk disperses.

Powdered chalk falling from one plate to another placed upon the instrument, produces resinous electricity.

Other methods of producing electricity, with chalk and other powders were tried; as projecting chalk from a goose wing, chalking the edges of a book, and clapping the book suddenly together; also sifting the powder upon the cap, all which electrified it resinously; but the instrument being placed in a dusty road, and the dust excited with a stick near to it, produced vitreous electricity.

Wheat flour, and red-lead are strongly resinous, in all cases where the chalk is positive. The following powders were like chalk; red and yellow ochre, resin, coal ashes, crocus powder, aurum mossicum, black-lead, lamp black, powdered quick-lime, umber, lapis calaminaris, Spanish brown, powdered sulphur, flowers of sulphur, iron filings, rust of iron, sand. Resin and chalk, which when separate are alike, changed their effect by admixture; this was often tried in dry weather, but did not succeed in damp; white lead also sometimes produced vitreous, and sometimes resinous electricity, when blown from a plate.

No sensible electricity is produced by blowing pure air, projecting water, by smoke, flame, or explosions of gunpowder. Bennet, Philosophical Transactions, 1787, p. 31.

In a communication shortly following the preceding one, Mr. Bennet says, "To the experiments on blowing powders from a pair of bellows, I have to add, that if the powder is blown at about three inches upon a plate which is moistened or oiled, its electricity is contrary to that produced by blowing them upon a dry plate."

(194.) The experiments of Professor Lichtenberg, by projecting powders upon the plate of the electrophorus, seem to have called Mr. Cavallaro's attention to this subject. For ascertaining the electricity of powders, he gives the following directions, and at the same time we may conclude from his speaking in these terms, that he considers the electricity to belong to the substances employed, and not to an extraordinary development arising out of the process. "Insulate a metal plate upon an electric stand, and connect it with the electroscope; then the powder required to be tried, being held in a spoon, at about six inches above the plate, is to be gradually let fall upon it. In this manner the electricity acquired by the powder being communicated to the metal plate, affects the electroscope; and its quality may be ascertained in the usual manner.

"If the powder be of a conducting nature, like the amalgam of metals, &c., it must be held in some electric substance, such as a glass phial or a plate of wax. Sometimes the spoon may be insulated, in which case, after the experiment, the spoon will be found possessed of an electricity contrary to that of the powder."

In performing these experiments, care is to be taken that the powders, and whatever they are held in, be as free from moisture as possible.

The most complete series of experiments in this

**E L E C T R I C I T Y.**

1. "That of sifting them on the cap of a delicate electrometer through a fine sieve, which was thoroughly cleansed after each operation."

2. "By bringing an insulated copper plate repeatedly in contact with extensive surfaces of them spread on a dry sheet of paper; the copper plate being brought in contact with the condenser after every repetition of the touching, until a sufficient charge was communicated.

"By each process the effects produced increased considerably, when the substances employed were reduced to a fine powder; and it was in this way I succeeded in obtaining very distinct effects from the alkalis, by contact with a copper or a silver plate; an experiment which Sir H. Davy had before attempted with great care but without success. The pure alkalis were broken into small pieces, and being placed in an open phial were exposed for a quarter of an hour to a moderate heat, not sufficient to fuse the alkali, which was then quickly reduced to a powder in a warm and dry mortar; and immediately spread upon a dry sheet of card paper, which for some time will continue to attract moisture from the alkali, as fast as the alkali receives it from the air. The whole operation was performed as rapidly as possible.

"The greater effect produced in all these experiments by an increased division of the powder, renders it highly probable that they are merely varieties of the usual process of excitation."

"The following substances produce negative electricity, when sifted on the cap of an electrometer: copper, iron, zinc, tin, bismuth, antimony, nickel, plumbago, lime, magnesia, barytes, strontia, alumina, silex, brown oxide of copper, white oxide of arsenic, red oxide of lead, litharge, white lead, red oxide of iron, acetate of copper, sulphate of copper, sulphate of soda, phosphate of soda, carbonate of soda, carbonate of ammonia, carbonate of potash, carbonate of lime, muriate of ammonia, common pearl ashes, boracic acid, benzoic acid, oxalic acid, citric acid, tartaric acid, cream of tartar, oxy-muriate of potash, pure potash, pure soda, resin, sulphur, sulphuret of lime, starch, orpinum, &c.

"The following substances produce positive electricity when sifted on the cap of an electrometer: Wheat flour, oatmeal, lycopodium, quassia, powdered cardamom, wood charcoal, sulphate of potash, nitrate of potash, acetate of lead, oxide of tin.

"Hence it appears, that there are comparatively but few substances that become positively electrified when sifted through hair, flannel, or muslin. For in experiments made with each of these substances separately, they were found to produce similar effects.

"The following table exhibits the results of experiments of contact with a copper plate. The different substances being arranged in classes under the electricity they really acquire, which is contrary to that of the copper plate. Positive: lime, barytes, strontia, magnesia, pure soda, pure potash, common pearl ashes, carbonate of potash, carbonate of soda, tartaric acid. Negative: benzoic acid, baric acid, oxalic acid, citric acid, silex, alumina, carbonate of ammonia, sulphur, resin.

(195.) In deference to the opinions of those philosophers who have made the most recent and the most judicious researches on this subject, MM. Van Marum, Paets, and Troostwyck, we shall include under the present section some short account of the electricity developed during the cooling of fused bodies, although at first sight it may appear improbable that the electrical effects so produced should owe their origin to friction.

The earliest experiments upon this subject were made by Mr. Stephen Grey, and principally upon bodies of a resinous nature. These substances were fused in iron ladles, and so managed as to get out cakes of the form of the ladle, having smooth surfaces. Resin, sulphur, lac, and various combinations of these, form a very considerable list in the detail of Mr. Grey's experiments. After these masses had been taken out of the ladle, and the surface had become hard, they did not exhibit any electricity, until the temperature had fallen about to that of a new laid egg. The electricity then gradually increased; and when the cakes had become cold, the electrical power had increased in a tenfold proportion. In order to preserve these bodies in their excited state, they were wrapped up in flannel, or in worsted stockings, and kept in a dry box.

The only one of these experiments that we are now in the habit of repeating, is that marked by Mr. Grey, No. 19. A cone of sulphur was cast in a tall glass. About two hours after it was taken out of the glass it attracted, and the glass also slightly. Next day the sulphur was taken out of the glass, and then it attracted strongly; but there was now no perceptible attraction in the glass. This experiment ended as any similar one may now do, by the sulphur and the glass both manifesting electrical properties for several weeks, whenever they are separated from each other.

Experiments of a similar kind are related in the respective Treatises of Wilcke of Rostock, and of Aepinus. Mr. Henley was led to return to this subject, by an observation communicated to him from Mr. Sanders, a maker of chocolate, who found that the chocolate became electrical during its cooling in the tin pans in which it had been cast. From some trials made under Mr. Henley's directions, it appeared, that by heating it over again repeatedly, this property of the chocolate gradually disappeared; but that it might at any time be restored by the addition of a small quantity of olive oil.

In 1784 M. Pabst published a short paper upon the same subject; and in 1787 Mr. Liphardt made further experiments; and seems in a great measure to have satisfied himself that friction was the true cause of this phenomenon.

The question was at length very carefully investigated by Van Marum and his associates; and of the numerous memoirs, ancient and modern, that in compiling this article it has been our business to examine, there are few to equal that of the associated chemists produced upon this occasion. The experiments are definite in their object, and ingenious in their contrivance; and want of room alone compels us to abstract only their concluding sentence.

"It is then (as we think) incontestably proved by the experiments we have just related, that the electricity developed whenever we separate an electric
Electricity.

Electricity is a constant attendant upon animal life. If our instruments were of sufficient delicacy to detect its presence, and examine its nature under all circumstances, we might then hope to be able to trace its beneficial or injurious influence upon the economy of animated beings. In addition to the electricity developed in the human frame, which seems to be entirely independent of volition, and may possibly arise partly from mechanical causes, and partly from those dependent upon chemical or vital action; there is a series of singular phenomena discovered to exist in the animal kingdom, by which some of its inferior orders of beings are enabled to defend themselves from the attacks of their enemies, or to take the prey which is destined for their support. The section now before us will contain a brief examination of these facts in the following order:

1. Electricity of the human body.
2. Electricity of the Raia Torpedo.
3. Electricity of the Gymnus electricus.
4. Electricity of the Silurus electricus.
5. Electricity of the Trichiurus Indicus.
6. Electricity of the Tetraodon electricus.

Electricity of the human body.

Of the human body, substance which has been fused and cooled from the body on which it has been poured, is not produced by that separation, neither is it produced by the fusion or by the cooling; but, that it is caused by the friction which the particles of the electric bodies undergo, when they disperse themselves over the surfaces upon which they are poured. The reason why this electricity does not manifest itself till after the cooled substance is separated from the body upon which it has been poured, is, doubtless, because the electricity which the body receiving the fused mass must acquire, is opposed to the electricity of the melted body itself, and these two opposite electricities so exactly counterbalance each other as to be quite imperceptible.

§ II. Electricity of animals.

It might be advanced as a conjecture by no means improbable, that some degree and species of electrical excitation is a constant attendant upon animal life. For our instruments were of sufficient delicacy to detect its presence, and examine its nature under all circumstances, we might then hope to be able to trace its beneficial or injurious influence upon the economy of animated beings. In addition to the electricity developed in the human frame, which seems to be entirely independent of volition, and may possibly arise partly from mechanical causes, and partly from those dependent upon chemical or vital action; there is a series of singular phenomena discovered to exist in the animal kingdom, by which some of its inferior orders of beings are enabled to defend themselves from the attacks of their enemies, or to take the prey which is destined for their support. The section now before us will contain a brief examination of these facts in the following order:

1. Electricity of the human body.
2. Electricity of the Raia Torpedo.
3. Electricity of the Gymnus electricus.
4. Electricity of the Silurus electricus.
5. Electricity of the Trichiurus Indicus.
6. Electricity of the Tetraodon electricus.

Electricity of the human body.

(196.) The excitation produced by the friction of articles of dress upon the human body, cannot in all instances be distinguished from that which results from the operation of other and less obvious causes. For this reason, and for greater convenience in referring to the original memoirs, we shall give a short abstract of our information upon these subjects without attempting to separate the one kind of action from the other.

J. J. Hemmer, who published a Memoir upon this subject in the Transactions of the Electoral Society of Mannheim, has collected the following instances of the electricity of the human frame; and to these more might, if necessary, easily be added.

More than one ancient author has related that fire streamed from the hair of Servius Tullius, the Roman King, during sleep, when he was about seven years of age. (Dionysius, Antiq. Rom. lib. iv.) Pliny says also, Hominum quoque capita vespertinis horis stellae magno presagio circumfulgent. (Hist. Nat. lib. ii. c. 37.)

Cardan mentions a Carmelite monk, whose hair emitted sparks whenever it was stroked backwards. (Lib. viii. De Rerum variet. c. xliii.) A woman at Caumont exhibited a phenomenon of the same kind, as her hair, when combed in the dark, always emitted fire. (Scaliger, Exercit. 174.) Father Faber, in his Palladium Chemicum, speaks of a young woman from whose head sparks of fire always fell when she combed her hair. Francisca Guida produced bright flames from his body, when he rubbed his arm with his hand as he lay in bed. (Bartholinus, De luce Animalium, Lugd. 1647, p. 121.)

Ezekiel di Castro, a physician of Verona, relates of Cassandra Buri, a lady of the same place, that, as often as she touched her body, even in a slight manner, with a linen cloth, it emitted sparks in great abundance, which could be perceived by every person standing near her, and were attended with a considerable noise. Her maid was often deceived by this phenomenon, and believed that they had through carelessness dropped some coals between the sheets; as she always caused her bed to be warmed in winter, at which time the sparks were most abundant and strongest. (Castro, De igne Lambente.)

Fortunius Licetus relates (De Caussis monstrorum, lib. ii. cap. 29) that Antonio Ciampi, a bookseller at Pisa, when he pulled off a narrow shirt and a piece of cloth which he wore upon his breast, emitted sparks from his back and arms, with a crackling noise, to the terror of the whole family.

Among us, says Gesner, where heated chambers are usual, it often happens that many persons when they have warmed themselves at a stove, and then pull off their shirt in a cold bedchamber, or move or shake it after it is pulled off, observe crackling flames to burst from it. (Lib. de Lunariis.) Bartholinus mentions a like phenomenon of a rope-dancer at Turin. (De luce Anim. p. 123.) Scaliger speaks of a white Calabrian horse, which, when combed in the dark, emitted sparks of fire. (Exercit. 174.)

Beccaria describes the following circumstance told to him by Vaudania: "For ten or twelve days past, since the cold set in, I wear between two shirts a piece of beaver's skin. Always when I pull off my upper shirt at night, I observe that it adheres to the piece of skin; and when I draw my shirt from it I see sparks which have a striking resemblance to those of electricity. Scarcely do I begin to pull off the piece of skin, when I find that it adheres, and with still greater force, to the under shirt. On taking it out, I observe when I hold it in the right hand that
In the next place it appeared desirable to make a similar series of experiments with the fish immersed in water instead of air. Mr. Walsh, therefore, held a large and powerful torpedo in both his hands, grasping the electric organs both above and below; and then

2. Electricity of the Raia Torpedo.

(187.) The electrical properties of this fish having Raia tor- pedo. The most singular is, that any person might even during the continuance of an experiment the electricity frequently changes from vitreous to resinous; but on the whole it appeared that in a quiescent state of the body the electricity was most frequently vitreous. Cold seemed to change the natural or vitreous electricity, into the opposite kind, or at least its transmission. Walsh was unable, however, to affect the balls of an electrometer, or to produce any appearance of a spark by the electricity of this fish.

94 experiments upon his maid, the electricity was 19 times vitreous, 33 times resinous, and 42 times 0.

In Dr. Bancroft's Natural History of Guiana the electrical nature of the torpedo's power is first suspected; but little was effected towards the proof of this fact until the valuable papers of Mr. Walsh appeared in the Phil. Trans. for 1773 and 1775. He placed a live torpedo upon a wet napkin, and formed a communication through five persons, who were all insulated; the person at one extremity touched some water into which a wire from the wet napkin terminated; and the last in the series had a similar mode of communication with a wire which at intervals could be brought in contact with the back of the torpedo. In this manner shocks were communicated to the five, and also to eight persons. In the general result it appeared that, as in the case of common electricity, glass and such substances intercepted the shock, while metals and those bodies known as ordinary conductors suffered its transmission. Walsh was unable, however, to affect the balls of an electrometer, or to produce any appearance of a spark by the electricity of this fish.

From Hemmer's long but rather irregular series of experiments it would appear, that electric excitement is a property of all mankind, that it varies not only in different persons, but in the same person at different times; being in many weak, in other strong, in some vitreous, in others resinous. The variations arise from causes which he was unable to trace. In 2422 experiments made upon himself, 1252 showed vitreous electricity, 771 times resinous, and 399 none at all.

In 94 experiments upon his maid, the electricity was 19 times vitreous, 33 times resinous, and 42 times 0.

Even during the continuance of an experiment the electricity frequently changes from vitreous to resinous; but on the whole it appeared that in a quiescent state of the body the electricity was most frequently vitreous. Cold seemed to change the natural or vitreous electricity, into the opposite kind, or at least Chap. VII. diminished its intensity. Lassitude produces the same effect. This animal electricity is stronger in winter than in summer, and is impeded by perspiration. Bodily motion is not necessary to its development; neither does it depend upon the motion of respiration, nor can it be attributed to the friction of the clothes, for M. Hemmer says, "my experiments leave no doubt upon this subject; as I found the electricity on my own body lively and durable for half an hour, or an hour, when I was on no clothes. I do not say, however, that the friction does not increase it." It appeared to be clearly proved that there is no species of electricity connected with the human subject, which is at all under the regulation of the will; instances of this kind from among the animal kingdom we now proceed briefly to mention.

In 94 experiments upon his maid, the electricity was 19 times vitreous, 33 times resinous, and 42 times 0.

In 2422 experiments made upon himself, 1252 showed vitreous electricity, 771 times resinous, and 399 none at all. The most singular is, that any person might avoid all sensation of the shock by holding his breath at the same time that he touched the animal. This, which at first appears improbable, has been confirmed by the accurate observations of Mr. Walsh.

In Dr. Bancroft's Natural History of Guiana the electrical nature of the torpedo's power is first suspected; but little was effected towards the proof of this fact until the valuable papers of Mr. Walsh appeared in the Phil. Trans. for 1773 and 1775. He placed a live torpedo upon a wet napkin, and formed a communication through five persons, who were all insulated; the person at one extremity touched some water into which a wire from the wet napkin terminated; and the last in the series had a similar mode of communication with a wire which at intervals could be brought in contact with the back of the torpedo. In this manner shocks were communicated to the five, and also to eight persons. In the general result it appeared that, as in the case of common electricity, glass and such substances intercepted the shock, while metals and those bodies known as ordinary conductors suffered its transmission. Walsh was unable, however, to affect the balls of an electrometer, or to produce any appearance of a spark by the electricity of this fish.

In the next place it appeared desirable to make a similar series of experiments with the fish immersed in water instead of air. Mr. Walsh, therefore, held a large and powerful torpedo in both his hands, grasping the electric organs both above and below; and then

In the next place it appeared desirable to make a similar series of experiments with the fish immersed in water instead of air. Mr. Walsh, therefore, held a large and powerful torpedo in both his hands, grasping the electric organs both above and below; and then
plunged it a foot beneath the surface of some water, and again raised it an equal height in the air. The moment the lower surface of the torpedo touched the water in descending, he always gave a violent shock; and a still more powerful one was produced at the instant that the same surface emerged from the water in ascending. Both these shocks were attended with a contortion of the body, as if the animal were anxious to make its escape. The intensity of the shock under water was scarcely one-fourth of that at the surface, and not much more than one-fourth of those given in the air. The number of the shocks appeared to be about twenty in a minute.

The shock of the torpedo was in general not perceptible beyond the finger with which it was touched; and out of 200 shocks Mr. Walsh found one only which affected him above the elbow. If the torpedo were insulated it was able to give forty or fifty shocks without any diminution of force, to persons who were also insulated. Each shock produced by the animal is attended with a depression of its eyes; and as this appearance seemed of invariable recurrence, Mr. Walsh could tell, by observing the eyes, when the animal attempted to produce an electrical discharge, even upon non-conducting bodies.

Mr. Walsh then put the torpedo into a flat basket open at the top, but secured by a net with wide meshes, and thus confined, the animal was lowered about a foot into the water. If then it was touched through the meshes by a single finger, on one of its electric organs, the other hand being held at a distance in the water, shocks were distinctly felt in both hands; but when the circuit was made by applying one finger above and the thumb below to one organ only, a shock was experienced twice as great as the former one, when two arms formed the circuit.

The torpedo in its basket, having been raised to within three inches of the surface of the water, was then touched with a short iron bolt held in one hand, half out and half within the water, while the other hand was immersed in the water at some distance; strong shocks passing through the bolt were experienced in both hands. By forming the communication through a wet hempen cord, the shock was conveyed as before.

By suspending a powerful torpedo in a net, and frequently dipping it into the water, slight shocks were communicated through the net to the persons holding it.

Mr. Walsh explains the difference between the effects of the electricity of the torpedo and of the Leyden jar, on these principles. The same quantity of electricity will produce very different effects according to the degree of condensation in which it is detained. A small jar having six square inches of coated surface will be able to force its charge through an inch of air, and exhibit attraction and repulsion, as well as the snap and spark. But by distributing the same quantity of electricity over two large connected jars having a coated surface of 400 times the extent of the small phial, effects analogous to those of the torpedo are produced. In this attenuated state the change will not pass through the hundredth part of an inch of air; the spark and snap, and the approach and recession of light bodies will no longer be produced; a point brought near will not be able to draw off the charge; and yet in this state of feeble intensity it will run through a considerable circuit of conducting bodies, and during its passage will produce sensible effects upon the animal system.

In 1773, Dr. Ingenhouz made many experiments at Leghorn upon the torpedo; he describes the shocks as producing the same sensation as if a great number of very small electrical jars were discharged through his head in very rapid succession. Sometimes the shock was very feeble, and at other times so strong as almost to oblige him to quit his hold of the animal. By pinching the fish with his nails, it did not give either more or fewer shocks than when not so irritated; but by folding the body, or bending its right side to the left, the shocks were rendered more frequent.

Other researches upon the irritability of the torpedo have been made by Spallanzani. He found the shock to be most powerful when the animal was laid upon a plate of glass. He states that in irritating the torpedo, he always obtained the shock, whether it was out of the water or in it. If instead of irritating the back, he irritated the breast gently, he received a shock, but not so frequently as by irritating the back. Spallanzani found that some minutes before the torpedo expired, the shocks were not given at intervals, as in the healthy state of the animal, but were changed into a reiterated succession of small shocks. During a space of seven minutes of this action his fingers experienced 316 shocks; the shocks then suffered an interruption, and the animal immediately before it died gave a few very languid shocks. Spallanzani discovered also the singular fact, that even the fucus of a torpedo possessed the same electrical property even before it was born.

The most recent experiments of importance upon the electric irritability of the torpedo, were made in 1805, by MM. Humboldt and Gay Lussac. The following has been given as a succinct account of the results obtained by these admirable experimentalists.

1. "A person much in the habit of receiving electric shocks, can support with some difficulty the shock of a vigorous torpedo fourteen inches long. The action of the torpedo below water is not perceptible, till it is raised above the surface of the water.

2. "Before each shock, the torpedo moves its pectoral fins in a convulsive manner, and the violence of the shock is always proportional to the extent of the surface of contact.

3. "The organs of the torpedo cannot be discharged by us at our pleasure, nor does it always communicate a shock when touched. It must be irritated before it gives the shock, and in all probability it does not keep its electric organs charged. It charges them, however, with astonishing quickness, and therefore is capable of giving a long series of shocks.

4. "The shock is experienced, when a single finger is applied to a single surface of the electric organs, or when the two hands are placed, one on the upper, and one on the under surface at the same time; and in both these cases the shock is equally communicated whether the person be insulated or not.

5. "If an insulated person touches the torpedo with his finger, it must be in immediate contact; as no shock is received if the animal is touched with a key, or any other conducting body.

6. "The torpedo being placed upon a metallic plate, so that the inferior surface of its electric organ touched the metal, the hand which supported the plate felt no
Electricity is insulated person, and when it was obvious from the
practical shock, although the animal was irritated by another
animal, irritation below, by the common skin of the animal, under
which pass directly across from its outer edge to the
semicircular cartilages. They are covered, above and
below, by the common skin of the animal, under which
there is a thin fascia spread over the whole organ.

This is composed of fibres, which run longitudinally,
and in the direction of the body of the animal. These
fibres appear to be perforated in innumerable places,
which gives the fascia the appearance of being reticulated.
Its edges all around are closely connected to the skin, and at the last appear to be lost or
to degenerate into the common cellular membrane of the skin.
Immediately under this is another membrane
exactly of the same kind; the fibres of which in some
measure decussate those of the former, passing from the
middle line of the body outwards and backwards.
The inner edge of this is lost with the first described;
the anterior, outer, and posterior edges, are partly
attached to the semicircular cartilages, and partly lost
in the common cellular membrane.

"This inner fascia appears to be continued into the
electric organ, by so many processes, and thereby
makes the membranous sides, or sheaths of the
columns, which are presently to be described; and
between these processes the fascia covers the end of
each column making the outermost or first partition.
Each organ of the fish under consideration is about
five inches in length, and at the anterior end three in
breadth, though it is but little more than half an inch
broad at the posterior extremity. Each consists wholly
of perpendicular columns, reaching from the upper to
the under surface of the body, and varying in their
length according to the thickness of the parts of the
body where they are placed; the longest column
being about an inch and a half, the shortest about
one-fourth of an inch in length, and their diameter
about \( \frac{1}{3} \) of an inch.

"The figures of the columns are very irregular,
varying according to situation and other circumstances.
The greatest number of them are either irregular hexagons,
or irregular pentagons; but from the irregularity of some of them, it happens that a pretty regular
quadrangular column is sometimes formed. Those of
the exterior one, are either quadrangular or hexagonal;
having one side external, two lateral, and either one
or two internal. In this second row they are mostly
pentagonal. Their coats are very thin, and seem
translucent, closely connected with each other, having
a kind of loose net work of tendinous fibres passing
transversely and obliquely between the columns, and
uniting them more firmly together; these are mostly
observable where the large trunks of the nerves pass.
The columns are also attached by strong inelastic
fibres, passing directly from the one to the other.

The number of columns in different torpedos of
the size of that offered to the Society, (which was
about eighteen inches long and twelve broad, and
about two inches thick in the thickest part,) appeared
to be about 470 in each organ; but the number varies
according to the size of the fish.”

In a very large torpedo found on the British coast,
which was four and a half feet long, and weighed
seventy-three pounds, the number of columns in
one electric organ was 1182. Walab. Phil. Trans.
1774.

"The columns now described, increase not only in
size but in number during the growth of the animal;
new ones forming perhaps every year on the exterior
edges, as they are much the smallest. This process
may be similar to the formation of teeth in the human
jaw, as it increases. Each column is divided by hori-
Practical Electricity

be then probable that these nerves are not necessary for the purposes of sensation or action, may we not conclude that they are subservient to the formation, collection, or management, of the electric fluid; especially as it appears evident from Mr. Walsh's experiments, that the will of the animal does absolutely control the electric powers of its body, which must depend upon the energy of the nerves."

M. Geoffroy St. Hilaire has by a recent examination, been enabled to bear testimony to the accuracy of Hunter's description of this fish. He states also, that a similar organic structure is found in other animals of the Maia genus, which nevertheless do not possess any electrical powers.

The singularity of action, manifested by the torpedo, led Walsh, and other experimentalists of the age, to attempt a full explanation of its properties, on the known principles of electricity. This was a task of considerable difficulty, as the shocks were sometimes obtained by contacts and connections to which the Leyden jar furnished no direct analogy.

In pursuance of these objects, Mr. Cavendish contrived an artificial torpedo. It was made of wood, connected with glass tubes and wires, and covered with a piece of sheep skin leather. To make the effect of this instrument more like that of the animal, with regard to the difference between the shock in air and out of water, it was necessary to substitute thick leather in place of the wood, and with this improvement the apparatus succeeded admirably. In air the sensation of the shock was sensible at the elbows, but under water it was felt chiefly at the hands. By touching this torpedo with one hand under water, a shock was obtained as strong as if it had been touched by both. Being touched under water with two metallic spoons, it gave no shock, but in air the shock was very strong.

Cavendish made also a comparative estimate between the strength of his artificial torpedo and that dissected by Mr. Hunter, with reference to surface. His own battery consisted of seventy-six feet of coated surface; and he calculated that the animal retained a charge fourteen times as great as that of the battery, or was equivalent to 1064 feet of coated glass.

The power of the animal to communicate a shock under water is explained on the principle of the different relative conducting powers of bodies; the shock preferring a long passage through a good conductor, to a comparatively short one through a substance of inferior capacity. It seemed also singular, that from the fish neither sound, nor spark, nor attraction, could by any means be made manifest. This led Mr. Cavendish to examine the effect of distributing a given quantity of electricity over a great extent of surface. His experiments led him to consider that the distance to which the spark will fly is, inversely, in rather a greater proportion than the square root of the number of jars. With regard to attraction and repulsion, Cavendish found, that in a large battery so weakly electrified that its shock will not pass through a chain, a pair of pith balls suspended from the discharging rod, do not exhibit any divergence.

Electricity.

3. Electricity of the Gymnotus electricus.

(199.) The electrical properties of this fish were first made public by M. Richer, who had been sent out for the purpose of measuring the length of the seconds pendulum at Cayenne. It is sometimes called the electrical eel of Surinam; and numerous and curious as are the experiments which have been made upon this animal, the hypotheses which writers and naturalists have advanced upon the subject are not less so.

Redi supposed that the benumbing effects depended upon a subtle but substantial emanation proceeding from the fish, which, entering within the pores of other bodies, produced by its accumulation the disturbance of a shock. Schilling imagined that the action of the gymnotus was of a magnetic nature, and makes mention of certain experiments, in which the loadstone and the fish seemed to produce an influence upon each other.

Omitting, however, these speculations, which are more curious than useful, and which, if necessary, may be traced from the references at the end of this section, we will only introduce a short abstract of the known phenomena of the electrical eel, and then give some description of the structure of the animal, from the researches of Dr. Hunter, Mr. Walsh, and Dr. Williamson.

By touching the eel with one hand, a shock is perceived in the fingers, the wrist, or the elbow; but by making the contact with an iron rod twelve inches long, the shock was perceptible in the finger and thumb only by which the rod was held.

The hand of one person being held in water at the distance of three feet from the animal, upon a second person irritating the eel, the former will feel a shock, but of less violence than if he touched the animal itself.

Dr. Williamson put a cat-fish into the same vessel of water with an eel, and then dipped his own hand into the water also. The gymnotus swam up to the fish, but turned away without offering any violence to it. It soon returned, however, and after regarding the cat attentively for some seconds, gave it a shock which made it turn up its belly and continue motionless. The shock was perceptible to Dr. Williamson the same time. Whenever fish that had been thus rendered motionless were removed to another vessel they recovered.

By irritating the gymnotus with one hand, and holding the other at some distance in the water, a shock was perceived in both arms like that of the Leyden jar. A similar effect might be produced by touching the water with a wet stick, irritating the animal with the other hand as before. Two persons also might, by joining hands, share in the effects of this experiment, as with a charged electrical jar.

When one of two persons joining hands touched the head roughly, while at the same time the other touched the tail gently, they both received a severe shock.

When the first of eight or ten persons, with joined hands, touched the eel, while the last put his hand into the water at some distance from it, they all received a gentle shock.

When the first of the eight pinched the tail, while the last touched the head, they all received a severe shock.

When two persons laid hold of the two extremities of a brass chain, and one of them put his hand into the water, while the other touched and irritated the eel, the shock affected both.

If a silk handkerchief be wrapped round the hand, and the eel be touched with it, no shock is experienced, though another person, who puts his hand into the water at a little distance from the eel, will feel the shock.

The connection between two persons was formed by various substances, such as charcoal, iron, brass, dry wood, glass, silk, &c., and it was always found that the shock of the eel was conveyed through those substances that conduct common electricity, while it refused to pass through non-conductors. The shock was not conveyed by a brass chain, unless the chain were stretched, or the shock severe.

An insulated person being electrified by the eel, he exhibited no marks of electricity; nor did cork balls diverge when suspended by silk threads over the eel's back, or when touched by the insulated person when he received the shock.

Dr. Williamson made several attempts to render the passage of the shock perceptible by the spark, but without success. Mr. Walsh, however, by making a minute separation in a piece of foil between two plates of glass, on the principle of the luminous word, obtained a visible spark.

On the whole, Dr. Williamson concludes that the gymnotus has the power of communicating a shock to those animals that touch it, either directly or by the intervention of a conductor; that this effect depends solely upon the will of the animal; and the magnitude of the shock is dependant also within certain limits upon some act of volition on the part of the fish. That the shock does not at all depend upon any muscular action in the animal, but upon some process purely electrical. M. Humboldt describes, in his Travels in South America, a singular method of catching the gymnotus, by driving wild horses into a lake which abounds with them. The fish are wearied or exhausted by their efforts against the horses, and then taken; but such is the violence of the shocks which they give, that some of the horses are drowned before they can recover from the paralysing shocks of the eels. He states also, that in giving the most powerful shocks, the gymnotus does not make any motion of the head, eyes, or fins, like the torpedo.

Gymnoti are described of different sizes. One examined by Hunter was not three feet long. Dr. Garden describes one three feet eight in length, and Dr. Bancroft, when in Guiana, was told of some having been seen in the Surinam river upwards of twenty
Electricity.

4. Electricity of the Silurus electricus.

(200.) This fish, as far as is at present known, is peculiar to some of the rivers of Africa. Adanson described it from the Niger, and Forskal, though he gave it another name, found it in the Nile. By the Egyptians it is called Raasch, a name which is also applied to the torpedo; they eat its flesh, and cure the skin with salt, for medicinal purposes. The Negroes of Senegal term it Onanienar; and, from its electrical properties, the French have sometimes called it le Trembleur du Senegal.

The length of this silurus is about twenty inches. It is broad towards the fore part, and, of a dark ash colour, with blackish spots towards the tail. By laying the fish upon one hand, and touching it with a metal rod held in the other, an electrical shock is distinctly perceptible, but by no means so strong as that given by the torpedo.

The anatomical structure of this fish has been described by M. Geoffroy, who states that the organs, by which the electrical effect is produced, are much less complicated than those adapted to a similar purpose in the torpedo or gymnotus. There is lying immediately beneath the skin, and encircling the whole animal, a mass of cellular substance so thick and compact, as to appear to consist of a stratum of fat. By microscopic investigation, however, it is evident that this is composed of a tissue of tendinous or aponeurotic fibres, interlacing each other, and forming a distinctly reticulated mass, containing, in the interstices or cells, an albuminous or gelatinous matter. All connection with the inside, is cut off by a strong aponeurosis extending over the whole reticular, and adhering very closely to it; and above this is a thick stratum of fatty matter. The nerves, distributed over the electric organ of the fish, proceed from the brain, and are analogous to those found in all other fishes beneath the lateral line of the body. The direction and arrangement of the eighth pair of nerves is peculiar to this species alone. As they issue from the cranium they approach each other and descend through the substance of the first vertebra; entering by distinct orifices, but reissuing from one common perforation on the opposite side. After reascending, they suddenly divide and proceed under each of the lateral lines, passing between the abdinal muscles and the aponeurosis, which extends over the articulate organ. Large branches then separate and pass beneath the skin, proceeding to the right and left of the principal nerve. These branches, of which there are twelve or fifteen on each side, penetrate the aponeurosis, lining the inner surface of the cellular tissue, and are there lost.

5. Electricity of the Trichiurus Indicus.

(201.) Of this fish, which is said to inhabit the Trichiurus Indian seas, and to be endowed with electrical properties, we regret that it is not in our power to
E L E C T R I C I T Y.

§ III. Change of temperature.

(203.) The subjects for experiment connected with this section, are derived principally from the mineral kingdom. All, in fact, that we feel sufficiently acquainted with to lay before our readers, but at the same time we wish to point out, is a curious paper of M. Dessaignes, in the second volume of the Annales de Chimie et du Physique, in which many experiments are recorded, which, if accurate, will prove that metallic bodies are capable of electric excitation, by the processes of heating and cooling only. The description of these researches forcibly recalls to our attention the modern thermo-electric processes, and as it is now proved beyond the possibility of doubt, that that species of electric excitation which affects the magnetic needle, may be developed in metals by the application of heat only, there is a strong analogy in favour of the supposition, that ordinary electricity is at the same time elicited, although its quantity may be so small as to render its presence difficult of detection.

The following is the order in which the minerals possessed of this property will come under our notice:

1. Boracite.
2. Topaz.
3. Axinite.
5. Tourmaline.
6. Prehnite.
7. Calcamine.
8. Sphene.

6. Electricity of the Tetraodon electricus.

Tetraodon electricus. (202.) The Philosophical Transactions for 1786, contains the only account, with which we are acquainted, of this fish, which seems to possess electrical powers of considerable intensity. It was discovered by Lieutenant William Patterson, in a voyage to the East Indies. The fish is described as being seven inches long, two and half broad, and as having a long projecting mouth. The colour of the back is a dark brown, the belly is sea-green, the sides yellow, and the fins and tail sandy green. The whole of the body is covered with red, green, and white spots, the latter being particularly bright. The eyes of the fish are large, with a red iris, having its outward edge tinged with yellow. Mr. Patterson caught the fish in cavities among coral rocks, where the water had a temperature of from 56° to 60° Fahrenheit; off the island of Joanna. Having caught two of them in a linen bag, he attempted to take one of them in his hand, when he received so severe an electrical shock, as to oblige him to quit his hold. He then carried them a distance of two miles to the camp, but on his arrival found that one of them had died, and the other was already reduced to a state of extreme debility. The fish was then put into a tub of water, and the surgeon of the regiment attempting to seize it with both his hands, received a distinct electrical shock. The adjutant also, upon touching the back with his finger, experienced the electrical effects, but in a much slighter degree. Phil. Trans. vol. lxxvi. p. 389.

(204.) In 1791, the Abbé Haüy having received two crystals of this substance, undertook a careful examination of their physical characteristics. Having exposed them to the action of heat, he perceived upon presenting them to the electroscope, that they were possessed of electrical properties. The next point was to ascertain the position of their electric poles, which the analogy of the tourmaline had led him to expect. By turning the crystal about, opposite to the extremity of an excited needle, he was surprised by the attractions and repulsions, which succeeded each other with such rapidity, as to make it difficult to determine the points upon which the opposite electricalities resided. Reasoning upon this new fact, and instituting a sort of comparison between the substance before him and the tourmaline; he considered that as the latter from its crystalline form possessed but one axis, which coincided with that of the nucleus, and that, consequently, it ought only to possess two electric poles, situate at the two extremities of that axis. The boracite, on the other hand, having a cube for its nucleus possessed four axes, each of which passed through two opposite solid angles; from whence it would follow that there ought to be eight electrical poles, two for each axis. Experiment verified this conjecture; and the position of the poles was found to be so arranged, that taken four and four with reference to each kind of electricity, each alternate one possessed the opposite property.

At that time M. Haüy had not carefully examined the facets which modified the cubic crystal, but the remark which he had been led to make, upon the positions of the electrical poles, induced him to fix his attention particularly upon the points at which these poles were situate. He already knew that tourmalines deviated from the perfect symmetry of ordinary mineral forms, by a difference of conformation in their summits, due to the influence which the electrical forces had exerted upon their crystallization. And as the same disturbing forces had existed during the formation of the crystals of boracite, the Abbé expected that some analogy would be found to exist between these and the tourmalines with regard to external form; and in fact, by an attentive examination of the parts of the cube at which the opposite electricities appeared, he remarked that some presented solid angles complete, while others presented certain small planes which intercepted the opposite angles. The resinous electricity was situate at the complete angles, and the vitreous electricity at the facets opposed to those angles.

Some time afterwards having received crystals of a second variety; he found that these had all their solid angles replaced by planes, and as the same took place with regard to their edges also, they appeared at first to be only cubes truncated upon all their solid angles and all their edges, and such in fact was the description given of them by Westrumb and others, who had examined them. But upon this hypothesis the symmetry would not have undergone any alteration, and yet every thing seemed to point out some such change; or else symmetry would itself become anomalous in exhibiting itself upon certain crystals, while others presented dissimilarity in the forms of their...
Practical Electricity.

By a more minute examination, however, it appeared that around the facets, which had replaced the solid angles, which were complete in the first variety, there were three other small planes, to which there were no corresponding ones at the opposite extremity of each axis. These were exceedingly small, and would have escaped the eye, had not their existence been connected with a certain physical fact, which called for a search after their presence. In this case it might be said that crystallization had only unwillingly submitted to the force which tended to remove it from its ordinary course.

Every variety of this mineral subsequently examined, presented the same variation from the laws of symmetry; it would appear that the two fluids, which are endowed with opposite properties, have introduced some discordancy among the harmony of their crystalline form. Of the eight solid angles of the cube, four are always replaced by single planes; the remaining four either remain untouched, or are replaced by more than one plane. The vitreous electricity always resides at the former angles, and the resinous upon the latter.

The electricity of these crystals is generally sensibly less than that of the tourmaline. Experiments for its exhibition require much delicacy, especially with respect to the repulsive effects which exist only throughout a very small space; so that to obtain the repulsive action of a resinous pole, upon a body resinously electrified, it is essential that this latter body should be directed exactly to the repulsive point, otherwise attraction will take place towards the adjacent parts, which are in their natural state, or nearly so.

2. Topaz (silicious fluoride of alumina.)

Topaz.

(205.) The excitability of the topaz upon the application of heat, was discovered by Mr. Canton in 1760. For the most accurate examination of its habits, we must, however, again refer to the Abbé Häüy. He states, that at first he had supposed the Brazilian and Siberian topazes alone possessed this property; but that he had subsequently discovered it in some of the Saxony ones, although these required to be insulated previously to its development. The Siberian varieties are capable of retaining the electricity acquired by heat, for many hours.

The transparent topazes only require a slight friction for the development of their electrical properties, or even manifest them upon pressure between the fingers. The duration of excitation upon this mine was determined for the development of their electrical properties, and upon any other, with the exception of transparent carbonate of lime. The blue topazes of Scotland have similar properties.

The electric poles of the topaz are situated upon the two opposite summits of the secondary crystal, but among some topazes from Siberia, Häüy recognised one with a singular property, which he thus describes:

"In attempting to determine its electric poles, I observed that both its extremities were resinously electrified, while the intermediate part of the crystal gave indications of vitreous electricity. This fact has a considerable degree of similarity to one presented by certain magnets which contain a consecutive series of opposite poles. I am not aware that a series of consecutive poles has been before remarked in an electrified body."

3. Axinite.

(206.) It was first remarked by M. Brard, that some crystals of this mineral became electric by heat. Upon this, Häüy attentively examined many crystals of axinite, and found several among them departing from the perfectly symmetrical form; and such were precisely the specimens wherein it was possible to develop electrical excitation by this method. A more minute examination of the crystalline forms of this substance, with a comparative reference to its electrical properties, was a task which, had life been longer continued to this distinguished mineralogist, it was his intention to have undertaken.

(207.) M. Häüy has added this mineral to the Mesotype number of those in which heat is capable of developing electrical excitation. Some crystals have this property, others have not; but in one fragment the Abbé was able to recognise the distinct effects of electrical polarity.

The analogy presented by all minerals thus circumstanced, would lead to the supposition that those crystals which are possessed of this property, are not perfectly symmetrical in their forms; but this is a subject left for the future researches of the mineralogist.

5. Tourmaline.

(208.) In the historical introduction to this article, Tourma-lwe have mentioned the description by Theophrastus line.

of a stone, the lyncarium, of great hardness, very difficult to polish, used for seals, and possessing the same properties as amber in the attraction of light bodies. Dr. Watson has ably identified this stone with the tourmaline of modern mineralogists, and the singularity of its electrical affections, has brought it under the notice of some of the most acute modern experimentalists.

In the year 1717, M. Lemery, of the French Academy, exhibited to the members of that body, a specimen of this mineral from Ceylon. In his Memoir he styles it pierre de l'Isle de Ceylon, qui attire et repousse diverses corps, mais d'une manière différente de l'aimant. Linnaeus, mentioning these experiments of Lemery, gives to the stone the name of the lapis electricus.

The Duke de Noya states, in his Treatise, that during his residence at Naples, in the year 1743, Count Picchetti, the King's Secretary, informed him that he had seen at Constantinople a stone, called tourmaline, which was possessed of attractive and repulsive properties. This circumstance he had forgotten, until the year 1758, the sight of some more of these gems in Holland brought the fact to his
remembrance. He then purchased the specimens, and, in conjunction with MM. Daubenton and Adanson, made a series of experiments, and published the results which they obtained. In 1756, however, Augustin published, in the Mémoires of the Berlin Academy, a paper, De quibusdam experimentis electricis notabilioribus; these experiments had been made upon two crystals of tourmaline, with which he had been furnished by Lechman. Mr. Wilson and Dr. Priestley were also industrious labourers in these fields of research.

Should any description of the tourmaline be thought necessary, it may thus be summarily given. It has every variety of colour from black, deep blue, deep green, brown, to a light green, hair brown or yellow. S. G. 3—3.4. Scratches glass. Is doubly refractive in a slight degree. Is frequently transparent in a direction perpendicular to the axis of its primitive crystals, but perfectly opaque in the direction of that axis. Its crystals are usually prisms, having an odd number of lateral planes, terminated by summits of three, six, nine, or more faces. Fuses before the blowpipe in a while or goes out. The electricity developed by friction is vitreous, but when two tourmalines are rubbed against each other, the one acquires the vitreous, the other the resinous electricity.

In addition to the excitability from heat, remarked by Lemery, Augustin discovered the electrical polarity of the tourmaline; which he justly compared to the known effects of magnetism. He states, that if the mineral be brought to a heat between 99½ and 212 of Fahrenheit, one extremity acquires the vitreous, and the other the resinous electricity, so as to be capable of affecting a delicate electroscope. Mr. Wilson heated a tourmaline intensely in a fire for half an hour, and did not find that any diminution took place in its electrical properties. By plunging the stone into cold water, after it had been made red-hot, it was not broken to pieces, but became shivered throughout, and had lost its electrical powers. Mr. Canton, however, found in one case that he was able to destroy the electricity by heat, but that in some others he was not able to do so. This subject has attracted the attention of the Abbé Haüy also; he found that a tourmaline may be raised to such an intense degree of heat as to no longer exhibit any electricity. As the stone gradually cooled, the attractive properties again presented themselves; and, in fact, it appeared that the electric condition of the mineral undergoes a tourmaline triclinic by the application of heat; and the direction of the electric poles corresponds with that which is observed in magnetic bodies.

By examining the distribution of electricity upon an excited tourmaline, Haüy found that the quantitative arrangement of the fluid might be compared to that upon any excited cylinder; there being a space of considerable extent throughout the middle of the crystal, where it was almost impossible to detect the presence of any free electricity; and that the principal accumulation was at the extremities of the prism. If a tourmaline excited by heat, be broken into pieces, each fragment will be found to possess a vitreous and a resinous pole, in this respect presenting a fact strictly analogous to that which is observed in magnetic bodies.

6. Prehnite.

The crystalline form of prehnite is a right Prehnite rhomboidal prism. It is capable of becoming electrical by the application of heat; and the direction of its poles is found to be parallel with the smaller diagonal of the crystal; while in the mesotype, the direction of the electric poles corresponds with that of the axis of the crystal.

7. Calamine.

The electrical properties of this mineral, Calamine, which is an oxide of zinc, were recognised by Haüy in 1785. It appears from his statement, that all those specimens which present appearances of crystallization are capable of excitement by heat; and that, like tourmaline, they are possessed of polarity; and also undergo the reversion of their poles, already remarked, during the process of cooling.

§ 152. He had a pole fixed vertically into the ground, which, at a height of thirty-two French feet, bore an insulated tin point, from which a metallic wire conveyed the electricity to an electroscope, or any other convenient apparatus for its examination.

The general statement of his result is, that some electricity might always be detected in the atmosphere; that in dry weather it was scarcely perceptible at sunrise, but increased gradually until three or four o'clock in the afternoon; it then diminished until the evening fall of dew, at which time it increased, and by a subsequent diminution it became almost insensible at midnight.

The general variations in the electrical state of the atmosphere, have been patiently investigated by Mazeas, Beccaria, Kinnersley, De Luc, Read, Saussure, and others; but as these may be reduced to a tabular form, and more properly fall under the registers of the Meteorologist, we refer them to the article peculiarly devoted to that subject.

§ 154. Dissimilar objects of pursuit, or the compulsion of local circumstances, have introduced a great and undescrable variety of instruments for the examination or reception of atmospheric electricity. All however may be reduced to three general forms. A common kite was employed by Franklin, Romas, Cavallio, and others. It requires no peculiarity of construction, except that a pointed wire must extend a short distance above the top of the kite, and to this must be attached a fine wire continuing down either within the string or along its course quite to the earth. Indications of electricity may almost always be obtained by elevating this apparatus; but on the approach of thunder clouds, the electricity is very powerful, and the experiment is one of great danger, unless proper precautions be made use of. These are described in the writings of Cavallio, Read, Cuthbertson, &c.

If, instead of being carried up by a kite, a considerable length of insulated wire be extended horizontally above the earth, it is found frequently to accumulate a very considerable quantity of electricity. Such were the conductors of Romayne, Mr. Crosse, and some others.

The experiments of Mr. Read and Mr. Singer appear principally to have been made by means of a conductor placed vertically in the ground. The advantages of such an instrument would arise from its being constantly ready for use, and little exposed to injury, but for extent of elevation it is much inferior to the kite.

§ 155. Dr. Wall, Grey, the Abbé Nollet, and several others, had observed certain instances of striking and lightning between the electric sparks and the spontaneous discharges of the atmosphere, well known by the name of thunder and lightning. Franklin drew up a scheme exhibiting these analogies, professing an intention to submit the question to the test of experiment. Before, however, the American philosopher could put his design into execution, it would appear that Buffon had elevated a conducting-rod upon the tower of Montbar, and that Dalibard had obtained some splendid electrical effects by employing a similar apparatus. It would appear, from a decision of the Academy of Sciences, dated February 4, 1764, that M. de Romas was the first person who elevated an electrical kite; but it is also clear that Franklin
ELECTRICITY.

Practical Electricity.

verified his conjecture and completed his discovery, independently of the French experimentalists. Few experiments, or perhaps none, are attended with such imposing grandeur as those by which copious quantities of atmospheric electricity are intercepted, and exhibited in a state subservient to the will of man; but at the same time it must be remarked that none require greater caution owing to the danger necessarily attendant upon them.

(216.) Having thus briefly traced the discovery of the true nature of thunder and lightning, we cannot be surprised that philosophers should have attempted to apply their newly-acquired information, to the useful purpose of preventing those dreadful effects with which the spontaneous discharges of the atmospheric electricity had so frequently been attended.

As far as we can ascertain, Franklin was the first to propose the application of a conducting-rod to the exterior of a building, in order to protect it from the lightning. It appeared very clear, that if a cloud highly charged with electricity came within a small distance of a house, the mast of a ship, or a tree, a discharge might take place, and if the body were not throughout a good conductor, the passage of the fluid would be marked by those violent effects which we have at times described. But if, in such a case, a metal rod were affixed to the building, the electrical discharge might be quietly conducted away without further damage.

Conductors to buildings were then generally considered a mode of protecting them from lightning; but in this country a discussion arose among some of the Members of the Royal Society, whether these conductors should have their summits terminated by balls or points. The latter in the end were most generally adopted.

(217.) The directions for the formation of proper conductors for buildings have been most clearly laid down by Mr. Morgan. The conductor should be formed of a rod of iron or copper, about half or three-quarters of an inch in diameter. Its point should reach four or five feet at least above the highest point of the building it is intended to protect, and its lower end must either terminate in a reservoir of water, or be affixed deeply into the earth. In large buildings it is advisable to have more than one of these rods, and great additional security will be obtained by nailing strips of lead round all the projecting points of the roof, at the same time allowing the lead to communicate freely with the vertical rods.

The conductors for ships, when employed, are made of chains, and affixed to the masts.

(218.) How far the aurora borealis may be a true electrical discharge, or how far recent experiments would almost lead one to suppose, it is only a visible state of a general current of electrical fluid always circulating in our terrestrial system, are points of difficulty which we must leave for further investigation. This only is known, that the changes of atmospheric electricity sometimes are continued, and sometimes not, during the exhibition of the aurora; and that no very strong bond of connection has yet been observed to subsist between them.

The fire of St. Elmo, so frequently seen upon the masts of vessels in the Mediterranean, and from very early times connected with the names of Castor and Pollux, meets with a very simple explanation on the principle of a pointed conductor imbibing electricity from a strongly excited atmosphere. On this ground also, there may be reason in the supposition of the sailors, who, invariably, consider this preternatural appearance as the forerunner of changes in the weather.

Very numerous have been the attempts to identify or connect electricity with the causes of water-spouts, meteors, and other terrestrial phenomena, but on these points little of certainty has yet been ascertained. A very considerable portion of the elaborate little Treatise on Electricity, by the late Lord Stanhope, is taken up with explaining what he termed the electrical returning stroke; a phenomenon now easily accounted for on the principles of electrical induction, while at the same time some of Lord Stanhope's cases are instances in which animals have been killed by a discharge proceeding from the earth and passing through them. Of this species of action numerous instances are now on record, and, indeed, it is evident, upon ordinary electrical principles, that if two clouds, or one cloud and the earth be oppositely excited and charged, the spark and the discharge may either pass from the cloud to the earth, or from the earth to the cloud, as circumstances to us imperceptible may direct.

(219.) The changes which have been already noticed, with reference to the electrical state of the atmosphere, may be supposed to have arisen from ordinary natural causes; those which may in some sense be considered as the production of artificial causes of impurity, have been carefully examined by Mr. Read, of Knightsbridge. He imagined that air, by being vitiated even in a small degree in various ways, as by respiration, putrefaction, &c. became resinously electrified.

The room in which he usually sat was small and confined, and he found by means of the electrical doubler, that the air was usually in this state of resinous electricity, while most of the regions and larger room was in the opposite state. Considering that there was nothing to occasion this difference, except what might be attributed to the respiration and effusion of his body, he thought it might be possible to apply that principle in producing a change in the electricity of the larger room. For this purpose he invited a gentleman to sit with him in that apartment after having closed the doors and windows, the day being still and warm, with the thermometer at 75°. After about twenty or thirty minutes, he found himself in a state of profuse perspiration, and, upon working the doubler, found, as he had expected, that the electricity had now changed to the resinous state.

The air of his sleeping-room was vitreous in the evening at his going to bed; but upon rising at six o'clock the following morning, it was found to be resinous. Mr. Read was also surprised to find the dispersion of electricity greatly increased by this state induced upon the atmosphere. He found also that the confined air in the upper part of his house was resinous, but that the kitchen and cellars were in the contrary state; but after the two kitchens had been filled with noxious effluvia by painting and whitewashing, the electricity became resinous.

Knightsbridge Charity-school, which, from the number of children confined in it, was liable to become filled with a very disagreeable smell, especially
when the door and windows were shut, was frequently examined, and found to indicate strong resinous electricity; and the schoolmaster's parlour adjoining, was found to possess rather more than its due proportion of vitreous electricity.

By a similar examination of the wards of the Lock Hospital with the doubler, it was invariably found that the close and confined parts were resinously electrical; while the more open and better ventilated parts were as constantly in the vitreous state.

The doubler was placed upon a heap of the loppings and leaves of shrubs in a state of putrefaction, and with some difficulty a charge of weak resinous electricity was obtained from the ascending vapour.

The surrounding atmosphere was positive. A hot-house filled with warm and moist air, was also found to be in the resinous state. "Phil. Trans. 1794, p. 266."

§ V. Electricity developed in the evolution of gases or vapours.

It is the opinion of some philosophers, that no chemical change can take place among the elementary molecules of bodies, without being attended by some electrical effect, although that effect may often be to us inappreciable. The considerations which this view involves will, with greater propriety, be brought forward under the head of Voltaic Electricity. In the instances however, which the title of this section enumerates, the excitation had been remarked and examined, long before that branch of science was known to the world. The precise physical distinction (if any such exist) between a gas and a vapour, can form no part of our present speculations, neither shall we here attempt to determine, whether in the instances about to be recited, depending upon chemical processes, the electricity evolved is due to the chemical change; that is to say, to the new modification undergone by the force of affinity; or simply to the physical change experienced by some one or more of the elementary molecules of the substance acted upon. By this species of generalization we class together the effects produced during the vaporization of a liquid; and during the disengagement of a gas from its state of combination, so that what before was a component part in a solid body, is enabled to become an aeriform fluid.

(390.) The earliest remarks with which we are acquainted, referring to this point, are from two of the most illustrious philosophers of modern times, MM. Lavosier and La Place. They state, that bodies in passing from the solid or liquid state to that of vapour, and conversely, in returning from the aeriform condition to the liquid or solid state, give unequivocal signs of either positive or negative electricity. In these researches they employed two kinds of apparatus; in both the substance from which the vapour was produced, was insulated by varnished glass supports. If they had reason to suppose, that the disengagement or absorption of electric matter would be slight and momentary, they allowed the vessel or substance to communicate freely with an electro-scope; but if they had reason to expect that the disengagement or absorption would be gradual, and of some continuance, they made use of Volta's condenser.

By the action of dilute sulphuric acid upon iron-filings, a violent effervescence was produced, with the evolution of hydrogen gas. After some minutes the electrometer of Volta was found so highly charged, as to be capable of communicating a spark; and the electricity thus produced was of the resinous kind.

By the action of very dilute sulphuric acid upon chalk, a very copious evolution of carbonic acid gas was produced, accompanied by electrical excitation; but not in so eminent a degree as in the former experiment. This electricity also was resinous.

The disengagement of nitrous gas produced a similar effect. In order to increase the electric tension, they combined together the action of six vessels, containing iron-filings, to which they had added dilute nitric acid. The effervescence and production of gas was extremely energetic, and at the same time undoubtedly indications of resinous electricity were obtained; but as this experiment was made under unfavourable circumstances, the excitement was very feebie.

Three small chafing-dishes insulated, and filled with lighted charcoal, being connected with Volta's condenser, gave such manifest indications of negative electricity, that it would have been easy to have obtained a spark, by increasing the quantity of charcoal employed in the combustion.

It resulted as a natural supposition from these results, that substances in the act of passing into the state of vapour, "carried off electricity," or, as we should phrase it, disturbed the electrical equilibrium between themselves and the surrounding bodies. This appearing conformable to the analogy existing between electricity and heat, they expected that in the vaporization of water negative electricity would be developed. Having arranged four insulated furnaces of hammered iron, so that they should communicate...
with the electroscope, the evaporation was produced by throwing water upon them in this state. In three successive experiments undoubted signs of electricity were apparent. The first appeared to be the resinos, but the two others were undoubtedly vitreous. They attempted to account for this discrepancy, on the supposition, that the cooling which accompanied the evaporation of the water, was able to augment the signs of vitreous electricity more than the evaporation itself had been able to operate in producing the opposite effect. In these experiments they were assisted by Volta, but do not express themselves satisfied with the results obtained.

(221.) A short time after, it would appear that M. Volta passed into England, and exhibited these experiments to Bennet, Cavallo, Kirwan, and others. His own account of them appeared in the Journal de Physique for August, 1783, and it is to this Memoir that Saussure, who has most attentively examined this subject, principally refers.

The following remarks are from a Paper by Mr. Bennet, in the Phil. Trans. for 1787:

"If a metal cup, with a red hot coal in it, be placed upon the cap of the gold-leaf electroscope, a spoonful of water thrown in electrified the cup resinosly; and if a bent wire be placed in the cup, with a piece of paper fastened to it to increase its surface, the vitreous electricity of the ascending column of vapour, may be seen by introducing the paper into it. Perhaps the electrification of fogs and rain is well illustrated by pouring water through an insulated colander containing hot coals, where the ascending vapour becomes vitreous, and the descending drops resinos.

"The experiments on the evaporation of water may be tried with more ease and certainty of success by heating the small end of a tobacco pipe, and pouring water into the head, which, running down to the heated part, is suddenly expanded, and will show its electricity when projected upon the cap of the electrometer, more sensibly than any other way that I have tried. If the pipe be fixed in a cloven metal. Sometimes water was poured upon the heated glass; at other times the glass, having been heated, was dropped into an insulated tin vessel containing the water. White and clear flint glass produced smoke without any change of electricity. In these experiments a long pipe is better than a short one."

(223.) By far the most extensive series of experiments on this subject, was published, in 1786, by M. de Saussure, in his Voyages dans les Alpes. Of these, we regret that want of space will confine us to a very faint outline; but perhaps this may be considered a more pardonable omission, as no general result can be deduced from these researches, though, confessedly, among the most elaborate that ever have been laid before the public.

Saussure first verified Volta's remark, that the electricity produced by the chemical processes of Lavoisier and La Place, and by the evaporation of water, was constantly resinos. He then examined the electrical excitation produced by evaporation carried on in vessels of different temperatures, and of different metals; estimating, at the same time, the rate of evaporation by the time required for the total dissipation of given quantities of the fluids employed.

He proved that the assertion made by Muschenbroeck, on the authority of Leidenfrost, stating that the hotter an iron vessel might be made, the more slowly would the process of evaporation be effected. There was, however, this singularity, that if given quantities of water, ether, or alcohol, were projected successively into an iron crucible, raised to nearly a white heat, the first such quantity would be dissipated with great rapidity; the second would require rather longer time, and so on for some more projections; but that at length a point or degree of heat might be found in the vessel, such as to produce the slowest possible evaporation; and that if further successive projections were made as the crucible still continued to cool, the rate of evaporation again increased; until from absolute want of heat the rate again diminished, and, finally, the power of vaporizing the fluid would of course be lost.

In an experiment conducted with ether, it did not appear that the combustion which the ether simultaneously underwent, produced any material effect upon the rate of its evaporation.

"To what conclusion shall I arrive," (says M. Saussure) "from all these experiments? Doubtless, not to any that is certain; the question has not even yet been sufficiently examined."

"Nevertheless it seems to me that since porcelain has always given a resinos electricity, and silver almost always; while iron and copper have almost always developed that which is vitreous, we may perhaps conclude that the electricity is vitreous from these substances which are capable of decomposing water, or of being themselves decomposed by contact with it; and resinos from those substances which neither cause nor undergo any alteration from the process."

(223.) Mr. Cavallo seems to have been acquainted with the researches of Volta, but not with those of De Saussure. He mentions also a work by a Professor at Mantua, Josephi Gardini Dissertatio de Electrici Ignis Natural, which treats upon this matter. The same difficulty of obtaining results accordant with those of Volta, occurred to Mr. Cavallo. He found, however, at last, that much depended upon the state of the iron employed in the experiment. If free from rust the electricity evolved would be resinos, if only partially rusted little or no electricity would appear, and if very rusty the excitation would be vitreous. The very same system of changes was found to arise from the use of different kinds of glass instead of metal. Sometimes water was poured upon the heated glass; at other times the glass, having been heated, was dropped into an insulated tin vessel containing the water. White and clear flint glass produced vitreous electricity, but the more impure glass, of which common wine bottles are made, gave the opposite kind.

It is almost useless to introduce more of this matter, for even after all these elaborate researches, no general law is deducible from the results obtained, and we must confess ourselves unable to produce a tolerably specious theory to account for the variety of action presented by these substances. If any one shall be able to point out to us the reasons for the singular changes produced by heat in the interesting thermo-electric researches of the present day, we may then hope to return to those curious facts left
Electricity.

Practical Electricity by Lavoisier, La Place, Volta, and Cavallo, with a prospect of obtaining a further elucidation of the matter.

§ VI. Electricity produced by the separation of the particles of bodies.

(224.) Of the observation of this fact, we are not aware of any earlier instance than the following from Mr. Bennet. "Breaking the glass tear upon a book electrified it negatively, probably by friction in the act of shivering; for when broken in water, it did not electrify it," Phil. Trans. 1787, p. 28.

Mr. Wilson states, that if a piece of dry and warm wood be suddenly rent asunder, the two surfaces which have separated become electrified, the one vitreously, the other resinously. The same is remarked if a flash of light is perceptible in the dark. If a piece of Muscovy glass, (mica,) and at the same time a flash of light is perceptible in the dark. If a stick of sealing-wax also be broken in two, the surfaces of fracture become vitreously and resinously electrical respectively.

The fracture of the glass tear, or Rupert's drop, has been subsequently examined by Dr. Brewster, in connection with his admirable researches upon light, the origin of which, in this instance, he seems to consider an electrical phenomenon. "Having laid one of these drops upon a table in a dark room, and covered it with a plate of thick glass, to prevent any of the fragments from reaching the eye, the drop was burst by breaking off a part of its tail, and the whole of it appeared luminous; so that at the instant of the fracture, a quantity of faint light, of the same shape and size as the drop itself, was distinctly visible. The same light appeared when these drops were burst under water."

(225.) We are under some doubt whether to refer the experiments of Mr. Wilson, upon the electricity produced by the process of shaving dry wood, to the present section, or to consider this mode of excitation only as a peculiar species of friction. In fact, the same difficulty applies to the whole of this subject. There can be no doubt that in the process of breaking any compact body, a certain kind of friction takes place between the proximate particles at the instant of their separation. Thus, perhaps, the electricity of the split wood, the sealing-wax, and the mica, might be accounted for. In the Rupert's drop, Bennet suspected some such source of excitation, and Dr. Brewster being occupied with a different object of inquiry, does not seem to have examined the electrical state of the powder. Even if no electricity were produced, it is possible that the concussion of the air in contact with the Rupert's drop at the instant of its explosion, might be sufficient to account for the production of light.

But if the edge of the knife be very keen, the chips will still be negatively electrified, whether the wood is hot or cold.

"The greatest number of trials was made with an insulated knife, which was always electrified contrarily to the chips; but the surface of the wood from which the chips were cut, was very seldom electrified, and when it was, it was always but weakly so, and of the same denomination as that of the weakest of the other two.

It has recently been remarked, that in some waterproof cloths manufactured at Glasgow, where two pieces are cemented together by caoutchouc, dissolved in the impure naphtha which is obtained from the gas works, the adhesion is such that when the two surfaces are torn asunder in the dark, there is a bright flash of electric light, similar to that produced by separating plates of mica, by breaking Rupert's drops, or by breaking sugar candy. Flashes of light also are distinctly produced, by tearing quickly a piece of cotton cloth.

Bennet, Phil. Trans. 1787, p. 28; Brewster, Phil. Trans. 1815; Wilson, Nicholson's Jour. vol. iv. p. 49; Brewster's Journal, No. 10, p. 183.

§ VII. Electricity produced by pressure.

(226.) With regard to this process for the development of electricity, we are unable to make any great assurance of the few facts which mineralogical writers have brought forward. The following are M. Hauy's remarks upon this subject:

"Chance fortunately so provided, that the first substance in which this property was remarked, is that which, by the energy of its action, claims the first place upon the list. This substance is the transparent variety of carbonate of lime, Iceland spar. It possesses in so eminent a degree that property which we may call electrical irritability, that if we take in the one hand a rhomboid of this spar, holding it by two of its opposite edges, at the same time lightly touching two of its parallel planes, by two fingers of the other hand; and then bring it near to the small needle of the electroscope, a decided attraction will be perceptible. If instead of contact, which is but a slight force of the same kind, a more powerful degree of pressure be exerted, the effects produced will be still more remarkable. The electricity evolved by both these methods is vitreous.

"I have remarked, in several substances, the property of becoming electrical by pressure, but as yet the maximum effect has been obtained from Iceland spar. In general the success of the experiments depends upon the degree of purity and transparency of the body operated upon. Those substances especially which are capable of being reduced by mechanical division to plane and smooth laminae. We may also employ such as have been reduced by art to a similar form. Of substances of the first kind are, topaz, especially the colourless variety, euclase, arragonite, flust of lime, and carbonate of lead. The fragments of limpid quartz which I have employed, have been polished specimens. All these substances acquire vitreous electricity by friction as by pressure. Sulphate of
Among those substances in which friction develops the resinous electricity, there are some which require only to be pressed, for the production of the same effect. Such, among others, is the elastic bitumen, when it has been cut into a proper shape for the experiment.

A small rhomb of Iceland crystal affixed to the extremity of an electrical needle, is employed by the Abbé Haüy for examining the feeble electricities of other substances, the electricity produced upon this standard by pressure being constantly vitreous. (Art. 59.)

For the only fact bearing upon this subject, and not connected with the mineral kingdom, we are indebted to the observation of M. Libes. Having taken a disk of metal insulated by a glass handle, he pressed it upon some varnished silk, (toffetos gommé,) either single or folded several times. By this pressure the disk acquires the resinous, and the silk the vitreous electricity; and the stronger the pressure is made, the more considerable will be the effect. Friction has no share in the production of this phenomenon; for if instead of pressing the disk upon the silk, it be merely set lightly down and rubbed backwards and forwards, so as to produce the effect of friction, then the disk becomes vitreous, and the silk resinous; a result the contrary of that which pressure alone produced.

Haüy, Mineralogie, vol. i. p. 190; Libes, Physique; Biot, Physique.
THEORY OF ELECTRICITY.

PART II.

INTRODUCTION.

It has been shown in art. 86, that the phenomena of electricity by induction, lead us to the supposition of two electric principles or fluids; each of them consisting of particles which repel those of the same fluid, and attract those of the other. It has been shown also, that this supposition will account for the general phenomena of the collection and distribution of electricity (art. 94. &c.) by the common apparatus. The discharge, or instantaneous transmission of one of these fluids from one body to another, has been shown to result (art. 98.) from its accumulation under given circumstances, according to those laws. And the attractions and repulsions produced by electricity have appeared (art. 17. and 84.) to be the results of the same principles.

The general and obvious character of the phenomena being thus seen to agree with the theory and its consequences, it becomes an object of extreme curiosity and interest to examine whether the quantities, and more complicated circumstances, of the observed effects agree with those which would result by calculation from our assumed principles. If we find this to be the case, and if it appears that whenever the comparison has been made, the laws of the distribution of electricity, and the quantity at each point, coincide, with great exactness, through a remarkable variety of complicated and at first sight anomalous cases, with the results of mathematical investigations founded on this theory, it will be difficult not to believe that the theory truly expresses the laws according to which nature operates. In order, therefore, to bring the evidence of this agreement before the reader, we shall proceed, in the present part, to trace, by analytical investigations, the consequences of the assumed principles, and to compare them with those experiments in which that mode of measurement has been employed which the comparison requires. It may be considered as a circumstance singularly fortunate, with regard to the evidence of the theory, that the experiments on which its reception must principally depend, (those of Coulomb,) were made long before the hypothetical laws with which they were to agree, had been deduced; and, indeed, before those theorems had been discovered, by which they have since been established. The mathematical reasonings on which these deductions are to rest, are of a character extraordinarily artificial and general, and equally remarkable for their beauty and their difficulty. The talents of La Place, of Ivory, and of Poisson, have been requisite to invent the processes which we shall have to follow; and if it be allowed, as we think it cannot be doubted, that in consequence of these investigations, electricity may be considered as an additional physical science brought under the jurisdiction of mathematics, this new province is inferior to no preceding one, not even to physical astronomy, in the refined analysis and elegant theorems in which it abounds. It will be our business to endeavour to introduce this subject in the simplest manner of which it admits, and we shall hope, by breaking it up into propositions, to present it in such a form that every mathematical student, who is familiar with the elements of analysis, may be put in possession of this new branch of mixed mathematics.

Except so far as this labour of simplification is concerned, we shall, in a great measure, follow the admirable Papers of M. Poisson, the first person who succeeded in the investigations which the subject requires. Founding his process on La Place's method of finding the attraction of a spheroid of small eccentricity, which its illustrious author had applied to the determination of the figures of the planets, M. Poisson, in a paper in the Mém. de l'Instit. 1811, overcame the principal difficulties of the subject, and solved the case of two conducting spheres in contact, which was one to which many of Coulomb's experiments were referable. In another Memoir in the same volume, he resumed the subject and completed the investigation for the case when the spheres were at any distance, in which the mathematical difficulties which were surmounted were truly remarkable, though, for the sake of brevity and simplicity, we shall be compelled to omit this part of his calculations.

For the purpose of laying before the reader a comparison of the results of these investigations with experiments, we shall adopt the following arrangement.

CHAP. I. On the mode of measuring electricity.
CHAP. II. On the mathematical theory of the distribution of electricity compared with experiment.
CHAPTER I.

On the mode of measuring electricity.

Theory of Electricity.

(228.) In art. 56, we have described the electrical balance of Coulomb, as an instrument by means of which we may measure the intensity of the repulsive or attractive forces which small electrified bodies exert upon each other. That we may be enabled to deduce accurate results from the experiments which we shall have to describe, we shall now obtain the formula by which the intensity of the force is determined.

It will be recollected, that in this instrument a small horizontal bar, B D, fig. 45, is suspended by a slender filament from its centre C. When this bar is horizontally moved round the centre C from its quiescent position, the tendency to return to that position is the torsion of the filament by which it hangs; and it is found that the force of this torsion is very accurately as the angle through which B D has deviated, and that this law continues true for a whole circumference. The bar B D carries a small ball D, which, being electrified, is repelled by a fixed ball at E, similarly electrified. The position in which B D rests, will determine the intensity of the repulsion between E and D. The same is true of the attraction of two balls dissimilarly electrified.

The upper end of the filament C is fastened to a button which can be turned round, and by this means the quiescent position of B D can be changed; and this button carries an index, which indicates the place of this quiescent position upon a graduated circle. Let C A be the quiescent position of C D when not repelled.

It will appear from experiment, that the attractive or repulsive force of electricity varies inversely as the square of the distance of the attracting or repelling points. Hence, if F be the force which two such points exert upon one another at a distance equal to unity, their force of repulsion at a rectilinear distance D, will be \( \frac{F}{D^2} \). And conversely, if, having represented the force by \( \frac{F}{D^2} \) and measured it for different values of D, it appears that F is constant; it will follow that the assumed law is the true one, and that the law of the attraction and repulsion is, that they vary inversely as the square of the distance.

(229.) Let E and D, fig. 91, be considered as points; D E = D; force of repulsion = \( \frac{F}{D^2} \). Let this force, which acts in the direction E D, be resolved into two in the directions C D and T D, T D being a tangent at D to the circle A E D. The latter of these only is balanced by the torsion. And by the laws of statics it will be equal to \( \frac{F}{D^2} \cos \theta \). Let E C D = \( \alpha \); and E D T = E B D = \( \frac{1}{2} \) E C D = \( \frac{1}{2} \alpha \). Hence the force which balances the torsion is \( \frac{F}{D^2} \cos \frac{1}{2} \alpha \).

Let C D = r, and we obviously have D E D = \( 2 \ r \sin \frac{1}{2} \alpha \). Hence the force of torsion is \( \frac{F \cos \frac{1}{2} \alpha}{4 \ r^3 \sin^2 \frac{1}{2} \alpha} \).

Let now A C D, the angle of torsion, = \( \alpha \). The force of torsion is proportional to this angle, and may be represented by \( n \alpha \), \( n \) being constant for the same filament. And this force may be considered as acting in the direction D T, and producing an equilibrium with the force first found. Hence

\[
\frac{F \cos \frac{1}{2} \alpha}{4 \ r^3 \sin^2 \frac{1}{2} \alpha} = n \alpha; \]

and

\[
\frac{F}{4 \ r^3} = \alpha \sin \frac{1}{2} \alpha \tan \frac{1}{2} \alpha.
\]

Hence, so long as we use the same apparatus, the force of repulsion, at a given distance, is as \( \alpha \sin \frac{1}{2} \alpha \tan \frac{1}{2} \alpha \).

By moving the button, we alter the position of the point A, and consequently we alter the angle \( \alpha \). By this means the position of C D, and the angle \( \alpha \) will also vary, and we may thus examine the magnitude of the force at different distances.

(230.) The following experiment of Coulomb will exemplify the mode of applying the machine, and will also prove the law of repulsion which has been mentioned.

After the balls E and D were electrified, they separated so that the arc E D was 36°.

He then turned the index C A in the direction D E, so as to make the arc C D 18°; and for this purpose it was necessary to turn C A through 126°.

He afterwards turned the index C A in the direction D E, till the arc E D was 8°; and this was done by moving C A through 567° from its first position.

It is manifest that the angle of torsion A is equal to A E + E D: hence we have

<table>
<thead>

</tbody>
</table>

If we suppose the values of \( \alpha \) to represent the distances, (which they do nearly, because the arcs are small, and therefore nearly as their chords,) it will appear that while the distances are nearly as 1, \( \frac{1}{2} \), \( \frac{1}{4} \), the angles of torsion, and therefore the forces, are as 1, 4, 16; that is, the forces are inversely as the squares of the distances.

(231.) To examine this result more accurately, we shall apply the formula of art. 229. We shall thus have by calculating the values of \( \alpha \sin \frac{1}{2} \alpha \tan \frac{1}{2} \alpha \).

The last column should be constant, in order to prove the law to be such as we have supposed it. It may be seen that the numbers are very nearly equal. The deviation of the last corresponds, as it appears,
Thbegins this is not a greater error than may be conceived to be committed, it is more probable that it is only apparent, and that it arises from the too great proximity of the two balls. It will be seen hereafter, that this proximity introduces a mutual action of the fluids on the surface of the two spheres, which gives rise to new circumstances, and makes the action of the spheres different from that of points.

Neglecting therefore this small discrepancy, which is perhaps rather a confirmation of the exactitude of the observations, we may consider as establishing the truth of the law which we have mentioned, that electrical forces vary inversely as the square of the distance.

(232.) The filament used by Coulomb in this experiment, was a silver wire of extreme fineness. Its length was twenty-eight inches, and one foot of it weighed only 4th of a grain. It was found that to twist it through a whole circumference, the force to be applied perpendicularly at the extremity of the bar was 4th of a grain; and since the forces of torsion are as the angles of torsion, it follows from this, that to twist it through one degree, a force of 4th of a grain was sufficient; so that the slightest repulsive force between the two balls caused them to separate.

This thread, in consequence of its excessive tenacity, broke with the smallest agitation; and in succeeding experiments Coulomb found it more convenient to use one of nearly twice the diameter, though its flexibility for an equal length was necessarily sixteen times less.

Previously to making use of such a thread, it is advisable to keep it, for two or three days, stretched by a weight equal to about half of what it can sustain without breaking. We must also avoid twisting it through a greater angle than 300°; for beyond this limit it is liable to receive a wrench, in which case it no longer reacts with perfect elasticity.

(233.) The laws of electrical attraction may be determined in the same manner, and by means of the same apparatus as those of repulsion. In this case it is requisite that the balls should not touch each other originally, and it is convenient to fasten a fine thread of silk in a vertical position in the instrument, so as to prevent the bar CD from coming to E. The quiescent position of the bar CA, must, in this case, be on the other side of CD; and if it is found that the attraction of the fixed ball E is so great as to bring D up to the thread just mentioned, the torsion must be increased by turning the index which moves CA, in the direction ED, till we find a position where the equilibrium subsists.

(234.) Coulomb likewise determined the law of electrical attraction by another process of the following kind. A needle, of which the extremity only was electrified, was suspended horizontally at a certain distance from a globe charged with the opposite electricity. This needle, when disturbed, oscillated in consequence of the attraction of the globe; and from the number of oscillations which it performed in a given time, he determined the attractive force, in exactly the same manner as when we determine the force of terrestrial gravity from the oscillations of a common pendulum.

The needle was a slender stick of gum-lac of fifteen or sixteen lines in length, suspended by a single filamento of silk, and carrying on one of its extremities a small circle of gilt paper. The globe was of wood, a foot in diameter, covered with tin-foil, and supported by three slender tubes of gum-lac. The torsion of the filament of silk would be insensible for the angle of oscillation; and the variation of the distance and position of the end of the needle from the globe during the oscillation was also too small to affect the result. The action of the whole surface of the globe would be the same as if the attractive or repulsive energy were all collected in the centre. Hence we may apply immediately the principles on which we calculate the oscillation of a pendulum by gravity. Therefore the force will be inversely as the square of the time of an oscillation; or directly as the square of the number of oscillations in a given time. And if the force be inversely as the square of the distance, the times of oscillation will be as the distances of the needle from the centre of the globe. The following were the results of experiment:

<table>
<thead>
<tr>
<th>Distances of the circle of gilt paper from the centre of the globe.</th>
<th>Duration of fifteen oscillations.</th>
</tr>
</thead>
<tbody>
<tr>
<td>18</td>
<td>20</td>
</tr>
<tr>
<td>24</td>
<td>41</td>
</tr>
<tr>
<td>60</td>
<td>60</td>
</tr>
</tbody>
</table>

The times are nearly proportional to the distances. The former are as 20, 40, 54, and the latter as 20, 41, 60. The deviation of the last time from its proper value, is to be attributed principally to the last observation having been made four minutes after the first, in consequence of which the electrical force had become smaller than it was at first, as will be immediately explained.

(235.) In art. 66, it has been mentioned as a result Dissipation of Coulomb's observations, that in a given state of the atmosphere the dissipation in any given short time varies as the charge. This law was established, as has been stated, by experiments made with the torsion balance. Two balls, similarly electrified, repelled each other in such a manner that they were kept in equilibrium at a distance of 20° by a torsion of 160°.

After three minutes they approached nearer, and in order to restore them to the distance of 20°, it was requisite to untwist the thread by turning the index through 30°, so that the torsion was 150°. Hence it appeared that in this case the diminution of electrical intensity was 30° in 3°, or 10° in 1°. Also the mean torsion between 130° and 160° is 145°; and hence the loss of electricity on the day of this experiment was 4 per minute. Similar experiments were made with other degrees of torsion, and at other times, and the result was what has been mentioned.

From the law just stated we can, in such a case as the above, calculate the intensity of the electric forces after the lapse of any given time.

Let A be the angle of torsion after any time t. Then for a given small time the decrement of A is proportional to A; or, taking the differentials, - - dA = A dt. Also for small times this decrement is proportional to the time, that is - - dA is proportional to d t. Hence - - dA = A dt. Let a be a constant quantity, such that

\[ - - \frac{dA}{A} = a \frac{dt}{t} \]

Digitized by Google
A being the torsion when \( t = 0 \), and \( l \) the Napierian logarithm.

If the loss of electricity be \( \frac{1}{n} \) in one minute, we shall have, making \( t = 1 \),

\[
A = A_0 \left( 1 - \frac{1}{n} \right)
\]

\[
\frac{1}{1 - \frac{1}{n}} = a \quad \text{and if} \quad n \quad \text{be considerable},
\]

\[
\frac{1}{n} = a, \quad \text{nearly.}
\]

Hence \( a \) may be taken to be the fraction which expresses the loss of electricity in \( l \).

If \( M \) be the Napierian logarithm of 10; \( \log \), the common logarithm, we have

\[
M (\log A_0 - \log A) = a t, \quad \log A = \log A_0 - a t.
\]

(236.) The following example may illustrate the application of the above formulas.

On a certain day it was found that the primitive torsion \( (A_0) \) was 150°, and the diminution \( \frac{1}{41} \) per minute. It is required to find the torsion \( (A) \) at any observation made 45 minutes after the first.

\[
A_0 = 150, \quad a = \frac{1}{41}, \quad t = 45, \quad M = 2.302585.
\]

\[
a = \frac{1}{M} \times 2.302585 = 0.010595, \quad a t = 0.4766025;
\]

\[
\log A_0 = 2.1760913, \quad \log A = 1.6994288;
\]

whence \( A = 50^\circ 3' 10" \).

The value given by observation was \( A = 50^\circ 0' 0" \), which may be considered as an absolute coincidence with calculation, since it is hardly possible in such experiments to be accurate to fractions of a degree.

If we had other observations on the same day to calculate, the same value of \( \frac{a}{M} \) would answer for all.

The law of the decrease of the torsion being thus established, it is easily seen that when the balls are equal, the force of each decreases according to the same law. And if the balls be in any ratio of inequality, the decrement of their joint action will still follow the same proportion; which is found to be confirmed by experiment.

By means of calculations founded upon the formulas just given, we can make allowance for the continual dissipation of electricity; and we may thus use the observations and measures which are taken with respect to the same body at successive times, in the same manner as if they were all taken at the same time, or as if the electrical state of the body did not undergo any change.

CHAPTER II

On the mathematical theory of the distribution of electricity compared with experiment.

(237.) In articles 82, 83, 84, 85, 86. have been given the general reasons from which we infer the existence of two electric fluids, each consisting of particles which repel each other, and which attract those of the other fluid. The forces of attraction and repulsion are inversely as the squares of the distances, and at equal distances the attractive and repulsive forces are equal. We have also seen that the separated electricity, in any conducting body, arranges itself contiguous to the surface, so that no portion of the uncombined or active fluids remains in the interior of the body. From these principles it follows, that when two conducting bodies, containing any charges of electricity, are within the sphere of each other's sensible influence, the distribution of electricity in them will be regulated by laws depending upon the mutual action of the fluids. These laws may in some cases be deduced by mathematical processes, and their results compared with facts, by means of the methods, given in the preceding chapter, of measuring the electricity at any point of a conductor.

We shall give these mathematical processes, and their comparison with experiment, for the case of two spheres which act upon one another. We shall, in the first place, have to determine the attraction or repulsion of a stratum of fluid, distributed at the surface of a sphere, with its thickness varying according to any law; and we shall then have to determine, from the forces thus obtained, the variation of the thickness of the stratum upon each sphere, in order that the fluids may be in equilibrium by their mutual action. The agreement of the disposition, thus determined by theory, with that given by observation, will be shown in each case when the calculations have been executed.

The principle on which these calculations rest is this, that for the existence of a permanent state of electrical equilibrium, it is requisite that the stratum of fluid on the surface of the conductors should not exercise any attraction on any of the points in the interior of those bodies. If it do so, its action will decompose the combined electricity of the bodies, and the separated electricity will proceed to the surface of the bodies, and will require new conditions for its equilibrium.

§ I. Attraction of a stratum of fluid on the surface of a sphere.

(238.) To find the attraction of any body, the particles of which attract with forces which are inversely as the square of the distance.

Let \( a, b, c \) be the rectangular coordinates of the point attracted; \( x, y, z \) the coordinates of any point of the attracting body; \( d m \) the differential of the body corresponding to that point. Then the distance of these two points is \( \sqrt{(a - x)^2 + (b - y)^2 + (c - z)^2} \) and the attraction in the direction of this distance is as
Theory of Electricity.

And if this be resolved in the direction of \( x \), it must be multiplied by \( \frac{(a-x)}{\sqrt{(a-x)^2 + (b-y)^2 + (c-z)^2}} \).

Whence it will become \( \frac{(a-x)}{\sqrt{(a-x)^2 + (b-y)^2 + (c-z)^2}} \).

And if this be resolved in the direction of \( r \), it must be multiplied by \( \frac{(a-x)}{\sqrt{(a-x)^2 + (b-y)^2 + (c-z)^2}} \).

The integral of this for the whole mass of the body will be the whole attraction. Hence attraction in direction of \( x \) = \( \frac{(a-x)}{\sqrt{(a-x)^2 + (b-y)^2 + (c-z)^2}} \).

Let \( V = \int \frac{d}{a} \frac{dV}{a} \) which is the sum of each particle divided by its distance from the attracted point. Then differentiating with respect to \( a \), observing that \( d \) does not depend on \( a \):

\[
- \frac{dV}{da} = \int \frac{(a-x)}{\sqrt{(a-x)^2 + (b-y)^2 + (c-z)^2}}
\]

= attraction in direction \( a \).

Similarly

\[
- \frac{dV}{db} = \text{attraction in direction } b.
\]

\[
- \frac{dV}{dc} = \text{attraction in direction } c.
\]

In this case \( a, b, c \) may be measured in any directions whatever; and if \( f \) be the distance of the differential particle \( d \) from the attracted particle

\[
V = \int \frac{dV}{f}.
\]

(239.) We have now to find the quantity \( V \); this we shall do by expanding it into a series, the coefficients of which have peculiar properties, depending upon a partial differential equation to which they are subject. As these properties are connected with very curious analytical investigations, and introduce into this and other problems a simplicity and generality truly remarkable, it will be convenient to refer to them by name; and we shall therefore distinguish them by that of their illustrious inventor, calling the differential equation and the coefficients in question, Laplace's equation, and Laplace's coefficients.

Mr. Ivory, in the Phil. Trans. for 1812, has given the same method of finding the attractions of spheroids, with admirable simplicity and clearness. After pointing out a want of generality in the reasonings of Laplace, in one part of his formulas, Mr. Ivory has given an equation, which is of great service in performing the requisite integrations in a satisfactory manner: we shall have occasion to use this, and we shall call it Ivory's equation.

(240.) To deduce Laplace's equation.

Let \( f \) be the distance of the particle attracted from the attracting particle, \( d' \) the differential of the attracting surface, and \( y' \) the thickness of the stratum, at any point. Then \( V = \int \frac{dV}{f} \).

Let \( r' \) be the distance from the centre of the attracting particle \( y' \), \( r \) that of the point attracted, and \( \gamma \) the cosine of the angle between them. Then \( f = \sqrt{r^2 + r'^2 - 2rr'} \).

Take a fixed line drawn from the centre of the sphere, and let \( \theta \) be the angle which \( r \) makes with this line. Also let the plane in which \( \theta \) is, make an angle \( \omega \) with a fixed plane. Then the coordinates \( \omega, \theta, r \) determine the attracted point. Let \( \omega', \theta', r' \) be the corresponding coordinates for the attracting point, and we shall have, by spheres, making \( \cos \theta = \mu, \cos \theta' = \mu' \):

\[
\gamma = \mu \mu' + \sqrt{1 - \mu^2} \sqrt{1 - \mu'^2} \cos (\omega - \omega').
\]

We have now to prove that if \( \frac{1}{f} = u \)

\[
\frac{r^2 \cdot r}{1 - u^2} + \frac{d \cdot (1 - \mu^2)}{d \mu} \frac{dV}{d\mu} + \frac{1}{1 - \mu^2} \frac{d^2V}{d\omega^2} = 0 \quad \cdots \quad \cdots \quad \cdots \quad \cdots \quad \cdots \quad (A)
\]

Whence it follows, since \( V = \int \frac{dV}{f} \), and \( y', d \) are independent of \( r, \omega, \mu \), that

\[
\frac{r^2 \cdot r}{1 - u^2} + \frac{d \cdot (1 - \mu^2)}{d \mu} \frac{dV}{d\mu} + \frac{1}{1 - u^2} \frac{d^2V}{d\mu^2} = 0 \quad \cdots \quad \cdots \quad \cdots \quad \cdots \quad \cdots \quad (B)
\]

To prove equation \( (A) \), let \( k = \frac{1}{f} = r^2 + r'^2 - 2rr' \gamma \):

\[
\therefore k = r^2 + r'^2 - 2rr' \mu \mu' + \sqrt{1 - \mu^2} \sqrt{1 - \mu'^2} \cos (\omega - \omega').
\]
ELECTRICITY.

Chap. II. Electricity.

\[
\frac{du}{dr} = \frac{1}{k^2} - \frac{1}{2 k^2} \frac{dk}{dr} = -\frac{r - r' \gamma}{k^2};
\]

\[
\frac{d^2 r u}{dr^2} = r \frac{du}{dr} + u = -\frac{r^2 - r' \gamma}{k^2} + \frac{1}{k^2};
\]

\[
\frac{d^2 r u}{dr^2} = 3 \frac{r (r - r' \gamma)^2}{k^2} - \frac{2 r - r' \gamma}{k^2} - \frac{r - r' \gamma}{k^2};
\]

\[
= 3 \frac{r r' \gamma (\gamma^2 - 1)}{k^2} + \frac{2 r' \gamma}{k^2};
\]

\[
\Rightarrow \frac{d^2 r u}{dr^2} = 3 \frac{r^2 r' \gamma (\gamma^2 - 1)}{k^2} + 2 r r' \gamma.
\]

Again,

\[
\frac{d u}{d \mu} = -\frac{1}{2 k^2} \frac{dk}{d \mu} \frac{du}{d \mu^2} = \frac{3}{4 k^2} \frac{dk^4}{d \mu^4} - \frac{1}{2 k^2} \frac{d^2 k}{d \mu^2};
\]

\[
\frac{d (1 - \mu^2)}{d \mu} = (1 - \mu^2) \left\{ \frac{3}{4 k^2} \frac{dk^4}{d \mu^4} - \frac{1}{2 k^2} \frac{d^2 k}{d \mu^2} \right\} + \frac{\mu}{k^2} \frac{d k}{d \mu};
\]

Also

\[
\frac{d u}{d \omega} = -\frac{1}{2 k^2} \frac{dk}{d \omega} \frac{du}{d \omega^2};
\]

\[
\Rightarrow \frac{d (1 - \mu^2)}{d \mu} + \frac{1}{1 - \mu^2} \frac{d^2 k}{d \omega^2} = \frac{3}{4 k^2} \left\{ (1 - \mu^2) \frac{d k^4}{d \mu^4} + \frac{1}{1 - \mu^2} \frac{d^2 k}{d \omega^2} \right\} + \frac{\mu}{k^2} \frac{d k}{d \mu};
\]

Now

\[
\frac{dk}{d \mu} = -2 r r' \left\{ \mu' - \frac{\sqrt{1 - \mu^2}}{\sqrt{1 - \mu'^2}} \mu \cos (\omega - \omega') \right\};
\]

\[
\frac{dk}{d \omega} = 2 r r' \sqrt{1 - \mu^2} \sqrt{1 - \mu'^2} \sin (\omega - \omega');
\]

hence,

\[
(1 - \mu^2) \frac{d k^4}{d \mu^4} + \frac{1}{1 - \mu^2} \frac{d k^4}{d \omega^2} = 4 r r' \left\{ 1 - \mu^2 \mu'^2 - (1 - \mu^2) (1 - \mu'^2) \cos (\omega - \omega') \right\} \left\{ -2 \mu \mu' \sqrt{1 - \mu^2} \sqrt{1 - \mu'^2} \cos (\omega - \omega') \right\} = 4 r r' \left\{ 1 - \gamma^2 \right\}
\]

Also,

\[
\frac{d^3 k}{d \mu^3} = \frac{2 r r' \sqrt{1 - \mu^2}}{1 - \mu^2} \cos (\omega - \omega');
\]

\[
\frac{d^3 k}{d \omega^3} = 2 r r' \sqrt{1 - \mu^2} \sqrt{1 - \mu'^2} \cos (\omega - \omega');
\]

Hence

\[
(1 - \mu^2) \frac{d k^4}{d \mu^4} + \frac{1}{1 - \mu^2} \frac{d k^4}{d \omega^2} = 4 r r' \sqrt{1 - \mu^2} \sqrt{1 - \mu'^2} \cos (\omega - \omega').
\]

Again,

\[
\frac{\mu}{k^2} \frac{d k}{d \mu} = \frac{2 r r' \sqrt{1 - \mu^2}}{1 - \mu^2} \left\{ \frac{\sqrt{1 - \mu^2}}{\sqrt{1 - \mu'^2}} \mu \cos (\omega - \omega') - \mu \mu' \right\}.
\]

Hence the expression

\[
\frac{d (1 - \mu^2) \frac{du}{d \mu}}{d \mu} + \frac{1}{1 - \mu^2} \frac{d^2 k}{d \omega^2}
\]

becomes...
Theory of Electricity.

\[
\frac{3}{k^2} \left( 1 - \gamma^2 \right) - \frac{2}{r^2} \left\{ \sqrt{1 + \mu^2} \sqrt{1 + \mu^2 \cos(\omega - \omega') + \mu \omega'} \right\}
\]

\[
= \frac{3}{k^2} \left( 1 - \gamma^2 \right) - \frac{2}{k^2} r' \gamma
\]

Hence we have

\[
r \frac{d^2 u}{dr^2} + \frac{d (1 - \mu^2)}{d \mu} \frac{d u}{d \mu} + \frac{1}{1 - \mu^2} \frac{d^2 u}{d \omega^2} = 0 \quad \text{.................................. (A)}
\]

Whence

\[
\frac{d^2 r V}{dr^2} + \frac{d (1 - \mu^2)}{d \mu} \frac{d V}{d \mu} + \frac{1}{1 - \mu^2} \frac{d^2 V}{d \omega^2} = 0 \quad \text{.................................. (B)}
\]

which is the general equation.

(241.) Let

\[
\frac{1}{\sqrt{(r^2 - 2 r r' \gamma + r'^2)}} = \frac{1}{r} U_0 + \frac{r'}{r^2} U_1 + \frac{r'^2}{r^3} U_2 + \ldots + \frac{r'^n}{r^{n+1}} U_n + \ldots
\]

When \( U_n \) is a rational function of \( n \) dimensions in \( \gamma \).

And the equation (A), being true of \( u \), is true of this series. Hence, substituting and equating the coefficients of \( \frac{r'^n}{r^{n+1}} \) we have

\[
n (n + 1) U_n + \frac{d}{d \mu} (1 - \mu^2) \frac{d U_n}{d \mu} + \frac{1}{1 - \mu^2} \frac{d^2 U_n}{d \omega^2} = 0 \quad \text{.................................. (L)}
\]

which is Laplace's equation. And the coefficients \( U_0, U_1, \&c. \) subject to this equation are Laplace's coefficients.

It may be observed that \( U_n \) will involve \( \mu, \mu', \) and \( \omega, \omega' \) similarly.

(242.) To deduce Ivory's equation.

Let

\[
S = \frac{1}{f^{2m+1}}; \quad \text{then since } f = \sqrt{(r^2 - 2 r r' \gamma + r'^2)}
\]

\[
\frac{d S}{dr} = -(2m+1) \frac{r - \eta r'}{f^{2m+3}}; \quad \frac{d S}{d \gamma} = (2m+1) \frac{r r'}{f^{2m+3}}
\]

\[
\frac{d^2 S}{dr d \gamma} = (2m+1) \frac{(2m+3)(r - \gamma r') (r' - \gamma r) + \gamma f^2}{f^{2m+5}}
\]

\[
d \left( 1 - \gamma r' \right)^{m+1} \frac{d S}{d \gamma} = (2m+1) \frac{1 - \gamma r'}{f^{2m+5}}
\]

and by substituting for \( f^2 \) its value, it will be seen that the two fractions are equal,

hence

\[
r r' (1 - \gamma r') \frac{d S}{dr d \gamma} = \frac{d \left( 1 - \gamma r' \right)^{m+1} d S}{d \gamma} = 0 \quad \text{.................................. (C)}
\]

We have

\[
\frac{1}{f} = \frac{1}{r} U_0 + \frac{r'}{r^2} U_1 + \ldots + \frac{r'^n}{r^{n+1}} U_{n+1} + \ldots
\]

Differentiate \( m \) times in succession with respect to \( \gamma \), observing that \( \frac{d f}{d \gamma} = - \frac{r'}{f} \) : and we have

\[
\frac{1}{f^{2m+1}} = \frac{1}{3 \cdot 5 \ldots 2m - 1} \left\{ \frac{1}{r^{2m+1}} \frac{d^m U_n}{d \gamma^m} + \frac{r'}{r^{2m+2}} \frac{d^m U_{m+1}}{d \gamma^m} + \ldots + \frac{r'^{n-1}}{r^{2m+n+1}} \frac{d^m U_{n+1}}{d \gamma^m} \right\}
\]

Substitute this series for \( S \) in (C), and equate terms involving \( \frac{r'^n}{r^{n+1}} \), and we have

\[
(n - m) (n + m + 1) \left( 1 - \gamma r' \right)^m \frac{d^m U_n}{d \gamma^m} + \frac{d \left( 1 - \gamma r' \right)^{m+1} U_n}{d \gamma} = 0 \quad \text{.................................. (I)}
\]

which is Ivory's equation.
Chap. II.

The following equation might be deduced independently, but it is included in Ivory’s equation of making \( m = 0 \),

\[
\frac{d}{d\gamma} \left( n(n+1) U_\gamma \right) \frac{d U_\gamma}{d\gamma} = 0 \quad \text{.................................. (D)}
\]

Now let \( U_\gamma = N \gamma^m + N^{(1)} \gamma^{m-1} + N^{(2)} \gamma^{m-2} + \ldots + N^{(n)} \gamma^{m-n} + \ldots \) which, it will be recollected, is the form of \( U_\gamma \); and by performing the operations indicated in equation (D) we shall find \( N^{(1)} = 0 \), \( N^{(2)} = 0 \), &c. for all the odd powers, and

\[
N^{(2n)} = - \frac{(n-2m+2)(n-2m+1)}{2m(2n-2m+1)} N^{(2n-2)}
\]

whence putting \( m = 1 \), \( m = 2 \), &c. we find all the coefficients in succession in terms of the first. We have thus

\[
U_\gamma = N \left( \gamma^n + \frac{n(n-1)}{2(2n-1)} \gamma^{n-2} + \frac{n(n-1)(n-2)(n-3)}{2.4(2n-1)(2n-3)} \gamma^{n-4} + \ldots \right)
\]

In order to find \( N \), it is to be observed that \( U_\gamma \) is the coefficient of \( \frac{r^m}{r^m+1} \) in the expansion of \( \frac{1}{r} \). Now

\[
\frac{1}{r} = \sqrt{\left( \frac{r^m}{r^m+1} \right)} \left( \frac{1 - \frac{2}{r^m}}{r^m+1} \right)^{-\frac{1}{2}}
\]

and, by the binomial theorem, the term containing \( \gamma^m \) will be

\[
= \frac{1.3.5 \ldots (2n-1)}{1.2.3 \ldots n} \left\{ \gamma^m - \frac{n(n-1)}{(2n-1)} \gamma^{m-2} + \frac{n(n-1)(n-2)(n-3)}{2.4(2n-1)(2n-3)} \gamma^{m-4} + \ldots \right\}
\]

Whence it is clear that

\[
N = \frac{1.3.5 \ldots (2n-1)}{1.2.3 \ldots n}.
\]

Hence

\[
U_\gamma = \frac{1.3.5 \ldots (2n-1)}{1.2.3 \ldots n} \left\{ \gamma^m - \frac{n(n-1)}{(2n-1)} \gamma^{m-2} + \frac{n(n-1)(n-2)(n-3)}{2.4(2n-1)(2n-3)} \gamma^{m-4} + \ldots \right\}
\]

(244.) To expand \( U_\gamma \) in terms of \( \omega - \omega' \).

If we make \( \omega - \omega' = \phi \), since \( \gamma = \mu \phi' + \sqrt{(1-\mu^2)} \sqrt{(1-\mu^2)} \cos \phi' \), it is easy to see that \( U_\gamma \) may be expanded in terms involving successively \( \cos \phi \), \( \cos 2\phi \), \( \cos 3\phi \), &c. and our object is to find the coefficients of these terms. Also it is clear that the term which involves \( \cos m \phi \) will involve \( (1-\mu^2)^m \). Hence let

\[
U_\gamma = H^{(1)} + H^{(2)} (1-\mu^2)^{\frac{1}{2}} \cos \phi + H^{(3)} (1-\mu^2)^{\frac{3}{2}} \cos 2\phi + \ldots + H^{(m)} (1-\mu^2)^{\frac{m}{2}} \cos m \phi + \ldots
\]

Now substitute this series for \( U_\gamma \) in Laplace’s equation (L), and we shall find, by equating coefficients of \( \cos m \phi \),

\[
(n-m)(n+m+1)(1-\mu^2)^{\frac{m}{2}} H^{(m)} - 2(m+1) \mu (1-\mu^2)^{\frac{m}{2}} \frac{d H^{(m)}}{d\mu} + (1-\mu^2)^{\frac{m+1}{2}} \frac{d^2 H^{(m)}}{d\mu^2} = 0,
\]

And if we multiply this by \( (1-\mu^2)^{m+1} \), we shall have

\[
(n-m)(n+m+1)(1-\mu^2)^{m+1} H^{(m)} - 2(m+1) \mu (1-\mu^2)^{m+1} \frac{d H^{(m)}}{d\mu} + (1-\mu^2)^{m+1} \frac{d^2 H^{(m)}}{d\mu^2} = 0,
\]

which is equivalent to

\[
\frac{d}{d\mu} \left( n(n-1) \right) H^{(m)} + \frac{d^2 U_\gamma}{d\mu^2} = 0, \ldots \ldots
\]

This agrees with Ivory’s equation (I), if we make \( H^{(m)} = \frac{d U_\gamma}{d\gamma^m} \), and then put \( \mu \) for \( \gamma \). Hence \( H^{(m)} \) will be found by knowing \( U_\gamma \). The value of \( N \), (art. 243.) being indeterminate in this case, we have

\[
H^{(m)} = B^{(m)} \frac{d^m U_\gamma}{d\gamma^m},
\]

when \( B^{(m)} \) is a coefficient independent of \( \mu \).

Let \( Q \) represent the same function of \( \mu \) which \( U_\gamma \) is of \( \gamma \), or

\[
Q = \frac{1.3.5 \ldots 2n-1}{1.2.3 \ldots n} \left\{ \mu^n - \frac{n(n-1)}{2(2n-1)} \mu^{n-2} + \ldots \right\}
\]
Electricity.

Theory of then we shall have for the term of \( U_n \), involving \( \cos m \phi \),

\[
B^{(m)} \frac{d^m Q_n}{d \mu^m} (1 - \mu^m)^m \cos m \phi; 
\]

in which \( B^{(m)} \) does not involve \( \mu \). But \( \mu \) and \( \mu' \) enter alike into the expression of \( Q_n \); and hence they will appear similarly in every term of the expansion. Hence we shall have for the term involving \( m \phi \)

\[
\beta^{(m)} \frac{d^m Q_n}{d \mu^m} \cdot \frac{d^m Q'_n}{d \mu'^m} (1 - \mu^m)^m (1 - \mu'^m)^m \cos m \phi, 
\]

when \( \beta^{(m)} \) is independent both of \( \mu \) and \( \mu' \), and \( Q' \) is the same function of \( \mu' \) that \( Q \) is of \( \mu \).

Hence

\[
U_n = \beta^{(m)} Q_n Q'_n + \beta^{(1)} (1 - \mu^m) \frac{d Q_n}{d \mu} \frac{d Q'_n}{d \mu} \cos \phi 
\]

\[
+ \beta^{(2)} (1 - \mu^m) \frac{d^2 Q_n}{d \mu^2} \frac{d^2 Q'_n}{d \mu'^2} \cos 2 \phi 
\]

\[
+ \text{&c.} 
\]

In order to find \( \beta^{(m)} \), we may observe that \( \beta^{(m)} Q_n Q'_n \) is the term independent of \( \phi \) in the coefficient of \( \frac{r^{2n}}{r^{2n} + 1} \). Now we have

\[
\frac{1}{r^2} = \frac{1}{\sqrt{r^2 - 2rr' (\mu \mu' + \sqrt{(1 - \mu^m) \sqrt{(1 - \mu'^m) \cos \phi + \phi')}}} 
\]

\[
= \frac{1}{\sqrt{r^2 - 2rr' \cos \phi + \phi')} + \text{&c.} 
\]

the other terms involving \( \mu, \mu' \). And

\[
\frac{1}{\sqrt{r^2 - 2rr' \cos \phi + \phi')} = \frac{1}{r} \left( 1 - \frac{r'}{r} \cos \phi \right)^{\frac{1}{2}} \left( 1 - \frac{r'}{r} \cos \phi \right)^{-\frac{1}{2}} 
\]

c being the base of the Napierian logarithms,

\[
= \frac{1}{r} \left( 1 + \frac{1}{2} \frac{r'}{r} \cos \phi \right)^{\frac{1}{2}} \left( 1 + \frac{1}{2} \frac{r'}{r} \cos \phi \right)^{-\frac{1}{2}} + \text{&c.} 
\]

and the term which does not involve \( \phi \), and which does involve \( \frac{r^{2n}}{r^{2n} + 1} \) is obviously that which arises from the factors

\[
\frac{1}{r} \times \frac{1.3.5\ldots(2n-1)}{2.4.6\ldots2n} \frac{r^{2n}}{r^{2n}} \cos \frac{\phi}{2} \cos \frac{1}{2} + \text{&c.} 
\]

Hence it is clear that we have \( \left( \frac{1.3.5\ldots(2n-1)}{2.4.6\ldots2n} \right)^{\frac{1}{2}} \) is the part of \( \beta^{(m)} Q_{2n} Q'_{2n} \), which is independent of \( \mu, \mu' \). Now since

\[
Q_{2n} = \frac{1.3.5\ldots(4n-1)}{2.4.6\ldots2n} \left\{ \mu^{2n} - \frac{2n}{2(4n-1)} \mu^{2n-2} + \text{&c.} \right\} 
\]

it is easily seen that the part independent of \( \mu \) is

\[
\pm \frac{1.3.5\ldots(4n-1)}{2.4.6\ldots2n} \frac{2n}{2(4n-1)} \left( \frac{2n}{(2n-1)} \right) \ldots \left( \frac{2n}{2n} \right) 
\]

\[
= \pm \frac{1.3.5\ldots(2n-1)}{2.4.6\ldots2n} 
\]

And hence in \( \beta^{(m)} Q_{2n} Q'_{2n} \) the part independent of \( \mu, \mu' \) is

\[
\beta^{(m)} \left( \frac{1.3.5\ldots(2n-1)}{2.4.6\ldots2n} \right)^{\frac{1}{2}} \right) \frac{d Q_n}{d \mu} \frac{d Q'_n}{d \mu'} \cos \phi + \text{&c.} 
\]

Hence

\[
U_n = Q_n Q'_n + \beta^{(1)} (1 - \mu^m) \frac{d Q_n}{d \mu} \frac{d Q'_n}{d \mu} \cos \phi + \text{&c.} 
\]
To reduce the value of $V$ into a series of terms of double integrals.

It will be recollected that $y'$ is the thickness of the attracting stratum on the surface of the sphere. At a point, of which the coordinates are $r, \mu, \omega$, let it be $y$. We will suppose that the stratum is symmetrical with respect to the axis from which $\theta$ (the angle whose cosine is $\mu$) is measured; so that taking a ring perpendicular to this axis, the thickness is the same in every part. Hence $y$ is the same for any value of $\omega$, and depends on $\mu$ alone, of which it is a function. If we further assume that $y$ is a rational and integral function of $\mu$, we may expand it into a series of terms subject to Laplace's equation. Let therefore

$$y = y_0 + y_1 + y_2 + \ldots + y_n + \ldots$$

whence

$$n(n + 1) y_n + \frac{d}{d \mu} \left(1 - \mu^2\right) \frac{d y_n}{d \mu} = 0,$$

the term vanishing which supposes $y_n$ to involve $\omega$. And if we find $y_n$ by the same process as that of which we found $U_n$, we shall manifestly have a similar result. Hence

$$y = A_0 Q_0 + A_1 Q_1 + A_2 Q_2 + A_3 Q_3 + \ldots + A_n Q_n + \ldots$$

when $A_0, A_1, \&c.$ do not involve $\omega$, and $Q$ is the same function of $\mu$ as before. Hence if we suppose that we have $y' \mu'$, instead of $y, \mu$, we have

$$y' = y'_0 + y'_1 + y'_2 + \ldots + y'_n + \ldots$$

$$y' = A_0 Q'_0 + A_1 Q'_1 + A_2 Q'_2 + \ldots + A_n Q'_n + \ldots$$

Now $V = \int \frac{y' d \omega'}{f}$ where $d \omega'$ is the differential of the surface, at the point of which the coordinates are $\theta', \omega'$. And it is clear that this differential is $r' d \theta'$. $r' \sin \theta' d \omega' = - r^2 d \mu' d \omega'$. Hence

$$V = - \int \frac{y' r'^2 d \mu' d \omega'}{f},$$

the integral being taken from $\mu = 1$ to $\mu = -1$. Or, if we change the sign, $V = \int \frac{y' r'^2 d \mu' d \omega'}{f}$ from $\mu = -1$ to $\mu = 1$, and from $\omega' = 0$ to $\omega = 2 \pi$.

If now to put for $y'$ its value, we have

$$V = A_0 \int \frac{Q'_0 r'^2 d \mu' d \omega'}{f} + A_1 \int \frac{Q'_1 r'^2 d \mu' d \omega'}{f} + \ldots + A_n \int \frac{Q'_n r'^2 d \mu' d \omega'}{f} + \ldots$$

And we have the expansion of $\frac{1}{f}$, viz.

$$\frac{1}{f} = \frac{1}{r} U_0 + \frac{r'}{r^2} U_1 + \ldots + \frac{r^n}{r^{n+1}} U_n + \ldots$$

Hence it appears that the value of $V$ will consist of such terms as

$$A_n \int \frac{Q'_n r'^2 + \omega' d \mu' d \omega'}{r^{n+1}}$$

(246.) To execute the integration in $\omega'$. If we put for $U_n$ its value in (244), which we may represent thus,

$$U_n = Q_n + M \cos \phi + M' \cos 2 \phi + \&c.$$ 

$M, M'$ not involving $\phi$; we shall find for the general term of $V$, just mentioned, observing that $\phi = \omega - \omega'$,

$$A_n \left\{ \int \frac{Q'_n Q_n r'^2 + \omega' d \mu' d \omega'}{r^{n+1}} + \int \frac{Q'_n M r'^2 + \omega' d \mu' \cos (\omega - \omega') d \omega'}{r^{n+1}} \right\}$$

And when we perform the integration in $\omega'$, it is clear that the terms after the first will involve $\sin (\omega - \omega')$, $\sin 2 (\omega - \omega')$, &c. and will therefore vanish when taken from $\omega = 0$ to $\omega = 2 \pi$. Hence the whole expression will be reduced to terms such as

$$2 \pi A_n \int \frac{Q'_n Q_n r'^2 + \omega' d \mu'}{r^{n+1}}$$

or supposing $r'$ constant, the terms are

$$2 \pi A_n Q_n \frac{r'^2 + \omega'}{r^{n+1}} \int Q'_n Q' d \mu'.$$

And it is seen by referring to the value of Q, and Q'a, in (244.) that


Theory of Electricity

\[ \frac{d^n Q_a}{d \mu^n} = 1 \cdot 3 \cdot 5 \ldots (2n - 1). \]

Hence

\[ \int Q'_a Q'_a d \mu' = \frac{(1 \cdot 3 \cdot 5 \ldots (2n - 1)^2}{1 \cdot 2 \cdot 3 \ldots 2n} \int (1 - \mu'^2)^n d \mu'. \]

Also it may easily be shown that between the limits \( \mu' = -1 \) and \( \mu' = 1 \), we have

\[ \int (1 - \mu'^2)^n d \mu' = 2 \cdot \frac{2n \cdot 2 \cdot (n - 1) \ldots \ldots 2}{(2n + 1) \cdot (2n - 1) \ldots \ldots 3}. \]

Hence

\[ \int Q'_a Q'_a d \mu = \frac{2}{2n + 1} \cdot \frac{2n \cdot 2 \cdot (n - 1) \ldots \ldots 2}{(2n - 1) \cdot (2n - 3) \ldots \ldots 1} \cdot 1 \cdot 2 \ldots \ldots 2n. \]

(249.) To find the value of \( V \).

The general term of \( V \) is

\[ \frac{4 \pi}{2n + 1} A_n Q_n \frac{r^n + 2}{r^n + 1}. \]

And it has been seen that \( A_n Q_n = y_n \) where \( y_n \) is the general term of the expansion of the thickness at the point of which the ordinates are \( \theta, \phi \). Hence the general term of \( V \) is \( \frac{4 \pi}{2n + 1} r^{n + 1}. \) And hence, if for \( r' \) we put \( a \), the radius of the sphere, we shall have

\[ V = \frac{4 \pi a^2}{r} \left\{ y_0 + \frac{a^2}{3 \pi} y_1 + \frac{a^2}{5 \pi^2} y_2 + \frac{a^2}{7 \pi^3} y_3 + \ldots + \frac{a^n}{(2n + 1) \pi^r} y_n + \&c. \right\}. \]

(250.) If the point attracted be within the sphere, the process will be the same, except that we must expand \( V \) according to powers of \( \frac{r}{r'} \). We shall have \( \frac{1}{r'} = \frac{1}{r} U_0 + \frac{r}{r^2} U_1 + \frac{r^2}{r^3} U_2 + \&c. \) when \( U_0, U_1, U_2, \&c. \)

are the same as before; and we shall find that \( V \) consists of terms \( A_n \int \int Q'_a U_n \frac{r^n}{r^n - 1} d \mu' d \omega' \). Also the integrals will vanish, except when \( n = m \), and we shall have for \( V \) a series of terms \( \frac{4 \pi}{2n + 1} \frac{r^n}{r^n - 1} \cdot \frac{a^{2 n + 2}}{r^{2 n + 1}} \). And hence, making \( r' = a \), we have

\[ V = \frac{4 \pi}{r} \left\{ y_0 + \frac{r}{3 \pi} y_1 + \frac{r^2}{5 \pi^2} y_2 + \ldots + \frac{r^n}{(2n + 1) \pi^r} y_n + \&c. \right\}. \]

Hence, whatever be the law of the thickness of the stratum, we can find its attraction upon any point, in any direction, by expanding the expression for the thickness into a series of Laplace's coefficients, and giving to the terms those values which they have at the point where the surface is met by the line \( r \) drawn to the attracted point.

(251.) In these values of \( V \) the expressions involve \( \mu \) and \( \frac{r}{a} \).

If we put

\[ \phi (\mu, x) = A_0 Q_0 + \frac{x}{3} A_1 Q_1 + \frac{x^2}{5} A_2 Q_2 + \&c. \]

we shall have the value of \( V \),

for an exterior point

\[ = \frac{4 \pi}{r} \phi \left( \frac{x}{a} \right); \]

for an interior point

\[ = 4 \pi a \phi \left( \frac{x}{a} \right). \]

(252.) Knowing \( \phi \) when \( \mu = 1 \), to find its general value.

We have

\[ \frac{1}{\sqrt{(r^2 - 2 \mu r a + a^2)}} = \frac{1}{r} Q_0 + \frac{a}{r^2} Q_1 + \frac{a^2}{r^3} Q_2 + \&c. \]

And when \( \mu = 1 \), this becomes

\[ \frac{1}{r - a} = \frac{1}{r} + \frac{a}{r^2} + \frac{a^2}{r^3} + \&c. \]

Hence for this case \( Q_0, Q_1, Q_2, \&c. \) are each \( 1 \).

Therefore making \( \mu = 1 \), we have

\[ \phi (1, x) = A_0 + \frac{x}{3} A_1 + \frac{x^2}{5} A_2 + \&c. \]

Hence if when \( \mu = 1 \), the value of \( \phi (\mu, x) \) is \( f(x) \), we must expand \( f(x) \) in a series, according to powers of \( x \), and multiplying the terms of this series by \( Q_0, Q_1, Q_2, \&c. \) which are known functions of \( \mu \), we shall have the value of \( \phi (\mu, x) \) for any value of \( \mu \).
It appears from this, that if we know the value of $V$, for any point situate in the axis of the sphere, we can find it for any point in any other situation.

If we make $\mu = -1$, we shall have

$$\frac{1}{r + a} = \frac{1}{r} - \frac{a}{r^2} + \frac{a^2}{r^3} - \&c.$$ 

Hence

$$\phi (-1, x) = A_0 - \frac{x}{3} A_1 + \frac{x^4}{5} A_2 - \&c.$$ 

And hence, if in $f$ we put $-x$ instead of $x$, and multiply the terms by $Q_0, Q_1, Q_2,$ we shall have the value of $\phi (\mu, x)$ corresponding to the point opposite to the point where $\mu = 1$.

(253.) Knowing $\phi (\mu, x)$ to find the thickness at any point.

We have

$$\frac{d \phi (\mu, x)}{dx} = \frac{1}{3} y_1 + \frac{2 x}{5} y_2 + \frac{3 x^2}{7} y_3 + \&c.$$ 

Hence

$$\phi (\mu, x) + 2 x \frac{d \phi (\mu, x)}{dx} = y_0 + x y_1 + x^2 y_2 + x^3 y_3 + \&c.$$ 

and, making $x = 1,$

$$y = y_0 + y_1 + y_2 + y_3 + \&c. = y,$$

whence $y$ the thickness is known.

At the extremities of the diameter from which the angle is measured, we have $\mu = 1,$ and $\mu = -1; \&c.$ which gives the same result as putting $f$ for $\phi (\mu, x)$. Hence at these points we have

$$y = f x + 2 x \frac{df}{dx};$$

and we must make $x = 1$ for the thickness for the point where $\mu = 1,$ and $x = -1$ for the point diametrically opposite.

§ II. Distribution of a stratum of fluid on two spheres acting upon one another.

(254.) When a sphere contains equal quantities of positive and negative electricity, the two fluids will be uniformly distributed through its substance, and each particle of one fluid will be accompanied by an equal portion of the other; and hence, as one of them attracts what the other repels, their united effect on any point will be nothing. And hence, if we had two such spheres, their effect on one another will be nothing, and they will remain in this state. But if one of the spheres contain an excess of one of the fluids, as, for instance, of the positive, this excess will distribute itself on the surface, and form a thin stratum there. And this stratum will exert a certain action on the particles of another sphere; and by attracting the negative, and repelling the positive fluid, it may separate them, and cause portions of them to proceed to the surface. By this means the effective parts of the fluids will be a thin stratum at the surface of each sphere, the action of which may be calculated by the preceding formulas; and the law according to which the thickness will vary on each sphere will depend on their mutual action.

In order to calculate the thickness of the stratum of electricity on each sphere, we must know their magnitude and position, and the excess of one kind of electricity above the other on each sphere. By the mutual action of the two spheres, it may happen that besides the original excess of one kind of electricity, some portion of the fluids in the interior of the spheres may be separated, or decomposed, and carried to the surface. By this means the quantity of one fluid, the positive for instance, at the surface, may be increased; but in such cases the excess of the positive above the negative will remain the same as if no such action had been exerted, because equal quantities of both are always separated. The negative fluid will occupy a portion of the surface, and the thickness $y$ must be reckoned negative for all points when this occurs. In fact, the mechanical action of these points will be obtained by changing the sign of the quantities which express the mechanical action of the portions, supposing them to have been positive.

(255.) To find the quantity of fluid in a stratum on the surface of a sphere.

It is easily seen then

$$\int \int y \, a^2 \, d\mu \, d\omega$$

is the content of the stratum, in which the integrals are to be taken from $\omega = 0$ to $\omega = 2\pi,$ and from $\mu = -1$ to $\mu = 1.$ If both the fluids occur in different parts of the surface, $y$ will be positive in some points and negative in others, and the integral will still represent the excess as before. Let this excess $= E.$

Now

$$y = A_0 \, Q_0 + A_1 \, Q_1 + A_2 \, Q_2 + \&c.$$ 

Hence

$$Q_0 = 1, \, Q_1 = \mu, \, \&c.;$$

and we have

$$E = \int \int y \, a^2 \, d\mu \, d\omega = a^2 \left\{ A_0 \int \int Q_0 \, d\mu \, d\omega + A_1 \int \int Q_1 \, d\mu \, d\omega + A_2 \int \int Q_2 \, d\mu \, d\omega + \&c. \right\}$$

Now

$$\int \frac{1}{\sqrt{(r^2 - 2 \mu r \rho' + \rho'^2)}} \, d\omega = \frac{1}{r} \, Q_0 + \frac{\rho'}{r^2} \, Q_1 + \frac{\rho'^2}{r^3} \, Q_2 + \&c. \ldots \text{See (241.) and (244.)}$$

Hence
E = \alpha^2 \left\{ A_0 \int \int Q_0 \, d \mu \, d \omega + A_1 \int \int Q_1 \, d \mu \, d \omega + A_2 \int \int Q_2 \, d \mu \, d \omega + \cdots \right\}

= 2 \pi a^2 \left\{ A_0 \int \int Q_0 \, d \mu + A_1 \int \int Q_1 \, d \mu + A_2 \int \int Q_2 \, d \mu + \cdots \right\}

And by art. 247, all these terms vanish except the first. Hence \( E = 4 \pi a^2 A_0 \).

Cor. Since \( 4 \pi a^2 \) is the surface of the sphere, \( A_0 = \frac{E}{4 \pi a^2} \) is the thickness of the stratum of fluid, on the supposition that it is uniformly distributed; that is, supposing the fluid on the sphere not to be acted on by any other electrical body.

But

\[ f \times = A_0 + \frac{x}{3} A_1 + \frac{x^2}{5} A_2 + \cdots \]

Hence we have \( A_0 \) by making \( x = 0 \) in \( f \times \).

(256.) To find the action of two spheres on any point within one of them.

Let \( b \) be the radius of the second sphere, \( r, \mu \), the coordinates of the attracted point corresponding to \( r, \mu \); \( \psi (\mu, 1, x) \) the function analogous to \( \phi (x, \mu) \); and \( V_1 \) the sum of each particle of the second sphere, divided by its distance from the attracted point. We shall then have, by art. 251.

for an interior point

\[ V_1 = 4 \pi b^2 \psi \left( \frac{\mu}{b} \right) \]

for an exterior point

\[ V_1 = \frac{4 \pi b^2}{r_1} \psi \left( \frac{\mu}{r_1} \right) \]

Hence if \( W = V + V_1 \), the sum of each attracting particle divided by its distance, we shall have for an attracted point within the first sphere

\[ W = 4 \pi a^2 \phi \left( \frac{r}{a} \right) + \frac{4 \pi b^2}{r} \psi \left( \frac{\mu}{r_1} \right) \]

And, for a point within the second sphere,

\[ W = 4 \pi a^2 \phi \left( \frac{\mu}{a} \right) + b \psi \left( \frac{\mu}{b} \right) \]

And, as has been shown, art. 238, by differentiating \( W \) we find the attraction on the point in any direction.

(257.) To find the value of \( f \times \), art. 252, when the spheres act upon one another.

In order that the fluids may be in equilibrium, their action on a point within each of the spheres must be nothing; for if it were either attractive or repulsive it would separate the particles of the fluids in the interior of the body, and an additional portion of each would go to the surface. Hence the differentials of \( W \), with respect to \( r \) and \( \mu \), and also to \( r_1 \), and \( \mu_1 \), must = 0; and therefore \( W \) must be independent of \( r \) and \( \mu \), and \( r_1 \) and \( \mu_1 \). Hence it must be equal to a constant quantity, for any point within either of the two spheres. Therefore let \( h \) and \( k \) be two constant quantities, and let the line of origin be that which joins the centres.

Then

\[ a \phi \left( \frac{\mu}{a} \right) + \frac{b^2}{r_1} \psi \left( \frac{\mu}{r_1} \right) = h \]

\[ \frac{a^2}{r} \phi \left( \frac{\mu}{r} \right) + b \psi \left( \frac{\mu}{b} \right) = k \]

\[ r \text{ and } r_1, \mu \text{, and } \mu_1 \text{, being connected by the condition that } r \text{ and } r_1 \text{ are the sides of a triangle, of which the third side is the distance of the centres of the spheres, and } \mu \text{, and } \mu_1 \text{, the cosines of the angles adjacent to these.} \]

But it has been seen, art. 252, that it is sufficient to know \( f \times \) in order to determine \( \phi (\mu, x) \); and if \( g x \) be related in the same manner to \( \psi x \), we shall have, making \( \mu = 1 \),

\[ a f \left( \frac{r}{a} \right) + \frac{b^2}{r_1} g \left( \frac{b}{r_1} \right) = h \]

\[ \frac{a^2}{r} f \left( \frac{a}{r} \right) + b g \left( \frac{r_1}{b} \right) = k \]

where \( r + r_1 = c \), the distance between the centres; and \( r \) and \( r_1 \), may have any values, from \( r = a \) to \( r = -a \), and from \( r_1 = b \) to \( r_1 = -b \).

In order to eliminate one of the unknown functions \( f, g \), we shall, in the second equation, put \( r' = a \), and \( c - r' \) for \( r \) and \( r_1 \); and let \( r' \) be such that

\[ \frac{c - r'}{b} = \frac{b}{r_1} = \frac{b}{c - r} \]

therefore

\[ r' = c - \frac{b^2}{c - r} = \frac{c (c - r) - b^2}{c - r - b} \]

\[ \text{Vol. IV.} \]
and the equations (G) become
\[ a f \left( \frac{r}{a} \right) + \frac{b^2}{a + b - r} g \left( \frac{b}{a + b - r} \right) = h \]
\[ a \left( \frac{a (c - r)}{c (c - r) - b^2} f \left( \frac{a (c - r)}{c (c - r) - b^2} \right) + b g \left( \frac{b}{c - r} \right) = k \]
and eliminating \( g \)
\[ a f \left( \frac{r}{a} \right) - \frac{a^2 b}{a + b - r} f \left( \frac{a (c - r)}{c (c - r) - b^2} \right) = h - \frac{kb}{c - r} \]
whence \( f \) is to be determined.

The determination of \( f \) in this case has been considered by Mr. Poisson, (Mém. de l'Institut, 1811, part ii. p. 183.) but as the investigation is of considerable complexity, and as we have not a series of experimental results to compare with our theoretical ones, we shall leave it at present, in order to consider the simpler case, in which the spheres are in contact.

(258.) To find the constant quantities \( h \) and \( k \).

If in equations (G) we make \( r = 0 \), and observe that \( f(0) = A_0 \) art. 252. we have \( A_0 + \frac{b^2}{c} g \left( \frac{b}{c} \right) = h \).

And if \( B_0 \) be the corresponding quantity for the second sphere, making \( r = 0 \), \( g(0) = B_0 \) and
\[ \frac{a^2}{c} f \left( \frac{a}{c} \right) + b B_0 = k. \]

If \( E \) and \( F \) be the whole quantities of excess of electricity in the spheres, we shall have
\[ E = 4 \pi a^2 A_0, \quad F = 4 \pi b^2 B_0. \]

\( h = \frac{E}{4 \pi a} + \frac{b^2}{c} g \left( \frac{b}{c} \right), \quad k = \frac{F}{4 \pi b} + \frac{a^2}{c} f \left( \frac{a}{c} \right). \)

§ III. On the distribution of a fluid on the surfaces of two spheres in contact.

(259.) In this case to find the function \( f \).

When the two spheres are in contact, we shall have \( e = a + b \). Hence equations (G) become, observing that \( r + r_1 = c \)
\[ a f \left( \frac{r}{a} \right) + \frac{b^2}{a + b - r} g \left( \frac{b}{a + b - r} \right) = h \]
\[ a \left( \frac{a (a + b - r)}{a + b - r_1} f \left( \frac{a (a + b - r)}{a + b - r_1} \right) + b g \left( \frac{r_1}{b} \right) = k \]
And equation (H) will become
\[ a f \left( \frac{r}{a} \right) - \frac{a^2 b}{(a + b) (a + b - r) - b^2} f \left( \frac{a (a + b - r)}{(a + b) (a + b - r) - b^2} \right) = h - \frac{kb}{a + b - r} \]
Let \( \frac{r}{a} = 1 - z \), whence \( a - r = az \), and the equation becomes
\[ a f (1 - z) - \frac{a b}{(b + az) + b z} f \left( \frac{b + az}{(b + az) + b z} \right) = h - \frac{kb}{b + az} \]
or, multiplying by \( \frac{z}{a} \) &c.
\[ z f (1 - z) - \frac{b z}{b + az + b z} f \left( \frac{b z}{b + az + b z} \right) = h - \frac{kb z}{a(b + az)}. \]

If we make \( \frac{b}{a + b} = m, \) we shall have \( b = \frac{ma}{1 - m} \) and
\[ z f (1 - z) - \frac{m z}{z + m} f \left( \frac{m z}{z + m} \right) = h z - \frac{km z}{a (m + (1 - m) z)} \]
If the right-hand side of this equation were = 0, it is manifest that it would be satisfied by making \( z f (1 - z) = C \) a constant, or \( f (1 - z) = \frac{C}{z} \); for then, putting \( \frac{m z}{m + z} \) for \( z \), we should have also
\[ \frac{m z}{m + z} f \left( \frac{m z}{m + z} \right) = C. \]
Theory of Electricity.

If we consider the term \( \frac{h^2}{a} \) on the right-hand side, it will be seen that we may satisfy the equation, by Chap. II.

supposing \( z f(1 - z) \) to be equal to a certain definite integral, depending on a new variable \( t \), which disappears in performing the integration between certain limits. Let \( z f(1 - z) = C' \int \frac{t^{m - 1}}{1 - t} \, dt \) from \( t = 0 \) to \( t = 1 \); then putting \( \frac{m z}{m + z} \) for \( z \), \( \frac{m z}{m + z} f \left( 1 - \frac{m z}{m + z} \right) = C' \int \frac{t^{m - 1}}{1 - t} \, dt \),

and the first side becomes \( C' \int \frac{m z}{m + z} \, dt = \frac{C' z}{m + 1} \), (when taken from \( t = 0 \) to \( t = 1 \)) = \( \frac{C' z}{m + 1} \);

and satisfies the condition if \( \frac{C'}{m} = \frac{h}{a} \), or \( C' = \frac{m h}{a} \).

In the same manner, if we consider the term on the right-hand side, \( \frac{k m z}{a (m + 1 - m z)} \), it will be seen that we may satisfy it by making

\[ z f(1 - z) = C'' \int \frac{t^{m - 1}}{1 - t} \, dt \text{, from } t = 0 \text{ to } t = 1. \]

By this assumption we have, putting \( \frac{m z}{m + z} \) for \( z \),

\[ \frac{m z}{m + z} f \left( 1 - \frac{m z}{m + z} \right) = C'' \int \frac{t^{m - 1}}{1 - t} \, dt, \]

and thus the first side of equation (c) becomes

\[ C'' \int \frac{m t^{m - n}}{z - n + 1} \, dt = C'' \int \frac{m t^{n - n}}{z - n + 1} \, dt \]

(taking \( t \) from \( 0 \) to \( 1 \))

\[ \frac{C'' z}{m + (1 - m) z} \]

which coincides with

\[ - \frac{k m z}{a (m + 1 - m z)} \]

if

\[ C'' = - \frac{k m}{a}. \]

Hence the whole equation (c) will be satisfied, if we add together these terms, and make

\[ z f(1 - z) = C + \frac{m h}{a} \int \frac{t^{m - 1}}{1 - t} \, dt - \frac{m k}{a} \epsilon \int \frac{t^{m - 1}}{1 - t} \, dt \]

for each part on the left hand will produce a term agreeing with the corresponding one on the right hand as before, and the whole equation will be satisfied.

Cor. In this case, \( h = k \).

For making \( r = a, r_1 = b \) in equations (G), (art. 257), we have

\[ a f(1) + b g(1) = h, \]

\[ a f(1) + b g(1) = k. \]

Hence the above expression in (d) reduces to

\[ z f(1 - z) = C + \frac{m h}{a} \int \frac{1 - t^{m - 1}}{1 - t} \, dt, \]

whence the form of \( f \) is known,

\[ f(1 - z) = \frac{C}{z} + \frac{m h}{a z} \int \frac{1 - t^{m - 1}}{1 - t} \, dt. \]
The quantity \( f \left( \frac{r}{a} \right) \) must be finite from all values from \( r = -a \) to \( r = +a \); therefore \( f(1 - z) \) must be finite when \( r = a \), or \( z = 0 \). Hence the term \( \frac{C}{z} \) must vanish, and

\[
f(1 - z) = \frac{m h}{a} \int \frac{1 - t^{m - 1} - \frac{m}{t^{m}}}{1 - t} \, dt,
\]

and

\[
z f(1 - z) = \frac{m h}{a} \int \frac{1 - t^{m - 1} - \frac{m}{t^{m}}}{1 - t} \, dt, \quad (t = 0, t = 1).
\]

(260.) To find the function \( g \).

Take the second of equations \( a \), viz.

\[
\frac{a}{a + b - r} f \left( \frac{a}{a + b - r} \right) + \frac{b}{b} g \left( \frac{r}{b} \right) = k = h.
\]

Let

\[
\frac{a}{a + b - r} = a z, \text{ or } r = b - a z;
\]

\[
\frac{b}{b} = b z, \quad \frac{a}{a + b - r} = a z,
\]

and

\[
\frac{b}{b} g \left( 1 - \frac{a z}{b} \right) = \frac{h}{a} - \frac{a z}{1 + z}, f \left( 1 - \frac{a z}{b} \right) = \frac{1 - a z}{1 + z},
\]

Putting \( \frac{a z}{1 + z} \) for \( z \), in the result of the last article, the second side becomes

\[
\frac{h}{a} = \frac{m h}{a} \int \frac{1 - t^{m - 1} - \frac{m}{t^{m}}}{1 - t} \, dt
\]

\[
= \frac{m h}{a} \int \frac{1 - t^{m - 1} - \frac{m}{t^{m}}}{1 - t} \, dt, \quad (t = 0, t = 1).
\]

(as appears by taking the integral from \( t = 0 \) to \( t = 1 \))

\[
= \frac{m h}{a} \int \frac{1 - t^{m - 1} - \frac{m}{t^{m}}}{1 - t} \, dt
\]

\[
= \frac{m h}{a} \int \frac{1 - t^{m - 1} - \frac{m}{t^{m}}}{1 - t} \, dt, \quad (t = 0, t = 1).
\]

And if we make

\[
\frac{a}{a + b - r} = a z, \quad \frac{b}{b} = b z, \quad \frac{a}{a + b - r} = a z,
\]

we find

\[
z g \left( 1 - z \right) = \left( 1 - m \right) h \int \frac{1 - t^{m - 1} - \frac{m}{t^{m}}}{1 - t} \, dt.
\]

(261.) To find the constant quantity \( h \), knowing the whole quantity of fluid on the two spheres.

When the spheres are in contact, it is supposed that the fluid can pass freely from one to the other. Hence it is only the sum of the quantities on the two spheres which is given. And it has been shown, art. 258, that if \( E \) be the quantity on the sphere with radius \( a \), \( E = 4 \pi a^{4} f(x) \), making \( x = 0 \) in \( f(x) \); or \( E = 4 \pi a^{4} f(1 - z) \) making \( z = 1 \). So if \( F \) be the quantity on the other sphere, \( F = 4 \pi b^{4} g \left( 1 - z \right) \), making \( z = 1 \). Hence \( E + F = 4 \pi \left( a^{4} f(1 - z) + b^{4} g \left( 1 - z \right) \right) \) making \( z = 1 \).

And by the values just found, putting \( \frac{m a}{1 - m} \) for \( b \), and 1 for \( z \),

\[
E + F = 4 \pi a h \int \left\{ \frac{1 - t^{m - 1} - \frac{m}{t^{m}}}{1 - t} + \frac{1 - t^{m - 1} - \frac{m}{t^{m}}}{1 - t} \right\} \, dt
\]

\[
= 4 \pi m a h \int \frac{1 - t^{m - 1} - \frac{m}{t^{m}}}{1 - t} \, dt,
\]

whence \( h \) is to be determined.
To find the thickness of the stratum of fluid at the point of contact.

By art. 253, we have the thickness at this point by the formula

\[ y = f(x) + 2x \frac{df}{dx} \]

making \( x = 0 \); or

\[ y = f(1 - z) - 2(1 - z) \frac{df(1 - z)}{dx}, \]

making \( x = 0 \).

To find the value of this, let \( t = \theta \), and the expression for \( f(1 - z) \) becomes

\[ \frac{m h}{a z} \int \frac{1 - \theta^{(1 - m)s}}{1 - \theta^z} \theta^{m-1} \theta^{z-1} d\theta = \frac{m h}{a} \int \frac{1 - \theta^{(1 - m)s}}{1 - \theta^z} \theta^{m-1} d\theta, \]

the limits being \( \theta = 0, \theta = 1 \).

Expanding according to powers of \( z \), we find

\[ 1 - \theta^{(1 - m)s} = (1 - m) z \theta + \frac{1}{2} (1 - m)^2 z^2 (\theta^2) + \&c. \]

\[ = (1 - m) \left\{ 1 - \frac{m z}{2} \theta + \&c. \right\} \]

\[ \therefore f(1 - z) = \frac{(1 - m) m h}{a} \int \left\{ \theta^{m-1} \theta - \frac{m z}{2} \theta^{m-1} \theta \right\} d\theta + \&c. \]

And between the limits we have

\[ \int \theta^{m-1} d\theta = \frac{\theta^m}{m} = \frac{1}{m} \]

\[ \int \theta^{m-1} \theta d\theta = \frac{\theta^m \theta}{m} - \frac{1}{m} \int \theta^{m-1} d\theta \]

\[ = \frac{\theta^m}{m} - \frac{\theta^m}{m^2} \]

\[ = \frac{1}{m^2} \]

\[ \therefore f(1 - z) = \frac{m h}{a} (1 - m) \left\{ \frac{1}{m} + \frac{z}{2 m} + \&c. \right\} \]

\[ = (1 - m) \frac{h}{a} \left\{ 1 + \frac{z}{2} + \&c. \right\} \]

\[ \frac{df(1 - z)}{dz} = (1 - m) \frac{h}{2a} + \&c. \]

And when \( z = 0, f(1 - z) = (1 - m) \frac{h}{a}; \frac{df(1 - z)}{dz} = (1 - m) \frac{h}{2a} \).

Hence, at the point of contact, we have for the thickness of the fluid on the sphere whose radius is \( a \),

\[ y = 0. \]

And in the same manner the thickness of the electrical stratum on the other sphere will be \( 0 \) at the point of contact.

(263.) The spheres being separated after being in contact, there is always a greater excess of fluid on the greater sphere.

When the spheres are separated, so as no longer to act on each other, the thickness of the stratum at the surface of each will be uniform; and it will be found by art. 253, be found by making \( x = 0 \) in \( f(x) \) for the first sphere, and \( x = 0 \) in \( g(x) \) for the second. Hence, if \( E \) and \( F \) be the quantities of these strata, we have

\[ E = 4\pi a^2 f(x), \]

making \( x = 0 \).

\[ F = 4\pi b^2 g(x) \]

Hence

\[ F - E = 4\pi (b^2 g(x) - a^2 f(x)), \]

making \( x = 0 \).
LECTRITY.

By art. 259 and 260. 4π \left(1 - \frac{m}{n}\right) \tan (1 - m) \pi = \pi \cot (1 - m) \pi.

But if b > a, m > \frac{1}{2} and \cot (1 - m) \pi is positive: also by art. 261. h is positive when E and F are positive; therefore F - E is positive, and F > E.

(264.) Two spheres, after being in contact, are removed out of the reach of each other's influence; it is required to find the ratio of the thicknesses of the strata at their surfaces.

The thickness on each will be uniform; and if A and B be the thicknesses, we have

E = 4π a² A; F = 4π b² B. Therefore if \beta be the ratio

\beta = \frac{B}{A} = \frac{a^2}{b^2} \cdot \frac{F}{E} = \frac{a^2}{b^2} \left(1 + \frac{F - E}{E}\right).

And putting for F - E and E their values, from art. 263.

F - E = 4π m h a \cot (1 - m) \pi

E = 4π a² \frac{m h}{a} \int \frac{t^{m-1} - 1}{1 - t} \; dt

we have

\beta = \frac{a^2}{b^2} \left(1 + \frac{\pi \cot (1 - m) \pi}{\int \frac{t^{m-1} - 1}{1 - t} \; dt}\right).

And when the radii a and b are known, m = \frac{b}{a + b} is known, and \beta may be determined.

(265.) We have now the means of comparing the results of this theory with observation, by determining the value of \beta for the cases in which Coulomb has made the experiments. He had spheres of which the radii were respectively as 2 : 1; 4 : 1; 8 : 1; and therefore the values of m are

\frac{1}{3}, \frac{1}{5}, \frac{1}{9}, \text{ respectively.}

The integrals to be found for these cases are

\int \frac{t^{m-1} - 1}{1 - t} \; dt, \int \frac{t^{m-1} - 1}{1 - t} \; dt, \int \frac{t^{m-1} - 1}{1 - t} \; dt,

taken from t = 0 to t = 1.

If in the first we make t = \theta^2, in the second t = \theta^4, and the third t = \theta^8, they become respectively

3 \int \frac{1 - \theta^2}{1 - \theta^2} d \theta, 5 \int \frac{1 - \theta^4}{1 - \theta^4} d \theta, 9 \int \frac{1 - \theta^8}{1 - \theta^8} d \theta,

taken from \theta = 0, to \theta = 1.

These integrals can be found by the usual methods for rational fractions, and substituting the numerical results thus obtained, in the last article, we have the values of \beta for the cases above mentioned.

Coulomb gives the name of electrical density to that which we have called the thickness of the stratum; and the following is the comparison of the results of his experiments with theory.
The agreement of the two first observations with theory is remarkable. In the third case the difference may still be attributed to the errors of observation; and it may be noted, that in this case Coulomb did not determine the distribution of the fluid directly, but having touched the large sphere with the small one twentyfour times in succession, he calculated from the result of this, the distribution of electricity at each contact.

(266.) To find the limit of $\beta$ when $b$ is infinitely small.

When $b = 0$, $m = 0$,

$$
\int \frac{t^{n-1} - 1}{1 - t} \, dt = \int \left( \frac{t^{n-1}}{1 - t} + t^{n-1} \right) \, dt
$$

But, by the values of $E$ and $F$, art. 263, we have

$$
\beta = \frac{a^2}{b^2} \cdot \frac{F}{E} = \frac{a^2}{b^2} \int \frac{t^{n-1} - 1}{1 - t} \, dt
$$

$$
= \frac{a^2}{b^2} \left( \frac{1}{m} + \int \frac{t}{1 - t} \, dt \right)
$$

$$
= \frac{a^2}{b^2} \frac{1}{m} - \int \left\{ \frac{mt}{1 - t} + \frac{m^2 (\frac{t}{1 - t})^2}{2} + \text{&c.} \right\} \, dt
$$

Or since $\frac{a^2}{b^2} = \frac{(1 - m)^2}{m^2}$,

$$
= (1 - m)^2 \cdot \int \left\{ \frac{t}{1 - t} + \frac{m (\frac{t}{1 - t})^2}{2} + \text{&c.} \right\} \, dt
$$

$$
= 1 - m^2 \int \left\{ \frac{t}{1 - t} + \frac{m (\frac{t}{1 - t})^2}{2} + \text{&c.} \right\} \, dt.
$$

And it is clear that when $m$ becomes 0, this becomes

$$
= \int \frac{t}{1 - t} \, dt;
$$

$$
= \int \left\{ t \cdot \frac{1}{1 - t} \cdot t \cdot dt + \frac{1}{t} \cdot t \cdot dt + \frac{1}{t} \cdot t^2 \cdot dt + \text{&c.} \right\}.
$$
Hence when $b$ is infinitely small, $\beta = 1.6449$.

Coulomb conjectured, from his observations, that by increasing the disproportion of the spheres, the ratio of the electrical densities could never be made to surpass that of $2 : 1$. This exceeds the true limit by about one-fifth of the whole.

(267.) To find the thickness at the point opposite to the point of contact.

In the expression for the thickness, art. 253,

$$y = 2x \frac{df}{dx} + fx$$

we must make $x = -1$; or $z = 2$ in

$$y = -2 (1 - z) \frac{df}{dz} (1 - z) + f (1 - z).$$

Now (art. 259.) $zf (1 - z) = \frac{m}{a} \int \frac{1 - t^{1-m}}{1 - t} \frac{m}{t^2} - \frac{1}{t} \, dt$, from $t = 0$ to $t = 1$.

Differentiating with respect to $z$,

$$f (1 - z) + z \frac{df (1 - z)}{dz} = \frac{m}{a} \int \frac{1 - t^{1-m}}{1 - t} \frac{m}{t^2} - \frac{1}{t} \, dt \, l \, \frac{1}{t} \cdot \frac{m}{t^3},$$

$$= \frac{m^2}{a} \int \frac{1 - t^{1-m}}{1 - t} \frac{m}{t^2} - \frac{1}{t} \, dt \, l \, \frac{1}{t},$$

$$d \int \frac{1 - t^{1-m}}{1 - t} \frac{m}{t^2} - \frac{1}{t} \, dt \, l \, \frac{1}{t}.$$
(268.) To find the thickness opposite the point of contact, when the spheres are equal.

Here

\[ m = \frac{b}{a + b} = \frac{1}{2}, \]

and by last article

\[ Y = \frac{h}{16} \int_1^0 \frac{t^{-\frac{1}{4}} - t^{-\frac{1}{2}}}{1 - t} \, dt. \]

And also

\[ Z = \frac{h}{16} \int_1^0 \frac{t^{-\frac{1}{4}} - t^{-\frac{1}{2}}}{1 - t} \, dt. \]

Let

\[ t = \theta^4 \quad \Rightarrow \quad dt = 4 \theta^3 \, d\theta, \]

\[ Y = \frac{h}{a} \int_0^1 \frac{1 - \theta^4}{1 - \theta^4} \frac{1}{\theta} \, d\theta = \frac{h}{a} \int_0^1 \frac{1}{\theta} \, d\theta, \]

the integral taken from \( \theta = 0 \) to \( \theta = 1. \)

By expanding, we have

\[ Y = \frac{h}{a} \int \left\{ 1 \frac{1}{\theta} - \theta^4 \left( 1 \frac{1}{\theta} + \theta^4 \right) \right\} \, d\theta. \]

And, between the limits,

\[ \int_0^1 \frac{1}{\theta} \, d\theta = \frac{1}{(n + 1)^4}. \]

\[ \therefore \quad Y = \frac{h}{a} \left\{ \frac{1}{1^4} - \frac{1}{3^4} + \frac{1}{5^4} - \ldots \right\}. \]

And taking a sufficient number of terms for the approximation, we find

\[ Y = .916 \frac{h}{a}. \]

(269.) To compare this with the mean thickness.

If \( \bar{A} \) be the mean thickness, which will be the same on both spheres,

we have

\[ \bar{A} = \frac{E}{4 \pi a^2}. \]

And since \( m = \frac{1}{2} \), by art. (264.)

\[ A = \frac{h}{2} \int_1^0 \frac{t^{\frac{1}{4}} - 1}{1 - t} \, dt = \frac{h}{a} \int_1^0 \frac{d \sqrt{t}}{1 + \sqrt{t}} = \frac{h}{a} \frac{1}{2} = .693 \frac{h}{a}. \]

between the limits.

\[ \therefore \quad \frac{Y}{A} = \frac{.916}{.693} = 1.322. \]

Coulomb found, by experiment, this ratio equal to 1.27, which differs by less than one twenty-fifth from the value given by theory.

(270.) To compare the greatest thickness on the lesser sphere with the mean thickness on the greater sphere.

Let \( \frac{Z}{A} = \gamma \), the ratio sought

By arts. (267.) and (264.)

\[ Z = \frac{(1 - m)^2 h}{4} \int_1^0 \frac{t^{\frac{1}{2}} - t^{-\frac{1}{2}}}{1 - t} \, dt \]

\[ A = \frac{m h}{a} \int_1^0 \frac{t^{m-1} - 1}{1 - t} \, dt \]

\[ \therefore \quad \gamma = \frac{(1 - m)^2 a}{4 m b} \frac{\int_1^0 \frac{t^{\frac{1}{2}} - t^{-\frac{1}{2}}}{1 - t} \, dt}{\int_1^0 \frac{t^{m-1} - 1}{1 - t} \, dt}. \]
EL E C T R I C I T Y.

Theory of and when the radii \( a \) and \( b \) are known, we know \( m = \frac{b}{a + b} \). The coefficient \( \frac{(1 - \frac{m}{a})^3}{4n^2} \) becomes Chap. II.

\[
\frac{4}{(a + b)^2} \left( \frac{a}{a + b} \right)
\]

(271.) Coulomb's experiments were made with spheres, of which the radii were as 1:1, as 2:1, as 4:1, and as 8:1. We shall have to calculate the value of \( \gamma \) for these cases, and to compare it with experiment.

When \( b = a, m = \frac{1}{2} \) and the value of \( \gamma \) is the same as that of \( \frac{\gamma}{A} \) in art. (269.)

When \( b = \frac{1}{2} a, m = \frac{1}{3} \); and the integral in the numerator of \( \gamma \) is

\[
\int \frac{t^{-\frac{3}{2}} - t^{-\frac{1}{2}}}{1 - t} \, dt ;
\]

and making \( t = \theta^2 \), this becomes \( -9 \int \frac{1 - \theta}{1 - \theta^2} \left( \frac{1}{\theta} - \frac{1}{\theta^3} \right) \, d\theta \). And by expanding, this may be integrated from \( \theta = 0 \) to \( \theta = 1 \).

The integral in the denominator is \( \int \frac{t^{-\frac{4}{5}} - 1}{1 - t} \, dt \), which may be made rational, by putting \( t = \theta^3 \).

When \( b = \frac{1}{4} a, m = \frac{1}{5} \). The integral in the numerator of \( \gamma \) is

\[
\int \frac{t^{-\frac{1}{2}} - t^{-\frac{3}{5}}}{1 - t} \, dt .
\]

And making \( t = \theta^4 \), this becomes

\[
-81 \int \frac{\theta^3 - \theta^5}{1 - \theta^6} \left( \frac{1}{\theta} - \frac{1}{\theta^3} \right) \, d\theta; 
\]

which may be integrated as before. The denominator may also be made rational as before.

Performing these calculations, and comparing them with Coulomb's experiments, we have the following results.

<table>
<thead>
<tr>
<th>Ratio of the Radii ( a : b )</th>

</tbody>
</table>

The last column contains the difference of the value given by theory and that given by observation, divided by the former value.

We now proceed to find the thickness at any point not in the line joining the centres, and for that purpose we must, by (252.), deduce \( \phi \) \( \left( \mu, x \right) \) from \( f \).

(272.) To find \( f \left( y \right) \).

\[
f \left( 1 - x \right) = \frac{mh}{a} \int \frac{1 - t^{1 - \frac{m}{a}}}{1 - t} \, dt, \text{ by } (259),
\]

\[
= \frac{mh}{a} \int \frac{\left( t^{\frac{m}{a} - 1} - t^{\frac{m}{a} - \frac{m}{a}} \right)}{1 + t^{\delta} + t^{\delta} + \ldots} \, dt
\]

Now

\[
\int \frac{t^{\frac{m}{a} - 1 + \frac{m}{a}}}{m + n y} \, dt = \frac{y}{m + n y} \text{ taken } t = 0, \text{ to } t = 1
\]
\[ \int_{t_1}^{t_2} \frac{z}{m + (t - t_1)} \, dt = \frac{z}{m + (n - m + 1)z} \]

and we have these terms occurring, with all values of \( n \) from 0 to \( \infty \).

\[ f(1 - z) = \frac{m h}{a} \left\{ \frac{1}{m + m + z} + \frac{1}{m + 2z} + \ldots + \frac{1}{m + nz} + \ldots \right\} \]

\[ \ldots \frac{1}{m + (1 - m)} - \frac{1}{m + (2 - m)z} + \ldots - \frac{1}{m + (n - m + 1)z} - \ldots \]

And if we put \( 1 - x \) for \( z \), we shall have \( f(x) \).

(273.) In order to find \( \phi(u, x) \), we must expand this expression in powers of \( x \), and multiply the successive terms by \( Q_0, Q_1, Q_2, \&c. \) which are such that

\[ \frac{1}{\sqrt{(1 - 2 \mu x + x^2)}} = Q_0 + Q_1 x + Q_2 x^2 + \ldots + Q_n x^n + \ldots \]

Hence the term \( \frac{1}{m + n + y} \) will become

\[ \frac{1}{m + n + y} = \frac{1}{m + n} \left\{ 1 + \frac{n x}{m + n} + \frac{n^2 x^2}{(m + n)^2} + \frac{n^3 x^3}{(m + n)^3} + \&c. \right\} \]

and will give, in \( \phi(u, x) \), the terms

\[ \frac{1}{m + n} \left\{ Q_0 + \frac{Q_1 n x}{m + n} + \frac{Q_2 n^2 x^2}{(m + n)^2} + \frac{Q_3 n^3 x^3}{(m + n)^3} + \&c. \right\} \]

which will clearly be equal to

\[ \frac{1}{m + n} \left\{ 1 - \frac{2 \mu n x}{m + n} + \frac{n^2 x^2}{(m + n)^2} \right\}^{1/2} \text{ or } \left\{ (m + n)^2 - 2 \mu (m + n) n x + n^2 x^2 \right\}^{1/2} \]

Let this be called \( R_n \).

In the same manner the term \( - \frac{1}{m + (n - m + 1)} (1 - x) \) will produce in \( \phi(u, x) \) the expression

\[ - \frac{1}{n + 1} \left\{ 1 - \frac{2 \mu (n - m + 1) x}{n + 1} + \frac{(n - m + 1)^2 x^2}{(n + 1)^2} \right\} \]

\[ \text{or } \left\{ (n + 1)^2 - 2 \mu (n + 1) (n - m + 1) x + (n - m + 1)^2 x^2 \right\}^{-1} \]

Let this be called \( S_n \).

We shall then have

\[ \phi(u, x) = \frac{m h}{a} \left\{ R_0 - S_0 + R_1 - S_1 + \ldots + R_n - S_n \ldots \right\} \]

(274.) To find the thickness of the stratum of fluid at any point of the surface of the spheres.

We have the thickness on the first sphere by the formula in (253.)

\[ y = 2 x \frac{d \phi(u, x)}{dx} + \phi(u, x), \]

using the value of \( \phi(u, x) \) in last article, and making \( x = 1 \) after the differentiation.

On the other sphere we must use \( g(x) \) and \( \psi(u, x) \) instead of \( f(x) \), and \( \phi(u, x) \). But it is clear, from (275.), that we shall find \( g(x) \) from \( f(x) \) by putting \( 1 - n \) for \( m \), and \( b \) for \( a \). Hence, by this process, we shall find \( \psi(u, x) \) from \( \phi(u, x) \).

(275.) When the spheres are equal, to find the distribution of the fluid.

Here \( m = \frac{b}{a + b} = \frac{1}{2} \).

\[ R_n = 2 \left\{ (2 n + 1)^2 - 2 \mu (2 n + 1) (2 n + 2) x + (3 n + 1)^2 x^2 \right\}^{-1} \]

\[ S_n = 2 \left\{ (2 n + 2)^2 - 2 \mu (2 n + 2) (2 n + 1) x + (3 n + 1)^2 x^2 \right\}^{-1} \]

Hence if we put

\[ \left\{ (n + 1)^2 - 2 \mu (n + 1) n x + n^2 x^2 \right\}^{-1} = T_n \]

we shall have

\[ R_n = 2 T_{2n}, S_n = 2 T_{2n+1}. \]
And hence, when we make \( x = 1 \), we have the value of

\[
2 x \frac{dT_{n}}{dx} + T_{n} = \frac{2 n + 1}{(n + 1)^{2} - 2 \mu (n + 1) a + n^{2}}
\]

And if we call this \( A_{n} \), we shall have the thickness of the stratum

\[
y = \frac{h}{a} \left\{ A_{0} - A_{1} + A_{2} - A_{3} + \ldots \right\}
\]

In this formula \( \mu \) is the cosine of the angular distance of any point from the point of contact, and the series will be sufficiently convergent for all cases, except when \( \mu \) is nearly equal to 1.

Thus for the point opposite to the point of contact, \( \mu = -1 \),

\[
A_{n} = \frac{1}{(2 n + 1)^{2}}, \text{ and hence}
\]

\[
y = \frac{h}{a} \left\{ 1 - \frac{1}{3^{2}} + \frac{1}{5^{2}} - \frac{1}{7^{2}} + \ldots \right\}
\]

which agrees with what was found in (268.) by a different method.

(276.) We shall compare the results in this case with those which Coulomb obtained from experiment. Placing two equal spheres in contact, he measured the electrical density at distances, from the point of contact, of 30°, 60°, 90°, and 180°. Now in this case we shall have

- at 30°, \( \mu = \frac{\sqrt{3}}{2} \), \( y = 0.137 \frac{h}{a} \);
- at 60°, \( \mu = \frac{1}{2} \), \( y = 0.599 \frac{h}{a} \);
- at 90°, \( \mu = 0 \), \( y = 0.603 \frac{h}{a} \);
- at 180°, \( \mu = -1 \), \( y = 0.916 \frac{h}{a} \).

We can only compare the relative values of these quantities with experiment. Hence let the value of \( y \), corresponding to 90°, be divided by each of the others; and let

\[
\text{thick at 90°} = a, \quad \text{thick at 60°} = a', \quad \text{thick at 30°} = a''.
\]

We shall then have the following comparison:

<table>
<thead>
<tr>
<th>Ratios of Electricity at different Points of equal Spheres in contact.</th>
<th>Difference of Theory and Observation compared with the whole.</th>
</tr>
</thead>
<tbody>
<tr>
<td>( a )</td>
<td>1.877</td>
</tr>
<tr>
<td>( a' )</td>
<td>1.342</td>
</tr>
<tr>
<td>( a'' )</td>
<td>5.857</td>
</tr>
</tbody>
</table>

The last column contains the excess of the value given by theory above that given by experiment, divided by the former value.
Theory of (277.) When the radius of one sphere is double that of the other, to find the distribution of the fluid, on the surface, Chap. II.

Electricity of the smaller sphere.

Let \( b = 2a \), therefore \( m = \frac{b}{a} = \frac{2}{3} \).

Hence
\[
\begin{align*}
R_a &= \frac{3}{3} \left\{ (3n + 2)^3 - 2 \mu (3n + 2) (3n + 1) x + (3n + 1)^3 x^3 \right\} - t \\
S_a &= \frac{3}{3} \left\{ (3n + 3)^3 - 2 \mu (3n + 3) (3n + 2) x + (3n + 2)^3 x^3 \right\} - t.
\end{align*}
\]

Make
\[
\begin{align*}
\left\{ (n + 2)^3 - 2 \mu (n + 2) n x + n^3 x^3 \right\} - t &= U_a, \text{ and we shall have} \\
R_a &= 3 \frac{U_a}{3} \quad S_a = 3 \frac{U_a}{3} + 1.
\end{align*}
\]

\[\phi(\mu, x) = \frac{2h}{a} \left\{ U_0 - U_1 + U_3 - U_4 + \&c. \right\} \]

\[
\frac{dU_a}{dn} = \frac{\mu (n + 2) n - n^2 x}{\left\{ (n + 2)^3 - 2 \mu (n + 2) n x + n^3 x^3 \right\} - t}
\]

\[
2x \frac{dU_a}{dn} + U_a = \frac{4 (n + 1)}{\left\{ (n + 2)^3 - 2 \mu (n + 2) n x + n^3 x^3 \right\} - t}.
\]

And if \( B_a \) be the value of this when \( x = 1 \),
\[B_a = \frac{4 (n + 1)}{\left\{ (n + 2)^3 - 2 \mu (n + 2) n x + n^3 x^3 \right\} - t},\]

and we shall have for the thickness
\[
y = \frac{2h}{a} \left\{ B_0 - B_1 + B_3 - B_4 + \&c. \right\} \]

If we give to \( \mu \) the values corresponding to the angles,
\[60^\circ, \quad 90^\circ, \quad 180^\circ, \]

viz. \( \mu = \frac{1}{2}, \quad \mu = 0, \quad \mu = -1; \)

we shall find for \( y \) the values
\[
.321 \frac{h}{a}, \quad .577 \frac{h}{a}, \quad .781 \frac{h}{a},
\]

and, as before, we shall make
\[
\frac{\text{thickness at } 90^\circ}{\text{thickness at } 60^\circ} = \beta, \quad \frac{\text{thickness at } 90^\circ}{\text{thickness at } 180^\circ} = \beta'.
\]

(278.) In the same case to find the distribution of fluid on the larger sphere.

We have here to find \( \psi(\mu, x) \), for which purpose we must put \( 1 - m \) for \( m \), and \( b \) for \( a \) in \( \phi(\mu, x) \). Hence in the general expressions for \( R_a \) and \( S_a \) we must put \( \frac{1}{3} \) for \( m \), and we have thus
\[
\begin{align*}
R_a &= \frac{3}{3} \left\{ (3n + 1)^3 - 2 \mu (3n + 1) n x + (3n + 1)^3 x^3 \right\} - t \\
S_a &= \frac{3}{3} \left\{ (3n + 2)^3 - 2 \mu (3n + 2) n x + (3n + 2)^3 x^3 \right\} - t.
\end{align*}
\]

And, as before, putting \( \{ (n + 1)^3 - 2 \mu (n + 1) n x + n^3 x^3 \} - t = T_a \), we shall have
\[
R_a = 3 \frac{T_a}{3}, \quad S_a = 3 \frac{T_a}{3} + 2.
\]

Hence
\[
\psi(\mu, x) = \frac{h}{b} \left\{ T_0 - T_2 + T_4 + \&c. \right\} \]

And \( A_a \) being the same as in art. (275.), we have for the thickness \( y \),
\[
y = \frac{h}{b} \left\{ A_0 - A_2 + A_3 - A_4 + \&c. \right\} \]

At \( 90^\circ \) from the point of contact \( y = .928 \frac{h}{b} = .464 \frac{h}{a} \).

At \( 90^\circ \) from the point of contact on the other sphere \( y = .577 \frac{h}{a} \). Hence, at the rings which are \( 90^\circ \) from the point of contact, the thickness of the fluid is greater on the smaller sphere.

Let
\[
\frac{\text{thickness on smaller sphere}}{\text{thickness on larger sphere}} = \beta''.
\]
166 ELECTRICITY.

We shall compare the results in the two last articles with experiment. The last column is calculated as before.

<table>

</tbody>
</table>

When one of the radii is four times the other, to find the distribution of fluid on the smaller sphere. As before, if we make

$$\{ (n + 4)^4 - 2 \mu (n + 4)^2 n x^4 \} - \frac{2}{h} = V_n,$$

we shall have

$$\phi (\mu, r) = \frac{4 h}{a} \{ V_0 - V_1 + V_2 - V_3 + &c. \}.$$ 

And if we make

$$\frac{8 (n + 2)}{\{ (n + 4)^4 - 2 \mu (n + 4)^2 n + n^3 \} - \frac{2}{h} = C_n,$$

we shall have for the thickness $y$,

$$y = \frac{4 h}{a} \{ C_0 - C_1 + C_2 - C_3 + &c. \}.$$ 

And at distances from the point of contact

$$90^\circ \quad 180^\circ$$

$$\mu = 0 \quad \mu = -1$$

$$y = \frac{349}{a} \quad y = \frac{584}{a}$$

Let

$$\text{thickness at } 180^\circ = \gamma,$$

$$\text{thickness at } 90^\circ = \gamma.$$

The last result being compared with experiment, we have

<table>
<thead>
<tr>
<th>By Theory.</th>
<th>By Observation.</th>
<th>Difference compared with the whole.</th>
</tr>
</thead>
<tbody>
<tr>
<td>$\gamma$</td>
<td>1.673</td>
<td>1.43</td>
</tr>
</tbody>
</table>

If we take the sums of the differences contained in the last columns of the tables in arts. (265.), (271.), (276.), (279.), (281.), and divide this sum by 14, the whole number of observations, we shall have the mean difference of the results of theory and of experiment. This difference is between .03 and .04, so that it is nearly $\gamma$. If we add all the differences together, neglecting the contrary signs, and divide by 14, we shall have a quotient less than $\gamma$; and hence it appears that in whatever manner we estimate the mean difference, it is always sufficiently small to be attributed to the errors of observation.

§ IV. On the distribution of the fluid on the surfaces of two spheres at a considerable distance from each other.

In this case to find $f x$ and $g x$.

The distances of the spheres is here supposed to be large compared with one of them, as $b$. Take the equations (G) of art. (257.)

$$af \left( \frac{r}{a} \right) + \frac{b^4}{r_1} g \left( \frac{b}{r_1} \right) = h \quad \text{............... (2)}$$

$$\frac{a^4}{r_1} f \left( \frac{a}{r} \right) + bg \left( \frac{r_1}{b} \right) = k \quad \text{............... (2)}$$

Let $r = a x, r_1 = b x = 1 - a x, 1$ being the distance of the centres,

$$af (x) + \frac{b^4}{1 - a x} g \left( \frac{b}{1 - a x} \right) = h \quad \text{............... (a)}$$

$$bg (x) + \frac{a^4}{1 - b x} f \left( \frac{a}{1 - b x} \right) = k \quad \text{............... (a)}$$
Expanding the terms in the second equation, we have

\[ \frac{a^s}{1 - b^x} = a^s (1 + b^x + b^2 x^2 + b^3 x^3 + \&c.) \]

\[ f \left( \frac{a}{1 - b^x} \right) = f(a) + a f'(a) b x + \left\{ a^s f'(a) + 2 a f''(a) \right\} \frac{b^2 x^2}{1.2} + \&c. \]

\[ f', f'', \&c. \] being the derived coefficients from \( f(x) \) making \( x = a \). Hence the second of equations (a) gives, omitting cubes, \&c. of \( b \),

\[ b g(x) = k - a^s f(a) - \left\{ a^s f'(a) + a^s f''(a) \right\} b x - \left\{ a^s f'(a) + 2 a^s f'(a) + \frac{1}{2} a^s f''(a) \right\} b^2 x^2 \ldots \ldots \ldots (\beta) \]

Put

\[ \frac{b}{1 - a x} \]

for \( x \), multiply by

\[ \frac{b}{1 - a x}, \]

omitting cubes, \&c. of \( b \), and we find

\[ f'(a) = \frac{k - a^s f(a)}{1 - a x} \cdot \frac{b}{1 - a x}. \]

Hence we have from the first of equations (a)

\[ a f(x) = k - \frac{(k - a^s f(a)) b}{1 - a x} \]

Hence differentiating with respect to \( x \), and then making \( x = a \),

\[ a f'(a) = \frac{k - a^s f(a)}{1 - a^s} \frac{b}{1 - a^s} \cdot \frac{a b}{1 - a^s} \]

\[ a f''(a) = \frac{k - a^s f(a)}{1 - a^s} \frac{2 a^s b}{1 - a^s} \]

\[ a f'''(a) = \frac{k - a^s f(a)}{1 - a^s} \frac{a^s b^2}{1 - a^s} \]

From the first of these three equations we have

\[ a f(a) = \frac{h}{1 - a x} - \frac{k b}{a b} \]

This formula requires \( b \) to be small, not only with respect to the distance of the centres, represented by \( l \), but also with respect to \( 1 - a \), the distance of the centre of the smaller sphere to the surface of the larger. Hence the formula cannot be applied to the case of contact.
(284.) Knowing the quantity of fluid on each sphere, to find \( h \) and \( k \).

Let \( E \) be the quantity on the one whose radius is \( a \), \( F \) on the one whose radius is \( b \).

We shall have, by art. (263.)

\[
E = 4 \pi a^3 f(x), \quad F = 4 \pi b^3 g(x), \quad \text{making} \quad x = 0.
\]

Or if \( A, B \), be the thicknesses, supposing them uniform, \( A = f(0), B = g(0) \),

\[ a \cdot A = h - \frac{(k - h) a (1 - a^3) b}{1 - a^3 - a b} \]

\[ b \cdot B = \frac{(k - h) a (1 - a^3)}{1 - a^3 - a b} \]

Hence

\[ a \cdot A + b \cdot B = h. \]

And from the second equation \( k - h a = \frac{1 - a^3 - a b}{1 - a^3} b \),

\[ k = a^3 A + a b^3 B + \left(1 - \frac{a b}{1 - a^3}\right) b \]

By introducing these values in (2) and (3) of last article, we find

\[ a f(x) = A a + B b^3 \]

\[ b g(x) = B b \left(1 - \frac{a b x}{(1 - a^3)^2}\right) - \left\{A a + B b^3\right\} \{a b x + a b^3 x^2\}; \]

or, omitting \( b^3 \),

\[ b g(x) = B b - A a^3 b x (1 + b x) \]

These values may be put in this form.

\[ a f(x) = A a - \frac{B a b^3 x}{1 - a x}; \]

\[ b g(x) = B b - \frac{A a^3 b x}{1 - b x}. \]

To find the thickness of the stratum of fluid on the sphere with radius \( a \).

From the method given in art. (273.) for obtaining \( \phi(\mu, x) \), it is manifest, from the values in last article, that

\[ a \phi(\mu, x) = A a + B b^3 - \sqrt{\{1 - 2 \mu a x + a^2 x^2\}}; \]

and putting this value of \( \phi(\mu, x) \) in the formula, \( y = 2 x \frac{d \phi(\mu, x)}{d x} + \phi(\mu, x) \), and making \( x = 1 \), we have

\[ y = A + \frac{B b^3}{a} - \frac{B b^3 (1 - a^3)}{a \sqrt{\{1 - 2 \mu a + a^2\}}}. \]

To find the thickness of the stratum of fluid on the sphere with radius \( b \).

By art. (252.)

\[ b g(x) = B b - A a^3 b x - A a^3 b^3 x^3, \]

if \( Q_0, Q_1, Q_2 \) be the coefficients in the three first terms of the expansion of \( \{1 - 2 \mu x + x^2\}^{1/2} \), we shall have

\[ \psi(\mu, x) = B Q_0 - A Q_1 a^3 x - A Q_2 a^3 b x^3. \]

But we find

\[ Q_0 = 1, \quad Q_1 = a^3, \quad Q_2 = - \frac{1 - 3 a^2}{2}; \]

\[ \psi(\mu, x) = B - A a^3 \mu x + \frac{1 - 3 a^2}{2} A a^3 b x^3. \]
And $z$ being the thickness on the other sphere,

$$z = 2x \frac{d\psi (\rho, z)}{dx} + \psi x,$$

making $x = 1$.

$$z = B - 3 A a^8 \mu + \frac{5}{2} (1 - 3 \mu^2) A a^8 b;$$

and knowing $A$, $B$, this will give us the distribution of the fluid.

$A$, $B$ are the excesses of the positive fluid on the respective spheres, and will both be positive if both the spheres are positively electrified. If one or both have an excess of negative or resinous electricity, the corresponding quantities $A$, $B$ must be negative.

(287.) Let the small sphere be not electrified; to find the distribution of the fluid upon it.

Here $B = 0$, hence

$$z = -3 A a^8 \left\{ \mu + \frac{5 b}{6} (3 \mu^2 - 1) \right\}.$$

At the point of the sphere which is in the line joining the centres

$$\mu = 1, z = -3 A a^8 \left\{ 1 + \frac{5 b}{3} \right\}.$$

At the opposite point

$$\mu = -1, z = 3 A a^8 \left\{ 1 - \frac{5 b}{3} \right\}.$$

Hence at the first point the fluid is accumulated, which is of a nature opposite to that whose thickness is $A$; at the second point the fluid is of the same kind as that with thickness $A$; and the intensities at those points are as $1 + \frac{5 b}{3} : 1 - \frac{5 b}{3}$, and therefore nearly equal.

(288.) In this case to find the line which separates the two fluids on the surface of the smaller sphere.

Make $z = 0$; hence

$$\mu = \frac{\sqrt{1 + \frac{25 b^4}{3}} - 1}{5 b}.$$

And neglecting $b^3$, &c., $\mu = \frac{5 b}{6}$. Hence the line which separates the fluids is a circle, distant by less than 90° from the vertex of the sphere. Hence the negative fluid (that which is of a different kind from the fluid on the sphere with radius $a$) occupies less than half the surface. As the distance of the spheres becomes greater with respect to the radius $b$, the circle which separates the fluids approaches perpetually to the circle bisecting the sphere.

(289.) When the excess of fluid on the smaller sphere is known, to find its distribution.

It appears, by art. (286.), that the thickness $z$, of the stratum at any point, will be that found in art. (287.) + $B$.

If the second sphere were negatively electrified, $B$ would be negative; and, in other respects, the conclusions would be the same.

(290.) Let the small sphere receive its fluid by contact with the first, to find the distribution when it is removed to any distance.

When $b$ is very small compared with $a$, we have, by art. (286.)

$$\frac{B}{A} = \frac{\pi^2}{6};$$

when $\mu = 1$, or at the vertex of the smaller sphere,

$$z = A \left\{ \frac{\pi^2}{6} - 3 a^8 \right\},$$

omitting the term in $b$.

This will be positive, 0 or negative, as $\frac{\pi^2}{6}$ is $>$, $=\$, or $< 3 a^8$.

$$z = 0 \text{ when } \frac{1}{a} = \frac{3 \sqrt{2}}{\pi}.$$
Electricity, contact, becomes negative after the separation. It continues so till the distance of the centres becomes \( \frac{4a}{3} \) nearly, at which point it is again 0. Beyond this situation the electricity becomes positive, or of the same kind with the other sphere.

(294.) In the case when spheres of any radii are not in contact, the investigation of the distribution of the fluid is more difficult and laborious; and, as we have no series of accurate experiments with which we can compare our results, we shall content ourselves with referring the reader to Mr. Poisson's second memoir on the subject, (Mém. de l'Inst. Année 1811, p. 163.) He has there shown how we may obtain the thickness of the electrical stratum at any point of the surface of two spheres, placed within the reach of each other's influence, and under any given circumstances of electrization.

We may observe, however, that a succession of effects at different distances, similar to that described in last article, as occurring when one of the spheres is very small, may occur for other cases: and we have an experiment of Coulomb's of this kind, with which we can compare our calculations.

Coulomb took two spheres, whose radii were as 11 and 4; after placing them in contact, electrifying them positively, and then separating them, he found that the smaller sphere exhibited signs of negative electricity till the distance of the surfaces was equal to the smaller radius: at this distance the electricity of the point on the smaller sphere which was nearest the larger was 0; beyond this it became positive.

In Mr. Poisson's formulae, if we substitute the values which correspond to the radii of the spheres, and to the position, where the distance of the surfaces is equal to the smaller radius, we find for the electrical thickness on the smaller sphere, \( A \) being the mean thickness on the smaller,

\[
y = -0.0372 \, A.
\]

The electricity is negative at the point in question; but so small that it might easily appear insensible.

(292.) From the preceding statements, the reader may be enabled to judge of the agreement between this theory, thus reduced to calculation, and the most careful experiments; and he may decide how far the near coincidence of the natural laws with the mathematical ones establishes the truth of the principles from which the latter are derived. We shall mention one other consequence which follows from the theory, and which agrees with observation, viz. the discharge of a conductor by a spark, though, from the nature of the calculations on which it depends, we can only give the results, without going through the investigation on which they depend.

Let, as before, \( a, b \) be the radii of two spheres, \( c \) the distance of their centres, \( A \) and \( B \) the mean thicknesses of electricity with which they are charged; and let \( A' \) and \( B' \) be the mean thicknesses of electricity which there would be upon the spheres if they were in contact. Mr. Poisson then finds for the thickness on the nearest point of each sphere, an expression, of which the first term is

\[
\frac{2 (A B' - A' B)}{(c - a - b) \Delta}.
\]

\( \Delta \) is a quantity which involves \( \log (c - a - b) \). But since \( x \log x \) is 0 when \( x \) is 0, it appears that if the numerator of the above fraction remain finite, the fraction increases indefinitely, as \( c - a - b \) diminishes; that is, as \( c \) approaches to \( a + b \), or as the surfaces approach to contact. Also the pressure of the electric stratum upon the air which envelopes and confines it is as the square of its thickness. Hence, before the spheres come in contact, this pressure will overcome the resistance of the air which separates them, and the fluid will escape from each to the other, under the form of a spark, or in some other way.

This will be the case, whatever be the total quantities of electricity, provided the numerator \( A B' - A' B \) be finite; but if \( A B' - A' B = 0 \), the above term will vanish, and there will be no discharge. That is, if \( \frac{A}{B} = \frac{A'}{B'} \), or if the quantities of electricity on the spheres be in the ratio of the charges which they would obtain by mutual contact.

ELECTRICITY.
GALVANISM.

PART I.

GENERAL PRINCIPLES.

1. Distinction between Galvanism and Electricity.

Galvanism. 

(1.) Galvanism is distinguished from ordinary Electricity, not by any difference in the nature of the agent by which its phenomena are produced, but merely by the mode in which its power is developed and brought into action. It is an error to consider it, as has sometimes been done, as a peculiar species or modification of Electricity: for it has been abundantly proved, as will appear in its sequel, that all the effects produced by Galvanism, are in fact derived from the agency of common Electricity, elicited by particular arrangements and combinations of metallic and other substances, and passing in very considerable quantities, and in a continued current, through the bodies which are placed so as to conduct it, and in which, in consequence of this difference in the circumstances of its transmission, it produces peculiar effects. All the definitions which have been attempted to be given of Galvanism, implying a specific difference in the principle of its action from that of Electricity, are consequently incorrect and fallacious.

Electrical effects. 

(2.) In the account we have already given of Electricity, the facts which strictly belong to that science, and which were known prior to the discovery of Galvanism, have been amply detailed. It has been shown, also, that all these phenomena, however various and complicated they may at first sight appear, are reducible to a small number of general facts, the assemblage of which constitutes the theory of the science. They are principally comprised in the laws of Electric attractions, repulsions, and inductions; in the different conducting powers inherent in different substances, and the mode of distribution of Electricity among the particles of bodies of various forms and in various relative positions. From the law of Electric induction we derive the power of accumulating Electricity in vast quantities, by means of the Leyden jar, and Electric battery, and of obtaining some of its most energetic effects. By the violent action of large quantities of Electricity, thus collected and suddenly transmitted through bodies, we have seen that metals may be fused and volatilized, or reduced to dust, and dispersed in air; that the hardest textures of mineral or organised bodies may be rent asunder, and scattered into fragments; that vegetable and animal life may be destroyed; in a word, that by Electric instruments all the effects of lightning may be imitated, and the walls of the laboratory be made to echo to explosions, which faintly mimic the awful crash and reverberating thunder of the clouds. Such appeared to be the extreme limit attainable by human means in the wielding of so subtile, so universal, and so mighty a power as Electricity,—a power which must rank among the highest of the energies of nature, and which enters as an essential element in all the operations of the material universe.

Our knowledge on the subject of Electricity had long been nearly stationary, when a simple fact which was accidentally presented to Galvani, but of which that philosopher at once perceived the importance, laid the foundation of a new science, and gave rise to a series of the most brilliant discoveries which have marked the present age. Great as were the effects of the Electric battery, its power was not susceptible of very advantageous employment as an instrument of delicate analysis, although it had occasionally been available as an agent for effecting combinations, and other changes of composition among gases. Its action, although sufficiently energetic, was but momentarily exerted; the power ceased the very instant after it was brought forth, and could not be recalled but by the slow and laborious repetition of the process by which it had been collected. The science of Galvanism has put us in possession of an instrument of incomparably greater power, and capable of the most extensive application in various analytical researches, and in various branches of physical science. The same power, which in the highly charged Electric battery is lavished and dissipated by a single discharge, is developed in great abundance in the Voltaic battery; and far from being rapidly expended, continues to be poured forth in profusion for an indefinite time, and may be directed at pleasure so as to produce different changes of composition, and other affections of bodies subjected to its action. The Voltaic apparatus, in its most active state, may be regarded as a vast magazine of Electricity, capable of furnishing a continued supply for a very long period, at the demand of the experimentalist, and placing this mighty agent entirely under his control. This instrument has opened a new field to the cultivators of science, and a rich harvest of discoveries has already rewarded their exertions.

(3.) Although no doubt can be entertained of the identity of the powers which are derived from the Voltaic and Electric batteries, yet it does not appear that the phenomena of Galvanism were capable of being deduced from the previously known laws of Electricity: of which laws we have already traced the more important combinations and consequences; and of which we have furnished the mathematical formulæ by which even their most complicated results may be calculated. Thus it would not have been possible, from the consideration of the laws of Electric equilibrium, to have foreseen that any disturbance of the
In the seventh Chapter of our Treatise on Electricity, (p. 119,) the several processes by which Electrical properties are developed are discussed, and are arranged under seven different heads: namely, friction of various kinds; processes connected with the exercise of the functions of animal life; changes of temperature; meteorological changes; atmospheric phenomena; evolution of gaseous matter, or its condensation into a liquid or a solid; the separation of the particles of a solid body united by cohesion; and pressure applied to crystalline bodies in particular directions. But these are not all the sources of Electricity. It was then stated that the consideration of the Electricity which is developed by the mere contact of metals was purposely omitted, being reserved for that branch of the subject which we are now investigating. But there is also another source of the development of Electricity, intimately connected with all the phenomena of Galvanism, namely, the chemical action of bodies on each other. It is indeed probable, as was remarked in the section relating to the development of Electricity during evaporation, that no chemical change can take place among the elementary molecules of bodies, without the production of some corresponding change in the Electric condition of those bodies, although such change may often not admit of being detected or appreciated. On these two circumstances; namely, the disturbance of Electric equilibrium by the contact of dissimilar metals, and the evolution of Electricity by chemical action, are the whole of the phenomena of Galvanism dependent. But as the theory by which these phenomena are connected and generalized, cannot be understood until the facts themselves have been studied, our first business must be to give an account of these facts, arranging them, for the sake of convenience, under their appropriate heads. We shall then be prepared to inquire into the theoretical reasons to which they have given rise, and the different hypotheses which have been devised for their explanation. We shall conclude by presenting a brief sketch of the history of the science, in which the principal discoveries will be reviewed in the order in which they were successively made by their respective authors: for we conceive that much greater interest will attach to such a review, as well as more instruction be derived from it, when the reader has already been made familiar with the subject, and is therefore capable of appreciating the relative importance of the facts it embraces, and of assigning to each discoverer the merit that is due to him.

2. Elements of Galvanic combinations.

(4.) Our attention is first to be directed to the general outline of the principal phenomena of Galvanism, as they are most usually presented to our observation. We shall begin by studying these phenomena in their simplest state, or greatest degree of generalization. We shall thus arrive most readily at the knowledge of what are the circumstances belonging to the Galvanic arrangements of bodies which are essential to the production of those particular effects. For this purpose we shall select such combinations developing Galvanic Electricity, as are the simplest possible. The elements of all Galvanic combinations are necessarily three in number, and it is essential to their action that they be arranged so as to compose a circle. Of these three elements one at least must be a fluid, and another must be a solid body; the third may be either a solid or a fluid, according to circumstances; but we shall, for the present, consider only the case in which the circle is constituted by two solids, and one fluid body. It is essential that the two solid parts be conductors of Electricity in a very eminent degree, and that they shall consist of different kinds of substance; and that the fluid part of the circle be capable of exerting a chemical action upon one of these solids. Thus, if a plate of zinc be in contact with a plate of copper at one of their extremities, and if in this state they be both immersed in a diluted acid, so that the zinc, the acid, and the copper all touch one another, a Galvanic circle is constituted, and the following Electric movements will take place. There will be a current of vitreous, or positive Electricity, passing from the zinc to the acid; from the acid to the copper; and from the copper to the zinc: while, on the other hand, a current of resinous or negative Electricity will circulate in the opposite direction; that is to say, will pass from the zinc to the copper; from thence to the acid; and from the acid to the zinc; and so on in a continued stream. The arrangement here described is represented in fig. 1, where Z and C are sections of the zinc and copper plates, which are in contact at their upper edges, and of which the lower ends are immersed in the diluted acid, A; the direction of the positive Electric current being marked above and below, being indicated by the position of the arrows.

(5.) If, while the two metals are immersed in the acid, they be removed from each other, as represented in fig. 2, so as to be no longer in immediate contact; Fig. 2. and a communication be established between them by means of a metallic wire, WX, bent so as to form a considerable arch, and touching each of the metals respectively at p and s, a Galvanic circle will, in like manner, be formed; the circuit of opposite Electricities taking place, as before, from one plate of metal to the other; through the fluid, from the one hand, and through the connecting wire, on the other. The direction of the stream of positive Electricity is that denoted by the arrows; namely, in the fluid, from the zinc towards the copper; and in the wire, from the copper to the zinc. The current of negative Electricity must, of course, be understood to flow in a direction exactly the reverse. The most convenient mode of interrupting or renewing at pleasure the Galvanic circuit is to have, in place of a single wire extending from one metal to the other, two separate wires, WX; one affixed to each of the metals, at one end, while by their other ends w, x, they may be made to touch or to separate from one another.

(6.) The intensity of the Electricity elicited by such Compound arrangement, will be increased by a repetition of the same combination in regular succession. The apparatus will then have the form represented in the section fig. 4; in which the zinc and copper plates, Fig. 4. denoted as before by the letters Z and C, are combined in pairs, being connected at their upper edges by slips of metal passing from the one to the other. They are immersed into a corresponding number of
Galvanism. separate vessels, containing the diluted acid; so that the two plates belonging to each pair shall be contained in two different, but adjoining vessels of the series; and care being taken that the same order of alternation of the metals be observed. Each vessel will thus contain one plate of zinc and one plate of copper, which, as they belong to different pairs, are not connected, and which must not come into contact with one another. To an arrangement of this kind, in which Volta employed a circular series of cups to contain the fluid, he gave the name of Couronne de tasses.

In order to obtain a similar apparatus in a more compendious form, the plates are brought nearer to each other by employing troughs of mahogany, divided into cells by glass partitions, or what is still more convenient, troughs made of Wedgwood ware, with the partitions of the same material. The plates of zinc and copper are soldered together in one point only, and each pair of plates is arranged so as to enclose a partition between them; there is consequently in each cell a copper plate connected with the zinc of an adjoining cell, and so on in regular succession. The troughs usually contain ten or twelve pairs of plates, and these are connected together by a slip of baked wood, so that they may be lifted out of the cells together, see Fig. 7. One advantage of this construction is, that the fluid may remain in the trough, while the action is suspended by lifting the plates from the cells; and another is, that the plates are easily replaced when worn or injured. It has been ascertained by Dr. Wollaston, that the power of a battery upon this construction is increased at least one half, by adding another copper plate to each member of the series; so that every cell will contain one zinc and two copper plates, and each surface of zinc is opposed to a surface of copper: for, in the usual arrangement, although both sides of the zinc are oxidated, that side only is efficient which has a copper surface opposed to it.

It will necessarily follow from the arrangements now described, that except in the case in which, as in the couronne de tasses, the vessels are placed in a circle, so as to form a recurring series, having properly neither beginning nor end, the plates at the two extremities of the series will not be received in any of the vessels, and therefore will not be in contact with any fluid; and as they will also, in this case, be at a distance from one another, it will be necessary to employ wires, or other metallic media of communication between them, in order to establish the Galvanic circuit. The directions of the currents of Electricity will here be the same as in the case of the simple arrangement of Fig. 6, and are pointed out by the position of the arrows in the figure.

Another form of construction for the Voltaic battery is the one invented by Mr. Cruickshanks, represented in Fig. 6, in which Z, C, Z, C, &c. represent sections of pairs of plates of zinc and copper, soldered together at their adjacent surfaces, arranged so that all the zinc plates shall be on the same side, and all the copper plates on the other, and fixed to the sides of a trough of baked wood, which is a non-conductor of Electricity, with intervals between them, such as that by means of the sides of the trough cells may be formed between each pair of plates, capable of containing a fluid. When these cells are filled with acid, and a communication between the two extremities of the battery is made, by bringing the ends of the wires, W, X, in contact with one another, the Galvanic circle is completed, and the usual currents are established.

What has been termed the Voltaic pile, from the name of its discoverer, Volta, is an arrangement of Volta precisely the same kind as the former, the series being arranged vertically instead of horizontally; the metallic part being composed of circular discs of zinc and copper arranged in pairs; and the fluid portion of the series consisting of pieces of some substance of spongy texture, such as card or linen, moistened with the liquid to be employed, which we have here supposed to be diluted acid. The column thus constituted, and which is represented in Fig. 5, either sustains itself by its own weight, or may be supported by a frame of glass rods, fixed vertically around it. The circuit will now require to be completed by forming a communication between the upper and lower plate by any conducting medium, such as the wire W.

It will be evident, upon a little consideration, that however the two modes of arrangement which we have last described, namely those exhibited in Fig. 5 and 6, may appear to differ from the preceding one, represented by Fig. 4, they are, in fact, all essentially the same. The principal difference between them, and it is a difference merely of form, consists in the connection between the copper, which is in contact with the fluid of one cell or vessel, with the zinc which is in contact with the fluid in the next cell or vessel, being made in the one case by means of a slip of metal extending from the one to the other; while in the other case it is affected by the actual junction of the two plates by the whole of their adjacent surfaces.

As we are at present occupied only with general views of the subject, we refrain from entering into any details concerning the particular construction of the various kinds of apparatus formed upon the preceding models, or concerning the relative advantages of each for particular purposes of inquiry. The subject will be resumed in the sequel, when the objects of the construction, and the reasons for which they have been adopted, can be better appreciated. It will be sufficient for our present purpose to observe, that in order to obtain the effects which we are about to describe, it is requisite that a sufficiently large surface of the metals be exposed to the action of the fluid, and that the oxidation of the zinc should proceed rapidly; it is also necessary for the exhibition of many of these effects, that the alternations of the series of the metals and fluids should be numerous.

There is one circumstance of considerable importance, that deserves attention in studying the properties of these Galvanic instruments. It may be observed, that every Voltaic battery, or combination calculated to produce Galvanic Electricity, is referable either to the class of the simple, or of the composite battery. The first consists of a single ternary arrangement of the elements of the battery; as we have described §4 and 5, and illustrated by Fig. 1 and 2. Each end of the communicating wire, by which, in the second of these cases, the circuit is completed, has a direct metallic communication with the whole of the metallic surface acted upon by the fluid, on its respective
In all these instances no ambiguity can arise as to the denomination of the two sides of the battery, with reference to the metals which are situated on those sides. The end of the wire in communication with the zinc must be designated the zinc side of the battery; and, in like manner, the end of the wire adjoining to the copper will be the copper side. As in this form of the battery the stream of positive or vitreous Electricity is found to issue from the copper side, and to be received by the zinc side of the battery, through the medium of the wire; while the reverse is to be understood as the course of the negative or resinous Electricity; so the copper side must be designated as the positive end or pole of the battery, and the zinc side as the negative end or pole.

Dr. Hare's Calorimotor.

(12.) A battery on a large scale, constructed upon this model, that is, consisting essentially of only one sheet of zinc, and one of copper, formed into coils, is often denominated a Calorimotor; a name given to it, for reasons which will hereafter be explained, by Dr. Hare of Philadelphia, who constructed a very powerful instrument of this kind. The zinc sheets were about nine inches by six, the copper fourteen by six; more of the latter metal being necessary, as in every coil it was made to commence within the zinc, and completely to surround it without. The sheets were coiled so as not to leave between them an interstice wider than a quarter of an inch. Each coil was about two inches and a half in diameter; their number amounted to eighty; and by means of a lever, they were made all to descend together into eighty glass jars, two inches and three quarters diameter inside, and eight inches high, properly placed to receive them. Fig. 8 shows the horizontal section of one of these coils.

Fig. 8.

Battery of London Institution.

(13.) The apparatus belonging to the London Institution, and which was constructed under the direction of Mr. Pepys, belongs also to this class. It consists of only two plates, the one of copper, and the other of zinc, coiled round a cylinder of wood, with ropes of horse hair interspersed between them, in order to prevent their being in contact with one another. Each plate is fifty feet in length, and two feet in width, making a total surface of 400 square feet. When its action is required, the whole coil is immersed in a tub containing acid.†

Fig. 9.

(14.) The more usual forms of Voltaic batteries are those which belong to the second, or composite class, and consist of a certain number of alternations of the ternary series of elements. Of these we have seen examples in the Voltaic pile, fig. 5; in the trough battery, fig. 9; and in the common plate battery, fig. 7. The battery of the Royal Institution, which consists of 200 separate parts, each part composed of ten double plates, and each plate containing thirty-two square inches, may be taken as an example of a very powerful instrument constructed upon this last model. The whole number of the double plates is 2000, and the whole surface 125,000 square inches.

(15.) It will be recollected, that in all these instances the metallic plates, which terminate the series at either end, are not in contact with any portion of the fluid in the battery; but are, on the contrary, in contact with a metallic plate of a different kind. Now the currents of Electricity in each fluid portion of the apparatus, pass between the surfaces of the metals that are separated by that fluid, in the same directions as in the single combination formerly described; that is, the positive Electricity flows from the zinc, through the fluid, to the copper. But the last copper plate has a plate of zinc attached to it, which is the last plate in the series on that side. The positive Electricity received from the fluid by the copper, will be transferred to the zinc plate, and by the zinc to the communicating wire on that side. It follows, therefore, as a necessary consequence, that the zinc end is the positive pole of the battery. The same mode of reasoning applied to the opposite current of negative Electricity, which flows from the copper, through the fluid, to the zinc, and thence to the terminal plate of copper, and the wire, which is continuous with it, will show that this copper end will be the negative pole of the battery. It will be perceived, that this is just the reverse of what takes place in the simple battery, or calorimotor, in which it is the copper end that is positive, and the zinc end that is negative. In attention to this circumstance has often been productive of much ambiguity in describing experiments, and in reasoning upon their results. The accurate distinction between the positive and negative poles of the battery is more especially to be kept in view in experiments on Electro-Magnetism, where the direction of the tangential Magnetic force depends altogether upon the direction of the Electric currents in the communicating wire.

The account which has now been given of the nature and different modes of arrangement of the component parts of Galvanic circles, and of the direction of the Electric currents, of which they occasion the rapid circulation, will be sufficient to prepare us for the consideration of the effects they produce on various bodies exposed to their action.

PART II.

THE EFFECTS OF GALVANISM.

CHAPTER I.

EffectspurelyElectrical.

The Electricity acquired by any conducting substance in a state of insulation, by previous contact with the prime conductor, or the rubber of the common Electrical machine, exists in that body in a very different state from the Electricity which is evolved by the different parts of the Voltaic battery. The former manifests its presence by various positive and striking indications. A conductor so charged will attract light bodies in its neighbourhood, and after imparting to them, by contact, a portion of its Electricity, will, in the next place, repel them to a distance. The divergence of the electrometer points out the degree of intensity of the Electricity under these circumstances, and indicates its high state of elasticity and mobility, or tendency to diffuse itself to the surrounding bodies capable of receiving it. On the other hand, the indications of the presence of Electricity at the extremities, or in any part of the Voltaic battery, even when the circuit is interrupted, by the separation of the wires which form the connection between them, are comparatively feeble; although the quantity of Electricity which is really developed, may be exceedingly great. But when the circuit is completed, and while the whole of the Electricity is in rapid circulation, the electrometer gives no indication of its presence.

The attraction of unelectrified, or of dissimilarly electrified bodies, and the repulsion of similarly electrified bodies, are among the most unequivocal and decisive tests of the agency of Electricity. But from a single combination of plates, such as that of the Calorimotor, no effect of this kind can be obtained, unless electroscopes of very extraordinary sensibility be employed. With electrometers of the usual construction, no sensible Electricity can be discovered to exist, either in the zinc or copper plate when separated by an acid solution, whatever extent be given to their surfaces in contact with the acid. When a few alternations of plates and interposed fluid are employed, either in the Voltaic pile or battery, Electrical appearances may be detected by means of the condenser; and the opposite extremities are found to be in different states of Electricity. With a series of fifty groups, a delicate gold-leaf electrometer will be affected, with the aid of the condenser. With one hundred pairs, the divergence of the gold leaves is sufficiently distinct; and with a series of one thousand groups, even pithe balls are made to diverge. In these experiments, a wire proceeding from one extremity of the battery, is to be connected with the foot of the electrometer, whilst a wire proceeding from the opposite extremity is brought to touch its cap. The Electricity of the zinc side is always positive, that of the copper side always negative. The ends of the wires which communicate with the two poles, being in opposite Electrical states, will be found, when they are brought together, to attract one another.

By means of a condensing electroscope of extreme sensibility, invented by M. Bohnenberger, and since adapted to this particular object by M. Becquerel, the latter has ascertained, that even in a single pair of plates of zinc and copper, not in contact with each other, but only immersed in an oxidating fluid, the zinc plate gives indications of negative Electricity, and the copper of positive Electricity; a result which, although apparently contrary to that which obtains in the composite battery, is yet perfectly accordant with the same species of Electric currents in the fluid in both cases, and is indeed, as has been already explained, the necessary consequence of the peculiar arrangement of the plates. The nature of the Electricity of the ends of the composite battery was first ascertained by Messrs. Nicholson and Carlisle, with the instrument called the Revolving Doubler.

(16.) We propose treating of the effects produced by Galvanism under the following heads: namely, 1st, the ordinary and purely Electrical effects of attraction, repulsion, and induction; 2dly, those attended with evolution of light and heat; 3dly, Electro-Magnetic effects; 4thly, chemical changes of composition; and 5thly, physiological effects.

(17.) The Electricity acquired by any conducting substance in a state of insulation, by previous contact with the prime conductor, or the rubber of the common Electrical machine, exists in that body in a very different state from the Electricity which is evolved by the different parts of the Voltaic battery. The former manifests its presence by various positive and striking indications. A conductor so charged will attract light bodies in its neighbourhood, and after imparting to them, by contact, a portion of its Electricity, will, in the next place, repel them to a distance. The divergence of the electrometer points out the degree of intensity of the Electricity under these circumstances, and indicates its high state of elasticity and mobility, or tendency to diffuse itself to the surrounding bodies capable of receiving it. On the other hand, the indications of the presence of Electricity at the extremities, or in any part of the Voltaic battery, even when the circuit is interrupted, by the separation of the wires which form the connection between them, are comparatively feeble; although the quantity of Electricity which is really developed, may be exceedingly great. But when the circuit is completed, and while the whole of the Electricity is in rapid circulation, the electrometer gives no indication of its presence.

The attraction of unelectrified, or of dissimilarly electrified bodies, and the repulsion of similarly electrified bodies, are among the most unequivocal and decisive tests of the agency of Electricity. But from a single combination of plates, such as that of the Calorimotor, no effect of this kind can be obtained, unless electroscopes of very extraordinary sensibility be employed. With electrometers of the usual construction, no sensible Electricity can be discovered to exist, either in the zinc or copper plate when separated by an acid solution, whatever extent be given to their surfaces in contact with the acid. When a few alternations of plates and interposed fluid are employed, either in the Voltaic pile or battery, Electrical appearances may be detected by means of the condenser; and the opposite extremities are found to be in different states of Electricity. With a series of fifty groups, a delicate gold-leaf electrometer will be affected, with the aid of the condenser. With one hundred pairs, the divergence of the gold leaves is sufficiently distinct; and with a series of one thousand groups, even pithe balls are made to diverge. In these experiments, a wire proceeding from one extremity of the battery, is to be connected with the foot of the electrometer, whilst a wire proceeding from the opposite extremity is brought to touch its cap. The Electricity of the zinc side is always positive, that of the copper side always negative. The ends of the wires which communicate with the two poles, being in opposite Electrical states, will be found, when they are brought together, to attract one another.

By means of a condensing electroscope of extreme sensibility, invented by M. Bohnenberger, and since adapted to this particular object by M. Becquerel, the latter has ascertained, that even in a single pair of plates of zinc and copper, not in contact with each other, but only immersed in an oxidating fluid, the zinc plate gives indications of negative Electricity, and the copper of positive Electricity; a result which, although apparently contrary to that which obtains in the composite battery, is yet perfectly accordant with the same species of Electric currents in the fluid in both cases, and is indeed, as has been already explained, the necessary consequence of the peculiar arrangement of the plates. The nature of the Electricity of the ends of the composite battery was first ascertained by Messrs. Nicholson and Carlisle, with the instrument called the Revolving Doubler.

(18.) Induction is one of the characteristic effects of Electricity, as well as attraction and repulsion; and from Galvanism the most remarkable of the results of induction is seen in the capacity of accumulation which the Leyden jar and Electric battery possess. Now the Electricity derived from Galvanism, is equally capable of being accumulated in those instruments, as the Electricity obtained in the common Electrical machine. If wires proceeding from each extremity of the Voltaic battery, be respectively connected with the inner and outer surfaces of an Electrical battery, of not less than twelve square feet of coated surface, the latter will be instantly charged, and all the usual Electrical experiments may be performed with it in this state, when removed from the Voltaic battery. If the discharge be made, and the same communications be renewed, it will again immediately receive a similar charge of Electricity; and the same will happen after an indefinite number of discharges. If, instead of removing the Electrical battery, its connection with the Voltaic battery be still continued, sparks may be obtained from it in rapid succession, by connecting a wire with.

* Singer’s Elements of Electricity and Electro-Chemistry, 329:
† Biot, Traité de Physique, II. 311.
‡ Annales de Chimie, xxv. 405.
Galvanism, the outer coating, and repeatedly striking the knob with the other end of the wire. These sparks are so strong when the charge is communicated by a series of three or four hundred alternations, that the end of wire, if it be of iron, is made to scintillate, or throw off abundance of its own particles in a state of intense combustion. With a series of one thousand, the sparks are attended by a distinct crackling noise, and have sufficient power to burn thin metallic leaves. This is the more remarkable, as the Voltaic battery, from which the Electric battery has derived its power, may itself be too weak to produce this effect. It always happens, indeed, that a single jar is charged by contact with a Voltaic apparatus, in which the fluid consists merely of water, to a degree of intensity rather greater than that of the apparatus itself; and it will consequently affect an electrometer somewhat more distinctly. In all cases the full charge is communicated by the shortest possible contact with the Voltaic battery. In the experiments made by Van Marum and Pfaff, a battery having 137½ square feet of coated surface was charged to the same degree of tension, as the pile with which it was made to communicate, by a contact which did not last for the twentieth part of a second.†

CHAPTER II.

Evolution of Light and Heat by Galvanism.

1. Luminous appearances.

Spark.

(19.) The transit of any considerable quantity of Electricity through the air is, as we have seen in the Treatise on Electricity, always attended with the evolution of light; and generally, in the form of a spark or luminous train. A similar appearance is observed during the transit of Galvanic Electricity, if the intensity be sufficient for that purpose. It is very readily obtained in a Voltaic battery composed of a considerable number of alternations of plates, when the communication between the two extremities is made by metallic wires. At the moment of contact a distinct spark is perceived, which occurs every time the contact is alternately broken and renewed. But the most striking effect of this kind is produced by placing pieces of charcoal, shaped like a pencil, at the two ends of the wires in the interrupted circuit, and bringing their points into contact. The appearances, when the experiment was tried with the powerful battery of the Royal Institution already noticed, were singularly beautiful. When the pieces of charcoal were brought within the thirtieth or fortieth part of an inch of each other, a bright spark was produced; and at the same time more than half the volume of the charcoal, which was about an inch long, and one-sixth of an inch in diameter, became ignited to whiteness. By withdrawing the points from each other, a constant discharge took place through the heated air, in a space equal at least to four inches, producing a most brilliant arch of light, of considerable breadth, and in the form of a double cone. This phenomenon is represented in fig. 3, in which W, X are the conducting wires communicating with the ends of the battery; C, C the pieces of charcoal; and A the luminous arch of Electrical light, making the transit of the Electricity through the air. When any substance was introduced into this arch, it instantly became ignited; platinum melted as readily in it as wax in the flame of a common candle; quartz, the sapphire, magnesia, lime, all entered into fusion; fragments of diamond, and points of charcoal and plumago, rapidly disappeared, and seemed to evaporate in it, even when the connection was made in a receiver exhausted by the air pump; but there was no evidence of their having previously undergone fusion. When the communication between the points positively and negatively electrified was made in air, rarified in the receiver of an air pump, the distance at which the discharge took place increased as the exhaustion proceeded; and when the air in the vessel supported only one quarter of an inch of mercury in the barometrical gage of the air pump, the sparks passed through a space of nearly half an inch; and by withdrawing the points from each other, the discharge was made through six or seven inches, producing a most brilliant coruscation of purple light, while the charcoal itself became intensely ignited, and some platina wire attached to it fused with bright scintillations, and fell down in large globules.* These phenomena may be exhibited on a smaller scale, by means of a hundred pair of plates of six inches square; an apparatus which is well suited for all experiments of fusion and ignition. The arch described on the stream of light passing between two charcoal points, is often very perceptible when the distance of the points does not exceed half an inch. Charcoal made from some of the harder woods, such as beech, lignum vitae, or boxwood, is the best for these experiments, and it should be carefully prepared.

(20.) The light thus evolved by the contact and its brilliance of charcoal points, forming part of the circuit of Voltaic Electricity, is more vivid and intense than any other that can be produced by art. It often exhibits all the variety of the prismatic colours. When the battery is powerful, the emission of light may be kept up for a considerable time; it is so dazzling as to fatigue the eye even by a temporary glance, and effaces by its superior lustre the light produced by lamps in an apartment otherwise brilliantly illuminated, and which, on the sudden cessation of the Galvanic light, appears for a short time as if left in darkness. It is a light which so nearly imitates the brightness of the sun's rays, as to be applicable for the purposes of illuminating objects in a solar microscope; and it has been spoken by Mr. Allen in his Lectures, to the exhibition, on a large scale, of the appearances in the kaleidoscope, by the magic lantern.

It is observed by Mr. Singer, that the light thus obtained appears to be derived principally from the immediate action of the Voltaic Electricity, and not from the combustion of the charcoal; for although the charcoal be at the same time in a state of ignition, yet it is found to suffer but little waste. The light is evolved with equal splendour when the experiment is made in gases that contain no oxygen, such as azote or chlorine, and in which, therefore, combustion could not be maintained; it is found, indeed, that no change takes place either in the gas or the charcoal in these experiments.† Light is also obtained, though with diminished intensity, under water, alcohol, ether, oil, and other fluids of imperfect conducting power.

* Davy's Elements of Chemical Philosophy, p. 152–154.
† Children, Philosophical Transactions for 1815, p. 369.
† Annals de Chimie, xl. 269.
(31.) The transit of Electricity which takes place in the discharge of the Electric battery, and even the spark from the prime conductor of the machine, at the same time that it gives out light, is attended with the evolution of heat, though in a degree far inferior to that which takes place during the continued discharge of the Voltaic battery. But there is also this more remarkable difference between the operation of the two instruments. The common Electrical apparatus never exhibits any effect of heat, unless when the restoration of Electric equilibrium is suddenly performed, an event which is always accompanied with the appearance of light: and it may even be questioned, whether the rise of temperature which then takes place, be not attributable rather to the mechanical concussion which the particles sustain during this violent action, than to any direct property which is due to the Electricity of producing heat. In the Voltaic apparatus, on the other hand, an elevation of temperature is observed to take place, when the circuit remains complete, and when no light is evolved. The mere passage of Voltaic Electricity through conducting bodies, raises their temperature; and when the apparatus is powerful, and the size and nature of the conductors proportioned to the quantity of Electricity to be transferred, the most intense ignition is produced in them.* If a fine iron wire of moderate length be made the medium of connection between the extremities of the battery, it becomes ignited, and may be fused into balls. Steel wire, under the same circumstances, burns with a brilliant and rapid combustion. If a platina wire be employed, it may be kept at a red or even white heat, for an indefinite length of time. There appears to be no limit to the continued evolution of heat, so long as the battery preserves its power. These effects appear to be those of an abundant and inexhaustible stream of Electricity, flowing in an equable and continuous current, and producing no other change in the metal through which it passes, than merely raising its temperature. It never produces its sudden and violent dispersion into fragments, as happens with the explosive discharges of an Electric jar.

(22.) An elegant mode of exhibiting the production of heat, by the passage of Voltaic Electricity through a metallic wire, is to make the wire pass through a known quantity of water, contained in a vessel in which a thermometer is placed. As soon as the wire is made to form a part of the Voltaic circuit, the thermometer will be seen to rise, and rapidly advance to the boiling point; after which the ebullition continues with great steadiness. The time required for raising the water to the temperature of ebullition, or the quantity evaporated during a certain time, will afford tolerably accurate modes of estimating the quantity of Electricity that has passed through the wire.

(23.) Inflammable bodies, such as oils, alcohol, ether, and naphtha, are easily inflamed, when charcoal points in the circuit of the battery are ignited by it, and brought near each other on the surface of these fluids. Gunpowder, under the same circumstances, may readily be made to explode. The order in which metallic wires are raised to a red heat by the action of Galvanism was ascertained by Mr. Children, who employed for that purpose a very powerful apparatus of his own construction, to be the following; viz. platina, iron, copper, gold, zinc, and silver. Between gold and copper the difference is trifling; and with regard to platina and iron, their relations to each other, in this circumstance, seem to be affected by elevation of temperature. These results were obtained by comparing together in each experiment two wires of dissimilar metals, but of equal diameter and length, (one end of each being in communication with one of the poles of the battery, and the other end bent to an angle,) and connected continuously by hooking them together. The length of each wire was eight inches, and the diameter one-thirtieth of an inch. The results were the same to whichever pole of the battery either wire was presented. The places which tin and lead should have occupied in the scale of capability of being heated by Galvanism, could not be ascertained in these experiments, because they melted before they acquired a red heat. Since it appeared that the facility with which the metals were ignited, varied inversely as their conducting power for Electricity, it was inferred by Mr. Children, that the degree of resistance to the passage of the Electric current, was the circumstance that occasioned the development of heat in all these instances. But the fact that the greatest heat is produced in air, where there is reason to suppose the least resistance, is, as Sir H. Davy observes, in opposition to this theory. A beautiful illustration of the difference which exists in metals as to their capacity of ignition, is to place in the Voltaic circuit a wire or chain composed of alternate portions or links of platina and silver soldered together; when the silver links are not sensibly heated, but all those of platina become equally and intensely ignited.

(24.) The following are among the most remarkable effects of the Mr. Children's battery in producing heat. Five feet and a half of platina wire rather more than one-tenth of an inch in diameter was raised to a red heat, visible in full daylight. A similar effect was produced upon a bar of platina one-sixth of an inch square and two inches and a quarter long, and the whole was melted. Several metallic substances, and the most refractory were fused by the action of this battery. The oxide of molybdena was readily fused and reduced; the oxide of tungstena was also fused, and partially reduced; the oxides of Urania, titanium and ceria were fused, but not reduced; and the oxide of tantalum was only partially fused. All these metallic oxides, previous to their being subjected to the Galvanic action, had been intensely ignited in a charcoal crucible, in a powerful furnace. The compound ore of iridium and osmium was fused into a globule; and iridium was formed into a globule containing small cavities. By heating iron in contact with diamond powder, the diamond was consumed, and the iron converted into perfect blistered steel. Blue sapphire and gadolinite were fused, and zircon from Norway imperfectly so. Magnesia was agglutinated; while ruby, sapphire, quartz, and silex, were not affected.*

* It would appear, therefore, that the heat produced by the Voltaic battery is more considerable than has hitherto been obtained by any other process.

* Philosophical Transactions for 1815, p. 368—370.
3. Deflagration.

(25.) Another mode in which the production of heat by the Voltaic battery is exhibited by very striking effects, is to direct its action on the metals beat out into very thin leaves. When these leaves are made the medium of communication between the poles of a powerful apparatus they take fire, and by continuing the action, may be made to burn with great brilliance. These effects are best obtained by suspending the metallic leaves to a bent wire proceeding from one extremity of the battery, and to bring in contact with them a broad metal plate connected with the opposite extremity. By covering the plate with gilt foil, the brilliancy of the effects is still further increased. Gold leaf, treated in this way, burns with a vivid white light tinged with blue, and produces a dark purple or brown oxide. Silver leaf emits a brilliant emerald green light, and leaves an oxide of a dark grey colour. Copper produces a bluish white light, accompanied by red sparks; its oxide is dark brown. Tin exhibits nearly the same phenomena, but its oxide is of a lighter colour. Lead burns with a vivid white light tinged with blue, and produces a dark purple or brown oxide. Silver leaf emits a brilliant emerald green light, and leaves an oxide of a light grey colour. Copper produces a bluish white light, inclining to blue, and fringed with red. For the distinct appearance of these colours it is essential to make the contacts with metal; for if charcoal be used, the vivid white light it emits effaces the colours produced by the combustion of the metal.* Van Marum noticed a beautiful effect which took place when a slender iron wire was connected with one extremity of a powerful battery, and its end brought to touch the surface of some mercury connected with the other extremity. A vivid combustion both of the wire and the mercury was produced. Sparks were dispersed in profusion on every side, forming thousands of rays, as if proceeding from a star or sun of considerable diameter. This splendid spectacle may be continued at pleasure, by gently depressing the extremity of the iron wire, in proportion as the metallic particles are dispersed by the combustion.

4. Effects contrasted with those of Electricity.

(26.) The effects which we have been describing as those of the Voltaic battery are highly instructive, as demonstrative of the vast quantity of Electricity evolved by the instrument; and they are also strikingly contrasted, in many essential circumstances, with those produced by the Electric battery. The violence with which the whole of the charge, in the case of the latter instrument, is instantaneously forced, as it were, through the substances which lie in its passage, produces all the effects of a powerful mechanical concussion. The heat which may occasionally appear to be evolved, seems to be merely a remote consequence of the forcible compression and collision of the particles of the body during the momentary transit of the Electricity. The passage of Voltaic Electricity, on the contrary, seems to produce, as one of its immediate and direct effects, an elevation of temperature, while the mechanical texture of the substance remains unchanged. Hence, whatever igniting power may be possessed by common Electricity, it is transient and scarcely perceptible, and its tendency is rather to separate and disperse the particles of bodies, than to unite them into globules by fusion. Charcoal, which is a substance most readily ignited by Voltaic Electricity, sustains a powerful discharge of common Electricity without its temperature being sensibly raised. Dr. Hare endeavoured in every mode he could devise to ignite charcoal by common Electricity, but without success. Exposed to the discharge of a powerful battery in pieces tapering to a point, in a glass tube, in thin strips, and in powder, by means of the apparatus usually employed for igniting it, it was either uninfluenced, or merely dispersed, without the smallest symptom of ignition, or even of increased warmth. Yet the same discharge was sufficient to cause the explosion of fulminating mercury, placed under the same circumstances as the powdered charcoal in the former experiment; thus clearly showing that its action was by mechanical concussion. We have seen that water is easily made to boil by immersing in it a wire which forms part of the Voltaic circuit. But in Dr. Hare's experiments, pointed wires, covered with spermaceti, and exposed to a current of Electricity from a fine plate machine of thirty-two inches diameter, exhibited no sign of fusion: nor was a differential thermometer, filled with ether, according to Dr. Howard's plan, affected sensibly, though the warmth of a finger applied to the bulb, caused the fluid in the stem to move nearly a foot. When a spherule of lead suspended by a slender filament of the same metal to one of the poles of Dr. Hare's Calorimotor, was made to communicate with the other pole of the instrument, the spherule was instantaneously fused, yet the filament, which was fifty times smaller, remained uninjured. The contrary happens when a similar mass of lead suspended by a filament is made the medium of discharging an Electrical battery; in this case the filament is destroyed, but the spherule remains unchanged.*

5. Circumstances on which the Igniting Power depends.

(27.) In all metallic wires the capability of being igniting ignited by a Voltaic battery is altogether dependent, power, not upon the intensity of the Electricity developed, but upon the quantity which is transmitted by the wire. It has reference, therefore, not so much to the number of alternations of plates of which the apparatus is made to consist: but to the total extent of the surfaces producing Galvanism. In instruments of similar construction, but differing in their magnitude, we should expect similar results, provided the same proportion were preserved between the extent of surface in the battery, and the area of the transverse section of the wire. The experiments of which we have lately stated the results, were made with large and powerful instruments; but it is evident that if the same relations of its parts were adhered to in a battery of the smallest dimensions, the same effects would be obtained. Dr. Wollaston occupied himself, about the year 1812, in making a series of experiments for the purpose of ascertaining the most compendious form of apparatus by which visible ignition might be produced. After several trials he found that a single plate of zinc one inch square, when properly mounted, is more than sufficient to ignite a wire of platina one three-thousandth of an inch in diameter, even when the acid employed is very dilute. The smallest battery

* Singer, p. 409; and Philosophical Magazine.

* Annals of Philosophy, New Series, i. 339.
that he constructed consisted of a thimble, without its top, flattened till its opposite sides were about one-fifth of an inch as under. The bottom part was then nearly one inch wide, and the top about eight-tenths; and as its length did not exceed nine-tenths of an inch, the plate of zinc to be inserted was less than three quarters of a square inch in dimensions. Previously to insertion, a little apparatus of wire, through which the communication was to be made, was soldered to the zinc plate, and its edges were then coated with sealing wax, which not only prevented metallic contact at those parts, but also served to fix the zinc in its place by heating the thimble so as to melt the wax. A piece of strong wire, bent so that its two extremities could be soldered to the upper corners of the flatted thimble, served both as a handle to the battery, and as a medium to which the wires of communication from the zinc could be soldered. The conducting apparatus consisted in the first place of two wires of platina, about one-fortieth of an inch in diameter, and one inch long, cemented together by glass in two parts, so that one end of each wire was united to the middle of the other. These wires were then tinned, not only at their extremities, for the purpose of being soldered to the zinc and to the handle, but also in the middle of the two adjacent parts, for receiving the fine wire of communication. One inch of silver wire, one-hundredth of an inch in diameter, containing platina at the centre one-thirtieth part of the silver in diameter, was then bent so that the middle of the platina could be freed of its coating of silver by immersion in dilute nitrous acid. The portion of silver remaining on each extremity served to stretch the fine filament of platina across the conductors during the operation of soldering. A little sal ammoniac being then placed on the points of contact, the soldering was effected without difficulty, and the two loose ends were readily removed by the silver attached to them. When the fine platina wire was reduced to the length of between one-thirtieth and one-fiftieth of an inch, it was readily ignited by immersing this miniature battery in water containing only one-fiftieth part of sulphuric acid. Though the ignition effected by so dilute an acid be not permanent, its duration for several seconds is sufficient for exhibiting the phenomenon, and for demonstrating that it does not depend upon mere contact, from which only an instantaneous spark should be expected.*

(28.) The length of wire ignited by the Voltaic battery, as well as the intensity of the ignition, will, as we have already remarked, be proportioned to the quantity of Electricity which that wire transmits in a given time. This will depend upon several circumstances; the quantity of the battery; others have reference to the capacity of transmission in the wire; and others, again, relate to the proportion between these different powers. The estimation of effects resulting from so great a complication of causes is, therefore, in many cases, very difficult; and the more so, because the influence of some of these circumstances has not yet been ascertained with any precision.

(29.) The powers of the Voltaic battery, it is reasonable to presume, increase with the number of plates it contains, at least within certain limits; but the ratio of increase, as well as the limits of that increase, appear to be, in fact, very different with reference to different kinds of series, and to different modes of employment. With wires capable of transmitting the whole of the Electricity in proportion as it is supplied by the battery, the igniting power has generally been found to increase in exact proportion to the number of plates brought into action. This result was obtained by Mr. Wilkinson,* and by Mr. Cuthbertson,† and has been confirmed by the researches of Mr. Singer.‡ It corresponds also with the results of the experiments of Van Marum and Pfaff. From some experiments made with the battery of the Royal Institution, indeed, Sir Humphry Davy had at one time suspected that the increase of power proceeded according to the square of the number of plates, instead of being in the exact ratio of that number. When, on the other hand, a very considerable number of plates is employed, the igniting power no longer follows the same ratio; and even increases more slowly than the augmentation of the number of plates; and in some experiments it appears even to diminish. Thus Sir H. Davy found that one hundred plates ignited three inches of platina wire, one-seventh of an inch in diameter; but one thousand similar plates, charged in the same way, ignited only thirteen inches.§ With a great number of plates it is, indeed, scarcely possible to obtain any satisfactory results; on account of so extensive a series being with difficulty equally charged in all its parts, and being also liable to various unavoidable sources of dissipation. All experiments of this nature require minute attention to a variety of circumstances which more or less affect the accuracy of the results.

(30.) When the same number of plates is employed, but their size is increased, the quantities of Electricity liberated are proportionally increased: but the power of ignition seems to increase in a much higher ratio with the increase of surface; probably higher than even the square. Thus twenty double plates each containing two square feet did not ignite one-sixteenth as much wire as twenty, each containing eight square feet, the acid employed being of the same strength in both cases.|| The general fact, of which this experiment is a particular instance, appears to have been first noticed by the French chemists; and corresponds to a similar relation which is observed to take place between the effects of Leyden jars of different sizes in fusing metallic wires. The same proposition has also been established by Mr. Wilkinson, who states that the power of ignition, in batteries of the same total surface, but with plates of different sizes, increases in the proportion of the squares of the surfaces of the elementary plates, taken singly in each.¶ The forces of batteries having unequal surfaces were more carefully investigated, from the same data, by Mr. Harrison of Kendal, in conjunction with Mr. Gough; and shown to be "in the ratio compounded of the number of plates, and the sixth power of the sides of the elementary plates, taken singly in each."** It follows that when the surfaces are equal,
Galvanism, the igniting force is as the fourth power of the sides or diameters of the individual plates.

(31.) Many are the circumstances which influence the continuance of the igniting power of the battery; but as they are connected with the condition of the plates and the agency of the fluid employed, they will come more properly under consideration in a subsequent part of our inquiries. It will be sufficient here to remark, that all Voltaic batteries require a certain time to produce their full effect; and that, accordingly, a sufficient interval must be allowed for the recovery of the Electricity which produces ignition. We have next to notice various circumstances relating to the wire through which it is transmitted, which tend to modify this effect. The capacity of transmission in a wire connecting the positive and negative surfaces, will cease to do so after the acid has acted on the plates for some moments; and ignition cannot be produced by the same apparatus, without a temporary removal from the fluid. Dr. Hare ascertained, that this recovery of the igniting power did not take place, if, during the removal from the acid, the galvanic surfaces be surrounded either by hydrogen gas, nitric oxide gas, or carbonic acid gas. When surrounded by chlorine, or by oxygen gas, the surfaces regain their igniting power in nearly the same time as when exposed to the air.

6. Requisite conditions in the communicating wire. And to the capacity, the same ratio: the former, being, in equal lengths of wire, as the square; and the latter, in the simple ratio of the diameters. Within a certain limit, therefore, a thicker wire, which conveys more Electricity in proportion to its cooling surface, will be more heated than one more slender. Dr. Wollaston verified the truth of these conclusions by trials on the very minute wires which he employed in his elementary Galvanic battery already described; and he afterwards took the opportunity of confirming them on the largest scale, by means of the magnificent battery of Mr. Children, in the summer of 1813.

(32.) Thus far we have considered the influence which different conditions of the Voltaic battery possess in regulating the quantity and power of the transmission Electricity which produces ignition. We have next to notice various circumstances relating to the wire through which it is transmitted, which tend to modify this effect. The capacity of transmission in the wire will depend upon the nature of the metal, which, as we have already seen, has a greater or less conducting power with respect to Electricity, and also with respect to heat. These two properties appear to be nearly akin to one another; for the different metals follow nearly the same order with regard to their conducting powers both of Electricity and of heat. The radiating power of the metal is also to be taken into account. This power is known to depend on the extent of the surface, as well as on the particular quality of the surface. The ratio of the surface to the mass, is on this account an important datum for the estimation of the igniting effect produced by the transmission of the same quantity of Electricity through different wires. It is evident that the elevation of temperature produced by the passage of a given quantity of Electricity in a given time through a certain mass of conducting metal, of given capacity for heat, will be ceteris paribus, inversely as the quantity of matter to be heated; and therefore, in wires of the same metal, inversely as the squares of the diameter. As far as this cause operates, therefore, the smaller the wire, the more intense will be its ignition, when other circumstances are the same. But, on the other hand, if we take into account the radiating power, we shall perceive that although the quantity of matter to be heated is thus lessened, yet the surface by which it is cooled does not diminish in the same ratio: the former, being, in equal lengths of wire, as the square; and the latter, in the simple ratio of the diameters. Within a certain limit, therefore, a thicker wire, which conveys more Electricity in proportion to its cooling surface, will be more heated than one more slender. Dr. Wollaston verified the truth of these conclusions by trials on the very minute wires which he employed in his elementary Galvanic battery already described; and he afterwards took the opportunity of confirming them on the largest scale, by means of the magnificent battery of Mr. Children, in the summer of 1813.

(33.) However highly the conducting power of metallic substances for Electricity is to be estimated, it is evident that such power is not infinitely great; and that however small the obstacle which they interpose to the transmission of that power may be, still such obstacle exists in a certain degree; and the facility of transmission will be greater in proportion to the shortness of the distance the Electricity has to traverse. Hence the lengths of wire in the Voltaic circuit, which different batteries are capable of igniting to the same degree, may be taken as tolerably accurate measures of their respective powers of ignition. The same criterion will apply to the conducting powers. Thus Sir Humphry Davy found that when six inches of platina wire of a certain thickness discharged the Electricity of ten double plates; three inches discharged that of twenty; one and a half inch that of forty; and one inch that of sixty. The products of each of these pairs of numbers being equal in every case, it follows that the number of plates discharged by the wire is inversely as the length of that wire. By employing this method, a ready and accurate comparison can be instituted between the different metals with respect to their powers of conducting Voltaic Electricity. The contacts requisite for these comparative experiments may be made in a very short time; the batteries need not be changed, and their charge will suffer but little variation during the experiment. The results of Sir H. Davy's experiments conducted upon this plan, when reduced to equivalent whole numbers, expressive of the lengths of each metal required for discharging a Voltaic battery of sixty pairs of plates, are as follows:

(34.) Another result connected with this subject, is that the conducting power is proportionate to the mass or thickness. The same mass, also, divided into a number of smaller wires, conducted equally well as when it only formed one wire of proportionate thickness. The extension of the surface of the wire by flattening through rollers, made no difference with regard to the conducting power, provided care was taken to preserve its temperature cool by surrounding it with water. It is perhaps scarcely necessary to remark, that this result is perfectly consistent with

† Annals of Philosophy, viii. 317.
‡ Thomson's Annals of Philosophy, vi. 211.
† Philo. Trans. for 1821, p. 433.
that which was formerly stated with regard to the influence of surface on the capacity of the wire for being ignited; for, in the experiments now referred to, all elevation of temperature was purposely prevented.

(35.) As a certain charge of Electricity contained in a Leyden jar requires for its complete discharge a conducting body of sufficient size, so is the quantity of Voltaic Electricity required for its full transmission a wire, or other conductor, of sufficient magnitude. If the wire which forms the sole channel of communication between the poles of the battery be, from the smallness of its diameter, inadequate to the passage of the whole of the Electricity which is presented to it, the discharge will be more slowly and imperfectly performed by such a wire than by one of larger dimensions; and its effects on the wire will be less in the same proportion.

This circumstance, then, in addition to the consideration of the increased power of radiation in smaller wires, limits still more the igniting power of the battery, which would otherwise increase in the proportion of the diminished diameter of the wire. That there is a limit to the quantity of Electricity which wires are capable of transmitting, is fully established by the experiments of Sir H. Davy, as related in the paper last referred to. With a view to ascertain the quantity of undischarged Electricity remaining in the battery, while a part only was conducted by the communicating wire, he established a second circuit, independent of that by the wire, between the poles of the battery; and by interposing a fluid which could be acted upon by Galvanism, in the way that will afterwards be fully explained, he could estimate, by the effects produced on that fluid, the quantity of Electricity which circulated through this second circuit, and thence draw an inference as to the residual quantity in the battery. Availing himself of this happy expedient, Sir H. Davy made a series of experiments, the general result of which was that a slender platina wire left a very considerable portion of the Electricity of a moderate sized battery undischarged.

(36.) It is also evident from the facility of the metal, and still more its volatilization by the heat attendant on the transit of Electricity, impose further limits to the quantity which metallic wires are capable of transmitting. These effects of increased temperature may, however, be in most instances obviated by surrounding the wire with fluids that rapidly conduct heat, and preserve it cool. It was in prosecuting experiments on this subject, that Sir H. Davy was led to the discovery of the influence which temperature exerts in altering the conducting power of metallic bodies for Electricity. His researches have established the important general fact that this conducting power is diminished as the temperature is higher; but in what exact ratio it is scarcely possible to determine. The consequences of this law are highly interesting, and have an influence on most of the phenomena of Voltaic action. A wire of platina, for instance, which under ordinary circumstances would be inadequate to the discharge of a battery of given power, in consequence of its becoming ignited, and thereby having its conducting power impaired, may be rendered sufficiently conducting to transmit the whole of the charge, if it be kept immersed in oil, or in water. The discharge of a battery by the wire may, on the other hand, be arrested by artificially raising its temperature; by applying to it, for instance, the flame of a spirit lamp, so as to make a portion of it red hot; for the same result may be obtained whether the heat be occasioned by the Electricity, or be applied to it from some other source.

(37.) Still more curious and surprising exemplifications of the same general principle presented themselves to Sir H. Davy, in the course of these inquiries. If the length of a platina wire be so proportioned to the quantity of Electricity transmitted through it, as that the whole of it be brought to the degree of red heat, and while in this state, one portion be still further heated by the application of the flame of a spirit lamp, so as to be raised to a white heat, the rest of the wire will instantly be cooled below the point of visible ignition. This latter effect is evidently the consequence of the interruption of part of the Electric current, arising from the diminished conducting power of that portion of the wire that is heated to whiteness. An experiment, exactly the converse of this, and showing the increased facility of transmission consequent on a reduction of temperature, may be made by applying a piece of ice, or blowing a stream of cold air on a portion of the red hot wire; it will then be found that the other parts of the wire immediately become much hotter, and from a red rise to a glowing white heat. Thus, as Sir H. Davy observes, the quantity of Electricity capable of passing through that part of the wire submitted to the changes of temperature, is so much smaller when it is hot than when it is cold, that the absolute temperature of the whole wire is diminished by heating a part of it, and vice versad, increased by cooling a part of it.*

(38.) That the nature of the medium by which the influence body is surrounded, has a considerable influence on the intensity of the heat it acquires by Voltaic Electricity, has been shown by the following experiment of Mr. Singer. "Stretch a fine wire of platina within a glass receiver, placed upon an air pump, so that the air surrounding the wire may be removed or restored at pleasure. Ignite the wire to a dull red heat, by passing a current through it from a Voltaic battery of sufficient power for that purpose. Rarefy the air by the action of the pump; and as the rarefaction proceeds, the ignition of the wire will become more vivid, until at length it obtains a glowing white heat. Admit air into the receiver, and the wire will lose its intense heat, and appear more dull than at first. Rarefy the air again; the ignition will increase. Restore it to its original density, it will again diminish. These effects may be repeated many times, and will maintain the same proportion to each other, though they are less intense at each repetition." Sir H. Davy also found that a wire of platina, which was readily fused by transmitting a charge from a Voltaic battery is the exhausted receiver of an air pump, acquired in air a much lower temperature. It was by reasoning on this circumstance, that the expedient suggested itself of placing wires in a medium much denser than air, such as ether, alcohol, oils, or

* Philosophical Transactions for 1821, p. 431. Some account of the experiments referred to in the text, has already been given by anticipation in the Treatise on Electro-Magnetism; but as they relate solely to Galvanism, it was necessary, in order to preserve the continuity of the subject, again to notice them in this place.

† Singer's Elements, p. 410.
Part II.

CHAPTER III.

Electro-Magnetic Effects of Galvanism.

(43.) The influence which the transit of Electricity through conducting bodies exerts upon Magnetism, and the effects which result from this action, form one of the most remarkable and interesting subjects of modern science. As long as our knowledge of the operations of Electricity was confined to its more ordinary forms, there was little probability that the circumstances attending its connection with Magnetic phenomena would ever have been discovered. The science of Electro-Magnetism owes its birth to that of Galvanism. By supplying the means of putting into motion a vast quantity of Electricity, and of continuing its circulation for a considerable period, Galvanism has enabled us to detect its influence on the Magnetic needle, and to ascertain with precision the laws of its action.

(44.) Among the more remarkable of the physical effects of Galvanism, are now, therefore, to be ranked the induction of Magnetism in certain bodies, and the determination of a mechanical force, operating according to a certain law, in the bodies in which Magnetism has been thus induced, or which have previously acquired Magnetic properties. But these effects having been already fully considered in our Treatise on Electro-Magnetism, it would now be superfluous to detail or discuss them further. There is one point of view, however, relating especially to the present subject, in which it will be proper here to consider them, as it will assist us in the course of our inquiries. So many and so various are the links of connection, by which all the physical sciences are associated together; and so material is the aid which they mutually afford one another, that no one subject can be properly understood, or satisfactorily treated, without in some degree treading upon the province of the neighbouring science. Thus, while to Galvanism we are indebted for the discovery of the Electro-Magnetic powers, these newly discovered properties have, in their turn, furnished us with further means of improving the parent science. The production of certain Magnetic phenomena, originally brought to light by the progress in Galvanic inquiry, have now themselves become the most delicate of all the known tests for ascertaining the operation of Voltaic Electricity, under circumstances where its quantity could not otherwise have been appreciated, nor even its presence detected. The phenomena of Thermo-Electric-Magnetism, as they have been called, and of which an ample account has already been given, are illustrations of this remark. The passage through wires of considerable quantities of Voltaic Electricity, when the circuit is complete, may be manifested by the ignition of the wires; but excepting the increase of temperature, no sensible

* Edinburgh Philosophical Journal, xiv. 57.
Galvanism. change is occasioned in the metal which transmits the
Electricity. But its influence on magnetised, or mag-
etisable bodies, in its vicinity, will, by means of
proper instruments, indicate the most minute quantities
of circulating Electricity.

(45.) The apparatus for examining these minute
quantities of Galvanism, invented by Professor Cum-
ing, and which he has termed a Galvanometer or Gal-
vanoscope, has already been described in the Treatise
on Electro-Magnetism, (p. 23.) as also another form
of the same instrument, contrived by Mr. Marsh.
The principle on which they operate is the equal
action exercised on the Magnetic needle by all the
parts of a conducting wire, when it transmits a cur-
rent of Electricity. It is on this principle that the
helicical turns of wire in communication with the
poles of a battery, conspire in producing Magnetic
effects in the direction of the axis of the helix, that
is, in a direction perpendicular to the plane of each of
the coils. It is evident that this effect will be still
further increased, the greater the number of coils
which are made to act together upon the Magnetic
needle. By using this idea, Professor Schweigger, of Halle, im-
mediately after the discovery of Electro-Magnetism,
invented an apparatus well adapted for detecting
the feeblest Electrical currents; and it was after-
wards somewhat improved in its form by Professor
Oersted. The multiplying wire is of silvered copper,
and its thickness about one-hundredth of an inch;
for the purpose of guarding every part from any
metallic contact, it is wrapped in its whole length in
silk thread, which prevents all Electric communication
between the different turns of the wire. In this
form it may be denominated the Electro-Magnetic
Multiplier. Dr. Kaerntz has laboured to prove exper-
imentally the amount of the advantage obtained in
these instruments by each additional circumvola-
tion of the wire; and succeeded in verifying the deduc-
tion from theory, that the quantity of power of the
instrument over the needle was exactly in proportion
to the number of convolutions.*

The Electricity developed by the contact of two
discs, the one of copper and the other of zinc, when
nothing but water is interposed between them, is per-
fectly appreciable by this instrument. It renders
manifest Galvanic actions, which would be too feeble
to excite contractions in the muscles of a prepared
frog.

(46.) It follows from the principles we have already
explained and developed, concerning the transmission of
Electricity through conducting wires, that in pro-
portion as we lengthen the circuit which it has to
traverse, by multiplying the number of coils, we in-
tereose a greater obstacle to the transmission of the
Electricity. It is necessary, therefore, to employ
wires of a thickness proportioned to the charge which
is to be measured. Thus, when the instrument is to
be used for the comparison of considerable currents of
Electricity, wires of much greater thickness must be
employed; for without this precaution, there might
be, instead of an increase, an absolute diminution of
effect, in consequence of the imperfection of the con-
ductor.

(47.) In every instrument constructed upon the
principles of the Galvanometer, or Electro-Magnetic
Multiplier, the delicacy of its indications is much in-
creased by placing one or more magnetised needles,
in such a situation as shall greatly diminish, or com-
pletely neutralize the directive force which the sus-
pended needle derives from the earth's Magnetism.
A very happy application of this principle, calculated
by M. Nobili's at the same time to increase the action of the wires Galvano-
on the needle, has lately been made by M. Nobili, in
the construction of his new and highly ingenious
galvanometer. The novelty of his contrivance con-
ists in the employment of two Magnetic needles,
instead of one. These needles are equal in size, and
as nearly as possible brought to the same degree of
Magnetism; they are placed the one above the other,
fixed on a axis of straw, in parallel directions, but
with their polarities directed in opposite ways, as re-
presented in fig. 12. Their distance from each other Fig.12.
on the straw is regulated by the construction of the
frame with its covering wire, in and about which they
are to move. This frame is twenty-two lines long,
twelve wide, and six high. The wire is of copper,
covered with silk; it is one-fifth of a line in thickness,
and from twenty-nine to thirty feet long. It makes
seventy-two revolutions about the frame. The needles
are twenty-two lines long, three lines wide, a quarter
of a line thick, and they are placed on the straw five
lines apart from each other. An aperture is made in
the tissue formed by the turns of the wire on the
upper surface of the galvanometer, by opening them
from the middle towards each side; the lower needle
on the straw is introduced through this aperture into
the interior; in consequence of which the upper needle
remains a little above the upper surface of the wire.
The aperture is retained open to a certain extent, to
allow freedom of motion to the needles and straw;
these being suspended in the usual way from the upper
extremity of the straw. The graduated circle, on
which the deviation is measured, is placed over the
wire on the upper surface of the frame, having an
aperture in its centre for the free passage of the needle
and straw. The upper needle is the index, the lower
being visible only from the sides of the instrument.

The superior sensibility of this instrument is owing
to the addition of the upper needle. Being magnetised
in an opposite direction to the lower one, it almost
totally neutralizes the influence of terrestrial Mag-
etism, leaving only so much of directive power as shall
induce the whole arrangement to return to a constant
position when uninfluenced by Electrical currents, and
yet combining with the lower needle, to cause deflection
when an Electrical current is passing through the wire.
As an illustration of the delicacy of this instrument,
M. Nobili observes, that if Seebeck's combination of
antimony and bismuth be attached to a common gal-
vanometer, and the point of junction be cooled, only
a very slight effect is observed on the instrument;
whilst, if attached to the new galvanometer, the same
influence is sufficient to make the needles revolve
several times. If a piece of iron wire, five or six
inches long, be used to connect the extremities of
the copper wire of the instrument, by twisting the ends
together, and one of the points of contact be warmed
by touching it with the hand, the needle will move
from zero, and in the first oscillation will return to it.
Even the mere approximation of the hand to the
junction of the metals, will produce a deviation of 20°.
In consequence of the situation of the graduated

CHAPTER IV.

Chemical effects of Galvanism

(48.) The effects of Galvanism to which our attention was first directed, and which might be regarded as more especially appertaining to Electricity in its ordinary forms, namely, attraction, repulsion, and induction, were obtained under circumstances in which the Galvanic circuit of the battery was incomplete, and were exhibited by the insulated and separate poles of the apparatus. The ignition of the communicating wires, on the other hand, or their elevation of temperature, and also their Electro-Magnetic effects, were the results of the free and uninterrupted transmission of Electricity through highly conducting substances, which formed the medium of connection between the positive and negative extremities of the battery. The class of phenomena which are next to be the subject of inquiry, depend, on the contrary, upon the influence of this astonishing agent on fluid conductors, which convey it only partially and imperfectly. They comprise certain chemical changes of composition, effected by the agency of Voltaic Electricity in the fluids which are interposed in the line of its circuit.

1. Chemical changes occurring in simple Galvanic circles.

(49.) In order to obtain clear ideas of the nature and connection of these effects, we shall first attend to what takes place in the simplest Galvanic circle, composed of two dissimilar metals and an interposed fluid; and as an example of most ordinary occurrence, we shall take the case which we originally assumed of a plate of copper, and another of zinc, occasionally communicating with one another at one end, either by direct contact or by means of an intervening wire; and immersed in an acid solution. Let us, in the first place, suppose this solution to consist of very dilute sulphuric acid. If the plates be immersed in this acid, without touching or communicating with each other, the acid will act upon the zinc; will first occasion the decomposition of the water in contact with it, the oxygen of which will combine with the zinc, forming an oxide of zinc; while the hydrogen will be disengaged in the form of gas. The oxide of zinc will then be dissolved by the acid, in proportion as it is produced. The plate of copper, on the other hand, will under no change; the acid, in its diluted state, having no power of acting upon it. Let the contact be now made between the metals, and the following consequences will ensue. The oxidation of the zinc, and its solution in the acid, will proceed with much greater rapidity and energy than before; but, what is still more remarkable, it will not be accompanied with the evolution of hydrogen from the oxidising surface. The proportion of hydrogen due to the oxygen which unites with the metal, will, indeed, be disengaged, but it will now make its first appearance on the surface of the copper plate, from whence it will arise in a copious stream of bubbles. The copper will itself be still unaffected by the new action that has been thus established. In process of time, indeed, when a considerable quantity of sulphate of zinc has been dissolved in the fluid, we find the quantity of disengaged hydrogen gradually diminish, and a film, composed partly of metallic zinc and partly of filaments of oxide of zinc, is deposited on the surface of the copper; as soon as this has been effected, the Galvanic action ceases.

(50.) If an acid capable of acting upon the copper as well as upon the zinc, be employed in the experiment, similar phenomena take place, with this additional circumstance, that the action of the acid upon the copper ceases the instant the Galvanic circuit is completed; and instead of nitrous gas being formed on the surface of the copper, which happens before the circuit is formed, only bubbles of pure hydrogen make their appearance, and the copper is protected from all further action; the zinc being, as in the former case, oxidated and dissolved with additional energy.

2. Changes effected in Fluid Conductors.

(51.) The same chemical changes, which we have just described as occurring in a simple Galvanic arrangement, also take place in each of the portions of fluid, which intervene between the plates in each alternation of the series which constitute the composite batteries. As soon as the Galvanic circuit is completed, by establishing a sufficient communication between the poles of the battery, the zinc surfaces become rapidly oxidated, while the copper surfaces appear to give out hydrogen gas, and are protected from all chemical action.

Decomposition of Water.

(52.) Chemical actions of a still more remarkable kind take place, when fluid conductors are placed in any part of the circuit by which the two poles of the battery are brought into communication with one another. The first discovery of the chemical agency of Galvanism was in its power of decomposing water; it was one of the earliest fruits of the happy invention of the pile by Volta; and was due to the united researches of the late Mr. Nicholson, and of Mr. now Sir Anthony, Carlisle.

Let two metallic wires, each respectively communicating with the positive and negative poles of the battery be made to pass through the opposite ends of a glass tube filled with water, which may be confined by two corks, one placed at each end, allowing the wires to be introduced through them, so that their extremities may not be in contact, but may be at the distance of a quarter of an inch from each other.

* Bibliothèque Universelle, xix. 110; and Journal of Science, xl. 179.
Its elements obtained from separate portions of water.

Decomposition of Saline substances.

(55.) If the above mentioned precautions be neglected, the presence of saline substances will soon give rise to other phenomena, which although they are now sufficiently understood, were the source of great perplexity and error to the experimentalists who first noticed them. Thus it had been observed by Mr. Cruickshanks, among his earliest discoveries on the chemical effects of the Voltaic pile, that an acid and an alkali were generated at the two ends of the wire, when immersed in water, in the interrupted circuit. The same appearances were observed by Professor Pfaff, who ascribed them to the combinations of azote, furnished by the atmospheric air which was contained in the water, with the oxygen on the one hand, and the hydrogen on the other, arising from the decomposition of the water, which thus produced nitric acid and ammonia.* Brugnatelli, and other inquirers, in like manner, obtained traces of acid and alkali by the Galvanic action of the wires on what they supposed to be pure water, with only an admixture of a small quantity of common air. Desormes asserted that the acid was the muriatic; and the same conclusion was deduced by Simmer.* This singular result led to the opinion, that muriatic acid on the one hand, and soda on the other, which had also been found under the same circumstances, were actually generated by some mysterious agency of Galvanism, out of the elements of pure water. A letter appeared in the Philosophical Magazine, in 1805, purporting to be written by a Mr. Peel, of Cambridge, and containing an account of an experiment, in which the water that remained after a large portion had been decomposed by Galvanism, yielded on evaporation a small quantity of muriate of soda. This salt, it was said, could not have been contained in the water employed for the decomposition, as every precaution was used to have it free from impurities. The experiment, it was pretended, had been repeated both by the writer and by a friend of his, with precisely the same result. It appeared, however, on inquiry, that no such individual as Mr. Peel could be found at Cambridge, so that the letter bearing that name turned out to be a gross fabrication. But the most singular consequence of this attempt to impose upon the scientific world, was that when the experiment was tried by others, it was actually found to succeed; and accounts were received of the same results in reality attended by experiments of Professor Pacchioni, of Pisa, as those mentioned in the fabricated letter. In order to account for the appearance of chlorine, or oxymuriatic acid, in water that had been subjected to the action of Galvanism, Pacchioni conceived that hydrogen might be susceptible of different degrees of oxidation; that muriatic acid was an oxide of hydrogen, being formed from water by the abstraction of part of its oxygen; while oxymuriatic acid consisted of hydrogen in a still higher degree of oxidation.|| Mr. Sylvester, also, in this country, was led to the very same conclusion as to the appearance both of muriatic acid and of soda, in galvanised water, although he had used every endeavour to exclude muriate of soda from every part of the apparatus. These singular results, obtained at the same period by so many independent observers, could not fail to excite considerable attention, and gave rise

Galvanism.

In the prosecution of these researches it was apparent, that the acid resulting from the decomposition of any neutral salt, which might be contained in the aqueous solution placed in the Voltaic circuit, was collected round the positively electrified metallic surface; and the alkaline matter round the negatively electrified surface. Thus was the power of the Voltaic battery as an instrument of chemical analysis made manifest; and the path of discovery which was thus laid open, was pursued with the greatest ardour and the most signal success. The apparatus employed consisted usually of two cups, sometimes of glass, but where more accuracy was required, of agate, or some times of gold; the cups were connected together by a few fibres of moistened asbestos, and respectively connected with the opposite poles of the battery. If a portion of any soluble saline compound was placed in each cup, and the action of the battery continued for a sufficient time, all the alkaline matter was found collected in the negative cup, and all the acid matter in the positive. If a solution of common Glauber's salt, or the sulphate of soda, be subjected to the action of the battery, after a few hours, the positive cup will be found to contain a solution of sulphuric acid, and the negative cup a solution of soda. Each of these elements must consequently have been transmitted in opposite directions through the moistened fibres, or rather through the water which they contain. Any other neutral saline compound will present similar phenomena.

(56.) In whatever part of the fluid between the positive and negative wires the compound substance be placed, the ultimate results are still the same. Thus if the neutral salt, whether it be alkaline or earthy, be contained in one of the cups, and the other cup be filled with distilled water, the same transfer of either element takes place into the latter cup, according as it is connected with the one or the other of the wires; and at the end of the experiment the positive cup will contain the acid, and the negative cup, the alkaline or earthy base. This curious species of transfer may be beautifully illustrated by placing three cups, side by side, in a line, and connected together by moistened cotton. Let a solution of sulphate of potash, or of any other neutral salt be put into the middle cup, and blue infusion of cabbage into each of the others. When the communication is made with the Voltaic battery by immersing the wires into the fluid in the outer cups, the sulphuric or other acid will collect in the positive cup, and render its blue

Law of the decomposition of saline bodies.

Explained by Sir H. Davy.

This illustrious philosopher soon ascertained that the muriatic acid which had been found owed its appearance to the animal or vegetable matters employed; for when the same fibres of cotton were made use of in successive experiments, and washed, after every process, in a weak solution of nitric acid, all the earthy matter was found to have disappeared, and the acid matter still present. By employing an agate point of contact with the wire, which he observed to be considerably corroded. By employing an agate cup, in place of the glass, this source of error was entirely removed, and the results of all experiments, in which approximations were successively made to the truer result, it was found that even well washed asbestos, as was happily suggested by Dr. Wollaston, neither acid nor alkali were at first produced by Galvanism. Yet in subsequent experiments they were found still to make their appearance. Vessels of pure gold were substituted for those of glass; acid and alkali were still developed, though in smaller quantities than before. By a series of careful experiments, in which approximations were successively made to the true result, it was found that even distilled water contained in ordinary cases sufficient saline matter to give rise to the observed phenomena. But when slowly distilled in a silver still, and decomposed in gold vessels, out of the contact of the air, no trace of either acid or alkali appeared; and it was finally established, after a very laborious investigation, that when the water is chemically pure, and that all access of foreign soluble matter is guarded against, the sole products resulting from its decomposition by Galvanism, are two elements, oxygen and hydrogen.*

(58.) In whatever part of the fluid between the positive and negative wire the compound substance be placed, the ultimate results are still the same. Thus if the neutral salt, whether it be alkaline or earthy, be contained in one of the cups, and the other cup be filled with distilled water, the same transfer of either element takes place into the latter cup, according as it is connected with the one or the other of the wires; and at the end of the experiment the positive cup will contain the acid, and the negative cup, the alkaline or earthy base. This curious species of transfer may be beautifully illustrated by placing three cups, side by side, in a line, and connected together by moistened cotton. Let a solution of sulphate of potash, or of any other neutral salt be put into the middle cup, and blue infusion of cabbage into each of the others. When the communication is made with the Voltaic battery by immersing the wires into the fluid in the outer cups, the sulphuric or other acid will collect in the positive cup, and render its blue

* Philosophical Transactions for 1807.
infusion red, while the alkali will be transferred to the opposite cup, and tinge its blue contents green. The separation of the constituent parts by Electricity continues till the last portions of the compound are decomposed; this invariably happens whenever the results are distinct. Strong or saturated saline solutions afford indications of the progress of decomposition much more rapidly than weak ones; but the smallest proportion of neutral saline matter seems to be acted on with energy.

(59.) When such mixtures of saline solutions as are compatible with one another are used, the different acids, and the different bases seem to separate together in a mixed state, and without any respect to the orders of affinity.

(60.) When metallic solutions are subjected to the decomposing action of Galvanism, a deposition of the metal, in the form of crystals, takes place on the negative wire, and oxide is likewise deposited around it: while the acid passes over into the positive cup. With solutions of iron, zinc, and tin, this effect takes place, as well as with the more oxidable metals; when muriate of iron is used, the black substance deposited upon the wire is magnetic, and dissolves with effervescence in muriatic acid: from sulphate of zinc, a grey powder, having the metallic lustre, and likewise soluble with effervescence, appears. When a solution of nitrate of silver is used on the positive side, and distilled water on the negative, silver appears on the whole of the transmitting amianthus, so as to cover it with a thin metallic film. These effects, it will be seen, are perfectly similar to those we have already noticed as occurring in the fluids which occupy the cells of the battery itself.

(61.) A series of phenomena of a still more extraordinary nature presented itself in the farther prosecution of these inquiries. Sir H. Davy discovered that the elements of compound bodies may actually be conveyed through chemical solutions of substances, for which under other circumstances they have a strong affinity, without combining with them, or even producing upon them any of the usual chemical changes. Thus acids may be transmitted from one cup, connected with the negative pole, to another cup on the positive side, through a portion of fluid contained in an intermediate cup, and tinge with the vegetable coloured infusions most susceptible of change by the presence of acids, without in the least affecting them. Such is also the case with the alkalies. If three cups be arranged as before, and connected with each other in a series by moistened cotton; the middle cup, and also the one next to the positive side of the battery, being filled with blue infusion of cabbage, or of litmus; while the cup next to the negative side is filled with a solution of sulphate of silver, the whole series of papers being placed between the glass tubes and the positive side, the redness will soon be perceived in the water of the positive cup, and it will rapidly become strongly acid. The sulphuric acid thus transferred must therefore have passed through the middle vessel; but yet the fluid contained in this vessel has experienced no change of colour. By reversing the connections with the poles of the battery, a similar transfer of the alkali may be made; it will be collected in the tinged water of the negative cup, and render it green; but no effect will be apparent in the intermediate infusion, through which it must necessarily have passed.

(62.) The same controlling power exerted by Galvanism over the ordinary operations of chemical affinity, is displayed in a still more striking manner by the following experiment. Solution of sulphate of potash, contained in one of the cups, being placed in communication with the negative pole, while distilled water occupied the cup on the positive side; a weak solution of ammonia, contained in the middle cup, was made the intermediate link of the conducting chain; so that the sulphuric acid could not arrive at the positive wire in the distilled water without passing through the solution of ammonia. Yet the result showed that such a transfer had actually been made, without the slightest indication of any union having taken place between the acid and the ammonia. Similar experiments were made with various saline compounds, and the results were analogous. Muratic acid, for example, from muriate of soda, and nitric acid, from nitrate of potash, were transmitted through concentrated alkaline menstrua, under similar circumstances: and, conversely, alkalies were made to pass through solutions of the mineral acids, without showing any disposition to combine with them.

(63.) But the result was very different whenever the transmitted substance formed with the intermediate fluid an insoluble compound. When, for example, sulphuric acid is attempted to be passed through a solution of sulphuric acid, sulphate of barytes is formed, which, being insoluble in the fluid, is immediately precipitated, and being thus carried out of the sphere of the electrical action, all further transfer is arrested. By means of a basis of mechanical support, however, such transfers may sometimes be effected: thus magnesia and lime will pass along moist amianthus from the positive to the negative sides; but if a vessel of pure water be interposed, they do not reach the negative vessel, but sink to the bottom. In like manner when nitrate of silver was on the positive side, and distilled water on the negative, the silver, as we have already seen, passed along the transmitting fibres of the amianthus, so as to cover it with a thin metallic film.

(64.) The following experiment, made by Sir H. Davy, combines in one view many of the above-mentioned facts. Two glass tubes were filled with solution of muriate of soda, and the intermediate vessel with solution of sulphate of silver; paper tinged with turmeric was placed on the positive side, and paper tinged with litmus on the negative side: as soon as the Electric circuit was completed, soda began to appear in the negative tube, and oxymuriatic acid in the positive tube, and the alternate products were exhibited passing into the solution of sulphate of silver, the muriatic acid occasioning a dense heavy precipitate, and the soda a more diffused and lighter one; but neither the transmitting the alkali, nor the litmus transmitting the acid, had their tints in the slightest degree altered.

(65.) Many minute circumstances require to be Modes of attended to, in conducting these and similar experiments on the chemical effects of Galvanism, in order to ensure success. A powerful Voltaic battery is, however, by no means an essential requisite; for although a very large surface is generally necessary in order to effect the ignition or deflagration of the metals, the chemical decomposition of bodies may be
Galvanism. exhibited by a very moderate power. The former effects are best obtained by a battery brought rapidly into full action, by means of strong acid solutions acting upon the metallic plates; but the latter are accomplished with more certainty by the continuance of a more moderate and equal action of the battery for a considerable time, an object which is best attained by weaker acid solutions. Mr. Singer has given minute directions as to the best mode of adjusting the different parts of the apparatus for exhibiting the transfer of acid and alkali, by means of a power not exceeding thirty pairs of two inch plates. An infusion of the leaves of red cabbage may be made, by adding two or three drops of sulphuric acid to a pint of water, and infusing in it as many of the minced leaves as it will cover. After it has remained a day or two, the fine red liquor should be decanted and preserved in a closely stopped bottle. When wanted for the purpose of experiment, a portion is to be neutralized, by carefully adding a few drops of solution of ammonia, till it assumes a blue colour. Two watch glasses are to be filled with this blue fluid, and connected by a moistened fibre of cotton, or birebulous paper; they are then to be placed in the Voltaic circuit, by connecting one of them with the positive, and the other with the negative wire of the battery. In a short time, the fluid which surrounds the negative wire will assume a green colour, and that around the positive wire will be converted into a red, in consequence of the double transfer of alkali and acid. The decomposition of the whole of the salt will be completed in half an hour, the fluid in the negative cup becoming of a beautiful green, and that in the positive a bright red. If the situation of the wires be reversed, so that the cup which was positive may now become negative, and vice veras, the colours will again change; the green will first become blue, and then red; and the red, after first returning to its original blue, will become green. This alternate transfer may be several times repeated with one charge.*

When different portions of fluid are placed in the same Voltaic circuit, which is formed by means of several pieces of wire communicating the connection between the separate portions of fluid, the same changes take place in each, as happen when the communicating wire is interrupted by a single portion of fluid. Thus, if water be the subject of the experiment, oxygen is developed at all the points of the wire, out of which positive Electricity is flowing into each portion of water; and hydrogen is disengaged from the other extremity of the same wire, which is receiving the positive Electricity from the water. Thus every intermediate wire, between those in immediate connection with the battery, is collecting and giving out hydrogen at one extremity, and oxygen at the other. An arrangement of this kind is shown in fig. 13.

The general fact which has thus been established with regard to the chemical agency of Voltaic Electricity is, that there is one class of bodies, comprehending hydrogen, the alkaline and earthy bases, and all metallic substances, which when they exist in a fluid, and are in the line of action of the Voltaic circuit, are impelled from the positive towards the negative surface, through which that influence is conveyed; and that there is another class of bodies, consisting of oxygen, chlorine, and of the compounds in which these elements predominate, such as all acid bodies, which are impelled in the contrary direction, that is from the negative towards the positive pole. These bodies, after being thus distributed, are retained at their respective poles as long as the Electric currents are maintained; and, if it be consistent with their natural chemical affinities, frequently enter into combination with the metallic or other conducting surface through which the Electricity is transmitted to the fluid. Thus, if the surface which transmits positive Electricity be an oxidizable metal, such as zinc, it becomes oxidized by the oxygen which is developed on that side from the decomposition of the water.

The converse of this has already been exemplified, in the suspension of the chemical action of the nitric acid upon the copper plates in the cells of the battery, when the Electric circuit is completed. The same result will be obtained if a platinum wire, proceeding from the positive pole of the battery, be introduced into a glass filled with diluted nitric acid. Let a copper wire be connected at one end with the negative pole, and the circuit completed by plunging its other extremity in the nitric acid. Under these circumstances the copper will not be acted upon by the acid; but the moment the Voltaic circuit is interrupted, it is dissolved rapidly.*

**Decomposition of the Alkalies and Earths.**

The important facts which were thus clearly established, indicated a relation between the chemical affinities of bodies, and their natural states of Electricity; opened a wide field of speculation on the whole theory of Chemistry; and pointed out new paths of discovery in this department of physical science. Sir H. Davy pursuing the train of reasoning which they suggested, was led to the conclusion that chemical affinity is destroyed by giving to a body an Electricity opposite to that which naturally belongs to it; and that it is, on the contrary, increased by giving it a greater share of its natural Electricity. He thence inferred, that all those bodies which possess a strong chemical affinity for each other, such as metals and alkalies, are naturally in opposite states of Electricity. By inducing, therefore, upon any body an Electrical state contrary to the natural one, we may change all its chemical relations, and even succeed in resolving into their elements substances which would have resisted any other mode of decomposition. Guided by a theory so happily conceived, and armed with so powerful an instrument of analysis, the genius of Sir H. Davy triumphed over every obstacle, and led him on to the brilliant career of discovery, which has constituted so distinguished an epoch in the history of modern science.

The two fixed alkalies had long been suspected of being compound bodies, but no reasonable conjecture had as yet been formed as to their real composition. After encountering some difficulties in contriving a proper apparatus, this great problem was at length resolved by the following experiment. A small piece of pure potash, which had been exposed for a few seconds to the atmosphere, so as to give, by its having imbibed a small quantity of moisture, conducting power to its surface, without perceptibly destroying

---

GALVANISM.

GALVANISM. By a similar process the new metallic substances were converted from their negative to their positive state. Thus sulphuric acid is resolved by its means into oxygen gas, at the positive wire, and sulphur, which is deposited at the negative wire. Phosphoric acid, in like manner, yields oxygen gas and phosphorus. Ammonia separates into hydrogen and azote, with a small proportion of oxygen. Oils, alcohol, and ether, when acted on by a powerful battery, deposit charcoal, and give off hydrogen, or carburetted hydrogen. Mr. Brande has shown that when animal fluids containing albumen are placed in the Voltaic circuit, the albumen is separated in combination with alkali at the negative wire, and in combination with acid at the positive wire. With a powerful battery, it separates at the negative wire in the solid form; and with a less power, in the fluid form: a fact which gives countenance to the hypothesis, that an Electric power is concerned in the animal process of secretion.*

Part IV.

Decomposition of the earths. And of Synthetic experiments. Soda.

Galvanism, its aggregation, was placed upon an insulated disc of platina, connected with the negative pole of the battery, of the power of 250 plates of six inches by four, in a state of intense activity; and a platina wire, communicating with the positive pole was brought into contact with the upper surface of the alkali. The whole apparatus was in the open atmosphere. Under these circumstances, a vivid action was soon observed to take place. The potash began to fuse at both its points of electrization. There was a violent effervescence at the upper surface; at the lower, or negative surface, there was no liberation of Electric fluid; but small globules, having a high metallic lustre, and being precisely similar in visible characters to quicksilver, appeared; some of which burst with explosion and bright flame, as soon as they were formed; and others remained, and were merely tarnished, and finally covered by a white film, which formed on their surfaces. Numerous experiments proved that these globules were a peculiar inflammable principle, the basis of potash. The platina used in the experiment was in use, and the connection with the result, except as the medium for exhibiting the Electrical power of decomposition; and a substance of the same kind was produced when other metals, or even charcoal, were employed for completing the circuit. The production of this substance was independent of the presence of air, for it was obtained when the alkali was in the vacuum of an exhausted receiver. By a similar process a substance was procured from soda, which exhibited properties of an analogous nature, and which proved to be the basis of the mineral, as the former was that of the vegetable alkali. Both these substances, on being examined in a variety of ways, the detail of which would be foreign to our present purpose, were found to possess every property which can be deemed essential to characterise the metals; and it was concluded that the two alkalies are respectively the oxides of these new metals. The theory of the decomposition of the alkalies by Galvanism, is therefore sufficiently obvious, and is only a particular instance of the general facts above stated; namely, that combustible substances are developed at the negative, while oxygen is evolved at the positive wire. Subsequent experiments supplied all the proofs that were requisite in confirmation of these views. When solid potash or soda, in its moistened, or conducting state, was included in glass tubes, furnished with electrified platina wires, the new substances, (afterwards denominated potassium and sodium,) were generated at the negative surfaces; the gas given out at the other surface, proved, by the most delicate examination, to be pure oxygen; and unless an excess of water was present, no gas was evolved from the negative surface.

(71.) The applications of the Voltaic battery to the purposes of chemical decomposition are various and extensive. Thus sulphuric acid is resolved by its means into oxygen gas, at the positive wire, and sulphur, which is deposited at the negative wire. Phosphoric acid, in like manner, yields oxygen gas and phosphorus. Ammonia separates into hydrogen and azote, with a small proportion of oxygen. Oils, alcohol, and ether, when acted on by a powerful battery, deposit charcoal, and give off hydrogen, or carburetted hydrogen. Mr. Brande has shown that when animal fluids containing albumen are placed in the Voltaic circuit, the albumen is separated in combination with alkali at the negative wire, and in combination with acid at the positive wire. With a powerful battery, it separates at the negative wire in the solid form; and with a less power, in the fluid form: a fact which gives countenance to the hypothesis, that an Electric power is concerned in the animal process of secretion.*

* Philosophical Transactions for 1809, p. 385.
3. Circumstances on which the Chemical power depends.

(72.) The relation which different circumstances of the battery itself bear to its power of chemical decomposition is a subject of very curious inquiry. It is intimately connected with the theory of Galvanism, of which we purpose postponing the consideration until the principal facts belonging to the science have been stated. At present, then, we shall content ourselves with a recital of the leading facts on this subject, which may serve as the basis of our future reasonings. In giving an account of the circumstances connected with the ignition of metallic wires by the Voltaic battery, we observed that the increase of surface in the plates was attended with a considerable augmentation of this igniting power; the increase of the number of the plates, on the other hand, was not productive of the same degree of augmentation. The comparative influence of these two circumstances on the power of effecting chemical changes appears to follow an order the reverse of this; this latter power depending almost exclusively on the number of alternations of the series of plates, and being but little influenced by their size. Much, however, will depend upon the nature of the fluid with which the battery is charged. When dilute acid is employed to act upon the metallic surfaces, the power of chemical decomposition appears to increase in the same proportion as the number of the plates. In this respect it seems to follow the same law as the power of producing the purely Electrical effects of attraction, repulsion, and induction. But when river water is used for charging the battery, the decomposing power ceases to increase after the number of the plates gets beyond four or five hundred. A similar circumstance was observed with regard to the powers of ignition, which, within the limits of one hundred plates, increased nearly in the proportion of the numbers; while beyond that limit, there was a loss rather than an increase of power.*

(73.) An investigation was instituted by Gay Lussac and Thenard, into the increase of chemical power compared with the increased number of plates; the quantity of gas evolved by the decomposition of water, being taken as a measure of this power. The apparatus they employed was constructed in the form of troughs, being part of a large apparatus constructed by order of the French Government. These philosophers announced that the increase of decomposing power was proportioned to the cube root of the number of plates.† Sir H. Davy made similar experiments with the large combination of porcelain troughs employed in the Royal Institution, and the results which he obtained indicate an increase nearly as the squares of the numbers.‡ Mr. Singer justly observes that the result of every experiment of this kind must be uncertain, if a series of minute attentions be not observed. The vessels employed for the decomposition should be of the same size and form; the wires of the same length and thickness, and placed at equal distances from each other, in a fluid of uniform conducting power.§

(74.) It is evident that in whatever manner the

Electricity is generated, it is necessary, in order to obtain its full operation, that the wires through which it is conveyed must be of a size and quality adequate to its transmission; and that therefore different quantities of Electricity, the result of different dimensions and constructions of batteries, will require wires of different magnitudes. A due proportion should also exist between the quantity of Electricity which is to act upon the fluid, and the extent of surface by which the fluid receives it. However obvious it may appear that it is necessary to attend to all these circumstances, in conducting comparative experiments on this subject, they seem to have been unaccountably overlooked in most of those which have hitherto been instituted.

(75.) The comparative action of different fluids, compared both as exciters of the chemical powers of the Voltaic battery, and as mediums for the exercise of this power, was more particularly made the object of inquiry by Gay Lussac and Thenard. It was found that the Electrical and the chemical energies of the battery were never at a maximum together, but required different conditions for their production.

Twenty-four of the large plates of the apparatus constructed by order of the French Government, excited by a mixture of acid and water, decomposed the alkalies, and produced many other chemical effects, but gave only slight indications of Electricity, by means of the condenser and electrometer. The whole series of 600 large plates, when charged with water, did not produce any similar chemical effect, although they exhibited a much more intense degree of Electricity. The chemical power of the apparatus was found to be materially dependent upon the nature of the fluid employed to excite it; and was probably regulated by its relative degree of conducting power. Saline solutions were more active than water; alkalies more so than salt; and acid mixtures were most powerful of all. In some instances, a mixture of acid and salt was more active than acid alone; and when acid mixtures of various strength were successively employed, the quantity of gas disengaged by two platinawires, from the same fluid, were nearly in proportion to the strength of the acid. The fluids which were most efficient in exciting the chemical powers of the battery, were most rapidly decomposed when subjected to its action. With sulphate of soda a curious result was observed; the facility of decomposition was as the cube root of the quantity of salt contained in the solution. In the employment of different series of plates for the decomposition of water, the effect was found not to increase by any means in proportion to the number of the plates; so that when many batteries are made use of with this view, it is more advantageous to employ them separately in different portions of water, than collectively in one portion.

4. Comparison with the effects of common Electricity.

(76.) The comparison of the powers of Electricity excited by the ordinary machine, and by the Voltaic agency of battery, in effecting chemical decompositions, is a subject of inquiry no less interesting than important. It had long been known that water might be resolved into its two gaseous elements by a succession of Electric discharges sent through it, by the aid of a powerful machine. This fact was discovered by
Differences. Periments the Galvanic phenomena of decomposition by ordinary means ever succeed in producing a very close imitation of Van Troostwyk employed for this purpose a glass tube gradually ground it down, till, with a pocket lens, he adhesed to the point, and coverd in every part, he to both sides of the water; but, in fact, observes Dr. Wollaston, the resemblance is not complete; for in every way in which he tried it, he observed that each wire gave both oxygen and hydrogen gas, instead of their being formed separately, as by the Voltaic apparatus.

(78.) When a solution of sulphate of copper was subjected to the action of common Electricity by means of these slender conducting wires, the metal was revived round the negative wire. Upon reversing the direction of the current of Electricity, the copper was soon redissolved, and a similar precipitate was formed on the opposite wire, which was now rendered negative. Analogous experiments made with other metallic solutions presented similar results. The oxidating power of positive Electricity was also proved by its effect on vegetable blue colours. A current of Electric sparks was transmitted along the surface of a moistened wire, coloured with a strong infusion of litmus, by means of two fine gold points touching the card at the distance of an inch from each other. The effect, as in other cases, depending on the smallness of the quantity of water, was most discernible when the card was nearly dry. In this state, a very few turns of the machine were sufficient to occasion a redness at the positive wire, very manifest to the naked eye. The negative wire being afterwards placed on the same spot, soon restored it to its original blue colour.* By employing an apparatus similar to that of Dr. Wollaston, Sir H. Davy has effected the decomposition of sulphate of potash by common Electricity; potash appearing at the negative, and sulphuric acid at the positive pole.†

(79.) The important series of experiments, of which Inference we have now given the results, have removed all doubt of the identity of the Electricity evolved by Galvanism, with that excited by the ordinary Electrical machine.

CHAPTER V.

Physiological Effects.

(80.) The effects of Galvanism on the animal body, are all ultimately referable to its action on the nervous system. The most obvious and immediate of these effects are the production of certain sensations, and the excitation of muscular contractions; the more remote and indirect effects are seen in its influence on the function of secretion.

1. Action of Galvanism on the external Senses.

(81.) If any considerable portion of the human body be placed in the circuit of a Voltaic pile or battery, a distinct shock will be felt every time that the connection of conductors is made. For the production of this effect, however, it is requisite that the cuticle, through which the influence is to be transmitted, be sufficiently moistened; for in its usual dry state, it acts as a non-conductor to Electricity of such feeble intensity as that which is presented by the poles of the Voltaic battery. The most effectual mode of receiving the whole force of the battery is to moisten both hands with water, or, what answers still better, with brine, and grasping a silver spoon in each, to touch one extremity of the battery with one spoon, and the opposite extremity with the other. Another

* Philosophical Transactions for 1801, p. 427.
† Ibid. for 1806.
Galvanism.

mode is to immerse the extremities of the two conducting wires into two separate vessels filled with water, into which a finger of each hand should be plunged.

(82.) The shock received from the Voltaic pile resembles very nearly the sensation produced by a weak charge from a very large Electric battery. Humboldt, in his Electrically mounted engine, measured the intensity of the various excited sensations in proportion to the number of alternations of plates composing the pile. Twenty pair of plates are sufficient to give a shock, which, when fully received, is felt in the arms. With a hundred pair it is felt in the shoulders. The current of Electricity, which continues to flow through the body as long as it makes part of the circuit, generally manifests itself by the continuance of a painful sensation. If it be received by a part of the body from which the cuticle has been removed, a severe smarting sensation is experienced, which, if the denuded surface be large, increases till it becomes almost insupportable. The smallest cut, burn, or excoriation, near the part in communication with the pile, will give rise to this painful feeling. When the cuticle is entire, it requires the accumulated power of a number of plates to produce any sensible effect; but in more sensible parts, where the nerves are exposed to their action, a single pair of plates, forming a Galvanic combination, is sufficient to excite a sensible impression.

Pain in the denuded nerve.

Circumstances attending it.

Professor Robison tried the experiment with the surface of a cut which he had accidentally received, and to which he applied one of the metallic substances, completing the circuit with other parts of the surface of the body with which the other metal was in contact; and afterwards effecting a communication between the two metals by means of a wire; an acute pain was immediately felt in the wound. He also succeeded in bringing on the tooth ache by applying one of the metals to the nerve of a carious tooth. Humboldt, who prosecuted experiments on Galvanism with an ardour and perseverance which have rarely been equalled, informs us, that with a view of ascertaining more precisely the nature of these effects, he purposely applied two blisters over the deltoid muscles of his arms. He covered one of them with a large silver medal, and the other with a plate of zinc, and by means of a zinc wire established a communication between the two metals by means of a wire; an acute pain was immediately felt in the wound. He also succeeded in bringing on the tooth ache by applying one of the metals to the nerve of a carious tooth. Humboldt, who prosecuted experiments on Galvanism with an ardour and perseverance which have rarely been equalled, informs us, that with a view of ascertaining more precisely the nature of these effects, he purposely applied two blisters over the deltoid muscles of his arms. He covered one of them with a large silver medal, and the other with a plate of zinc, and by means of a zinc wire established a communication between the two metals. The result of the contact was not only a violent smarting sensation on the blistered surfaces, but an alternate contraction of the muscles of the shoulder and of the neck. When the blistered surfaces had been exposed to the air for the space of half an hour, so as to have become covered with effused lymph, the effect of the Galvanic contact was much diminished. But when, under these circumstances, a few drops of an alkaline solution were poured on the coating of lymph, the sensibility was immediately restored, and the pain became extremely violent; and the contraction were renewed, and succeeded each other several times successively. Not satisfied with these results, he wished to obtain proofs of the further action of Galvanism on the actions of the blood-vessels. Having abraded the skin of the wrist, attended with the effusion of a small quantity of blood, at the part where the radial artery is extremely superficial, he laid on the wound a coating of zinc, which he touched with a silver coin. As long as the contact continued, he felt a tension which extended to the end of his fingers, together with a shooting and tremulous sensation in the whole extent of the palm of the hand. This painful sensation became manifestly more intense, whenever the edge of the coin was brought in contact with the zinc; and the irritation likewise augmented the discharge of blood. The coagulation of the blood, however, intercepted the action, and diminished the sensation. Humboldt next made a slight incision in the part, the Galvanic process, which he continued for several days successively, produced a very decided inflammation.*

(83.) On another occasion, the same intrepid experimentalist subjected the skin over the trapezium and deltoid muscles to a trial similar to the preceding; and ascertained that the continued application of Galvanism, renewed the serous discharge from the vessels of the skin, accompanied by a change of colour, a very acute pain, redness, and inflammation. On repeating this experiment, he remarked that the sensation which Galvanism excited in him, did not appear to have the slightest resemblance with that which is occasioned by Electricity. It appeared to him to be a pain of a very particular and distinct nature. It is to be observed, however, that Humboldt had adopted the opinion, that the agents which produced Electric and Galvanic effects were distinct from one another.

(84.) Volta has remarked, that the action of the pile on the parts where the true skin has been laid bare, was productive of a sharper kind of pain on the negative side of the apparatus, that is, where the positive Electricity flowed out from the wound, than where it entered. This fact has previously been noticed with regard to the pungency of the common Electric spark.†

(85.) If any part of the face near the eyes be included in the circuit of the battery, a vivid flash of light is perceived at the moment of contact by the person on whom the experiment is made. This sensation is felt whether the eyes be open or closed, or whether it be made in day light or in the dark; it depends evidently on an impression produced on the retina, or optic nerve, similar to that which is excited by the admission of light to the eye. It is a phenomenon analogous to the effect of a blow on the eye, which excites the sensation of a bright luminous coruscation, although no light be really present. If the pupil of the eye be attentively watched in this experiment, it will be seen to contract as often as the metals are brought into contact. The flash of light produced by a pile which contained 111 plates of silver was so powerful, that the physiologist who made the experiment was not disposed to repeat it.‡ But the simplest Galvanic combination, if applied to the tongue and lips, is sufficient to occasion the perception of a flash; while at the same time a strong metallic taste is perceived on the tongue, where it is in contact with one of the metals. The most effectual mode of obtaining the flash, is to place one metal between the upper lip and the gums; or to insert a wire of one metal into the nostrils, while a plate of the other metal is laid upon the tongue, and then effecting the contact between them. It is also produced by covering the bulb of the eye with tinfoil, placing a silver spoon in the mouth, and then completing a metallic communication in the whole extent of the palm of the hand. This painful sensation became manifestly more intense, whenever the edge of the coin was brought in contact with the zinc; and the irritation likewise augmented the discharge of blood. The coagulation of the blood, however, intercepted the action, and diminished the sensation. Humboldt next made a slight incision in the part, the Galvanic process, which he continued for several days successively, produced a very decided inflammation.*

Galvanism.

between the tinfoil and the spoon; or the tinfoil may
be placed upon the tongue, while the rounded end of
a silver probe is applied to the internal angle of the
eye.

Perceptions of taste.

The peculiar taste above alluded to, is perceived on
placing one of the metals on the upper, and the other
on the under surface of the tongue, whenever these
metals are brought into contact. This fact was the
first phenomenon strictly appertaining to Galvanism,
that had been noticed; it was originally mentioned by
Sulzer, a German metaphysical writer, in a work pub-
lished in 1767, entitled The General Theory of Pleasures.
The experiment was varied by Humboldt in the fol-
lowing manner. By applying a flattened piece of zinc
to one of the surfaces of the tongue, and a flattened
piece of silver to the other surface, without either of
their coatings touching the other, but each of them
provided with a long iron wire; and by passing the
wires, in a parallel direction through a door, behind
which they may be brought together, and separated
alternately; the person who makes the experiment
may ascertain, by the taste he feelson his tongue,
whether the extremities of the wires are in contact.
The presence of saliva is essentially connected with
the production of this phenomenon. Fabroni re-
marked, that when he wiped his tongue with all possi-
care, the sensation resulting from the contact of
the metals was diminished to such a degree as to be
scarcely distinguishable.

(86.) A difference has been remarked in the taste
perceived by the tongue, according to the metal which
is laid upon it; zinc giving rise to an acid, and silver
to an austeré, or alkaline taste. It is augmented when
one of the metals has been rubbed over with mercury,
which renders the contact more perfect. When the
power of several plates is combined, all these effects
are augmented, and attended with an abundant dis-
charge of saliva. Professor Robison remarked, that
the drinking porter out of a pewter pot produces a
more brisk sensation than when it is taken out of a
glass vessel; which he ascribes to a Galvanic effect.
In this instance there is a combination of one metal
and two dissimilar fluids, which, as we shall afterwards
find, constitutes a Galvanic circle. In the act of
drinking one side of the pewter pot is exposed to the
action of the saliva which moistens the lip, while the
other metallic side is in contact with the porter; the
circuit being thus completed, an agreeable relish is
communicated to the latter when it comes in contact
with the tongue.

(87.) The following experiment of Volta is another
illustration of the same general fact. He took a
basin of zinc, placed it on a silver stand, and filled it
with water. When a person applied the tip of his
tongue to the water, he found it perfectly tasteless as
long as he did not touch the silver stand; but when-
ever he laid hold of the stand with the hand previously
moistened, he experienced on the tongue a strong
acid taste. This experiment will succeed, although
the effect be weaker, with a chain of several persons
who hold each other's hands, after they have been
moistened with water; while the first person applies
the tip of his tongue to the water in the basin, and
the last lays hold of the silver stand.

(88.) With a view of increasing the effect resulting

from a single pair of plates of different metals, Pro-
fessor Robison arranged a series of zinc and silver
plates, about a quarter of the size of a shilling so as to
form a rouleau; and on applying his tongue to the
dge of the rouleau, the sensation experienced was
more manifest than when a single pair was employed:
but, for reasons that will appear hereafter, its power
is not in other respects more considerable. The
same philosopher also states, that he could ascertain
from the peculiar impression made upon the tongue on
the application of gold or silver trinkets, whether any
solder was employed in making them.

(89.) It may here be observed, that common Electric-
city received by the tongue excites sensations very
analogous to those which result from Galvanism. Ber-
zelius remarks that positive and negative Electricity
may be readily distinguished by the taste, on making
the Electric current pass by means of a point to the
tongue. The taste of positive Electricity is acid; that
of negative Electricity is more caustic, and, as it were,
alkaline.

Cavallo conceived that he had proved, by the
following experiment, the influence of Galvanism on
the olfactory nerves. Having brought together
a silver thread, forced as high up as possible into
the nostril, and a piece of zinc, laid on the tongue, he
was sensible of a putrid smell, more especially
after having forcibly pulled the silver in the nostril.
This experiment has however been frequently re-
peated by Reinhold, Fowler, and others, without
any such result having been obtained. Attempts
have likewise been made to excite the auditory nerves
by Galvanism so as to give rise to perceptions of
sound; but hitherto without the least success:
unless we consider as such the experiment described
by Volta, who, after having introduced into each ear a
blunt metallic probe, and directed through the head,
by their means, a current of Voltaic Electricity, was
sensible of a peculiar sound, similar to that of ebulli-
tion or decrepitation. He did not think it safe, how-
ever, to repeat this experiment.

(90.) Cavallo conceived that he had proved, by the
effects of Galvanism on the sense of smell and

(91.) The physiological effects of Galvanism which
Muscular contrac-

almost exclusively occupied the attention of philoso-
phers, previous to the discovery of the pile, were those
in which contractions in the muscular parts of animals
were exhibited. It was the observation of a fact of
this kind by Galvani which gave rise to the first
inquiries on the subject, and which may be said
to have laid the foundations of the science which
now bears his name. The source of that surprising
power which called forth such sudden and forcible
muscular contractions, as took place when the nerve
and muscles of the limb of a frog were respectively in
contact with different metals, which were themselves
made to communicate, either directly or by the inter-
medium of other metals, was most anxiously sought
for: and it was not till after a long period of laborious
research, in which a prodigious number of experi-
mentalsists in every part of Europe engaged, and
occasionally involved themselves in inextricable
mazes of perplexity, that the source of this power
and the Electric agencies was recognised and finally
established. An opinion had been very prevalent, that
the real source of the power developed existed in the
muscle and nerve which formed part of the circuit;

\[\text{Part II.}\]

\[\text{Effects of Galvanism on the sense of smell and}

\[\text{Eas.}\]

\[\text{Wilkinson, Elements, i. 121}\]
found that the Galvanic influence was communicable through a series of several persons who joined their hands, previously moistened, in order to render the cuticle sufficiently conducting. Having, in the course of his laborious researches, composed a chain of seven or eight persons, he occasionally remarked that the movements of the muscles did not take place, until one person, who constituted part of the chain, had quitted it. He was frequently at a loss to discover the non-conducting individual, until all the persons who composed the chain had withdrawn from it in succession. It was in vain that this individual wetted his hands; nothing could give them that conducting property which nature seemed to have refused to him.

(95.) The same process applied to other animals, and even to the human body, will succeed in producing similar effects. In the hospital of St. Ursula, at Bologna, similar trials on the amputated legs and arms of patients were made with perfect success. These experiments have been repeated by a great many physiologists, and varied in a great number of ways, with similar results. When large animals are made the subject of experiment, and the power of the Voltaic pile or battery is employed, the effects are exceedingly striking, and sometimes terrible in the eyes of the spectator, who can scarcely persuade himself but that the convulsive movements he beholds are indications of returning life, and of the most acute suffering. If two wires be placed in the ears of an ox, sheep, or other animal soon after its death, and one of the wires be connected with one pole of a battery of a hundred plates; whilst the other wire is brought occasionally in contact with the opposite pole, at every completion of the circuit very strong muscular actions will be excited; the eyes will be seen to open spontaneously, and roll in the sockets as if endowed with the power of vision; the pupils at the same time becoming dilated; the nostrils will vibrate in imitation of the act of smelling; and the jaws will immediately begin their usual actions of mastication. These convulsive actions, when the head is still warm, and has not long been separated from the body of the animal, are very considerable. The ears move with great activity and force; and when the tongue has been previously drawn out, and secured to the table by an iron skewer, which is made to penetrate more than half an inch into the wood, it is retracted with such force on the application of Galvanism, as to detach the skewer from the table, and to throw it up into the air to a considerable height. An entire sheep subjected to the action of the battery exhibited motions resembling the convulsive struggles of animals in an epileptic state, and much more powerful than the natural actions. Two horses, recently killed, which Mr. Wilkinson galvanised, required two persons to restrain the motions of each of the legs.*

(96.) Similar experiments have often been made both in this country and on the continent, and on the bodies of criminals soon after their execution. Vasali-Eandi, in conjunction with his friends Giulio, and Rossi, made a great number on several victims to the guillotine at Turin.† Aldini, by operating with a considerable series of plates, on the body of a criminal executed at Newgate, produced violent agitations of

(97.) Every species of animal appears to be susceptible of the Galvanic influence. The nervous organization of fishes particularly adapts them to these experiments. Humboldt has made a great number on this class of animals. "I have seen," he observes, "fishes, the heads of which had been cut off half an hour before, strike with their Galvanised tail in so forcible a manner, that the whole of the body was raised considerably above the table on which they were placed." When the excitation was increased by alkaline solutions, or by chlorine, the struggles of the fishes, more particularly of eels and tench, were such that it was scarcely possible to master them. The slightest contact of metallic substances made them spring to a considerable distance. If a live flounder be placed in a dish upon a slip of zinc, and a shilling be placed on its back; whenever the zinc and shilling are brought into metallic communication by means of a wire, strong muscular actions are excited.

On Fishes; (97.) Every species of animal appears to be susceptible of the Galvanic influence. The nervous organization of fishes particularly adapts them to these experiments. Humboldt has made a great number on this class of animals. (99.) The physiological condition of the amphibia renders this class of animals peculiarly fitted for the Amphibia. The exhibition of the effects of Galvanism, both on account of the great susceptibility to its influence which is inherent in their nervous system, and on account of the extraordinary tenacity of the powers of life which characterises them. The muscular and nervous organisation of a frog has accordingly been considered as the most delicate electroscope in nature. It is incomparably more sensible to the Electricity developed by the contact of two dissimilar metals than the gold-leaf electrometer of Bennet. But, on the other hand, it is much inferior to the Electro-Magnetic multiplier, of which we have already given a description.

(100.) Volta had asserted that the heart, and other Involuntary muscles whose action is not under the guidance of the will, were incapable of being affected by Galvanism; but Fowler has sufficiently shown that they might be acted upon, if the experiment be properly conducted: and his results were confirmed by Vassali, who proved that not only the heart, but the muscular fibres of the stomach and intestines might also be excited by Galvanism. Humboldt succeeded in producing contractions in the hearts of frogs, lizards, and toads; and also in those of fishes. Similar results were obtained by Nysten, who published an elaborate Treatise on the subject.* Bichat was of opinion that the nerves connected with the great sympathetic, and with the ganglia belonging to those which are distributed to the organs of which he calls the organic functions, are much less susceptible to the action of Galvanism, than the nerves which supply the voluntary muscles.† Circaud conceived he had discovered on the Fibrin of the Blood, immediately after it has been taken from the vessels, could be made to contract by the Galvanic apparatus. De la Metherie confirmed the statement of Circaud; but the experiment has not succeeded in this country, even when conducted in the most careful manner. When we consider the difficulty and delicacy of the process, we may be allowed, indeed, as Dr. Bostock observes, without impeaching the veracity of the narrators, to entertain some doubts on the subject.‡

(101.) The influence of Galvanism on the actions of the arteries, both in augmenting the force of their action.
Galvanism. — In the exciting and affecting nature of the secretions, has been proved by a great number of facts. The most remarkable of these latter effects are those which have been lately established by the researches of Dr. Philip; who found that the secretion of the gastric juice in the stomach, which had been suspended by the division of the eighth pair of nerves, was restored on establishing the Voltaic current of Electricity through the divided portion of the nerves next to the stomach. The accuracy of the experiments on which this conclusion is founded, was for a long time disputed; but it has lately been satisfactorily established, by their careful repetition at the Royal Institution by Mr. Brodie, in conjunction with Dr. Philip, in conjunction with Mr. Brodie. It appears, then, from these facts, that the Galvanic energy is capable, under certain circumstances, of supplying the place of the nervous influence; so that by means of its assistance the stomach, otherwise inactive, digests food as usual. Dr. Philip has advanced one step further in the inferences he draws from these experiments, and thinks they establish the "identity of Galvanic Electricity and nervous influence." Our limits preclude us from entering into the discussions of this question, which has given rise to much controversy, and which, although one of great interest, is more of a physiological nature, than appertaining to our present subject. We shall only observe, that although it must be allowed that a considerable analogy has thus been shown to exist between nervous and Electric agencies, yet it may with great probability be supposed that the Galvanic influence may operate more as a powerful stimulus, exciting the remaining portion of nerve through which it is transmitted to perform such an increase of action, as may compensate for the want of the principal trunk of the nerve.

(102.) Dr. Philip appears also to have succeeded in showing, that the Galvanic influence occasions an evolution of caloric from arterial blood, if the latter be subjected to it as soon as it leaves the vessels; but that it produces no such effect on venous blood. When the lungs and muscles of respiration are deprived of their due proportion of nervous influence, so that their functions are impeded, and the breathing has become difficult and laborious, increased facility is obtained in carrying on these movements, by the stimulus of the Galvanic power. He has therefore proposed its employment as a remedy for asthma, and gives several cases in which it was used with decided benefit.

(103.) The probability that animal secretions are effected by the agency of an Electric power operating as in the Galvanic circuit, is an idea that occurred to Dr. Wollaston and to Dr. Young, and which is corroborated by the existence of this power in some fishes, as already adverted to, and by the probability of the universal prevalence of similar powers of lower intensity in other animals, derived from the suddenness with which the nervous influence is communicated from one part to another in the living system. Dr. Wollaston proved by an experiment, that the weakest Electric energies may be capable of producing similar effects to those obtained by powerful batteries, although they would require a time proportionally great; such may, therefore, be the case with animal secretions.

The qualities of each secreted fluid, he observes, may hereafter instruct us as to the species of Electricity that prevails in each organ of the body. The general re-increase of acid in the urine, for instance, though secreted from blood that is known to be alkaline, appears to indicate in the kidneys a state of positive Electricity; and since the proportion of alkali in the bile seems to be greater than that contained in the blood of the same animal, it is not improbable that the secreting vessels of the liver may be comparatively negative.

It becomes, therefore, an interesting object to inquire, what other organs also may be considered as permanently different in their state of Electricity; and what others may possibly be subject to temporary states of opposite Electrical energies, and may by means of such relation produce the most powerful effects in the animal economy.*

Some experiments on this subject have been instituted by Mr. Brodie, but without any very satisfactory result. (104.) It is scarcely necessary to mention that powerful shocks from a galvanic battery are no less instantly destructive of animal life, than discharges from the ordinary electric battery. Small animals are easily killed by discharges, which would only produce a temporary stunning effect on larger animals.

4. Circumstances in the Galvanic apparatus on which these effects depend.

(105.) We have seen that in bodies of high conducting powers, such as metals, the effects produced will depend altogether on the actual quantity of Electricity which is collected in a state ready to be discharged; but it is otherwise in imperfect conductors, such as water, and all organic structures whether of an animal or vegetable nature. The quantity of Electricity which this class of substances is capable of transmitting is limited by several conditions: such as the extent of circuit the Electricity has to perform; and also the degree of intensity at which the Electricity is presented to the conductors. Thus the human body, which follows the same laws as imperfect conductors, is incapable of discharging a Voltaic battery composed of a single pair of plates, however large their surface; because the intensity of the Electricity to be discharged is, in this case, extremely low. As this intensity is augmented by increasing the number of alternations in the pile or battery, so the shock, and other effects on the animal system, follow the same law of increase. This point has been fully established by the researches of numerous experimentalists. It appears to have been first pointed out by Van Murum.†

(106.) The force of the shocks is also much influenced by the nature of the fluid with which the battery is charged. Thus a pile or battery of fifty pairs of plates, with only water interposed between them, will give but a very feeble shock; but if a considerable quantity of salt be dissolved in the water, the shock produced will be much more powerful.

PART III.

OF THE DIFFERENT FORMS OF GALVANIC APPARATUS.

Galvanism. (107.) We have hitherto, for the sake of perspi-
cuity, confined our attention to one order only of Gal-
vanic combinations, namely, those which are com-
piled of two dissimilar metals, and an oxidating fluid,
capable of acting with greater energy on the one metal
than on the other; and we have taken, by way
of example, the substances most usually employed,
namely, zinc, silver, and an acid solution. It will be
proper now to consider the variations which may be
made in the substances used, as well as in the nature
of their combination, so as still to be productive of
Galvanic action.

1. Different kinds of Galvanic circles.

Two classes of Galvanic elements. (108.) For this purpose the elements of Galvanic
combinations have been arranged into two classes,
with reference to their powers of conducting Electric-
ity. The metals, together with charcoal, being
ranked as perfect conductors; while aqueous solutions,
containing air, or saline substances, compose the class
of imperfect conductors. The principal metals, or
substances composing the first class, arranged in the
order of their oxidability, will form the following
series, namely, zinc, iron, tin, lead, copper, silver,
gold, platina, and charcoal. The fluid conductors
most commonly employed, arranged, in like manner,
in the order of their power of oxidizing the substances
of the first class, will compose the following series,
namely, solutions of nitric acid, muriatic acid, sulphuric
acid, muriate of ammonia, nitrate of potash, muriate
of soda, and other neutral salts; and water containing
oxygen gas, or atmospheric air.

(109.) A Galvanic circle formed by two of the bodies
enumerated in the first series, and one of those belon-
ging to the second, will constitute an arrangement of
the first class: and the Electrical effects will be similar
to those already stated in the former part of this Treatise,
namely, a current of positive Electricity will pass
directly from the substance which comes latest in the
series of perfect conductors, to the one which precedes
it; and will be transmitted back again, from the sub-
stance which comes first in the series, through the
interposed fluid, to the one that comes last. Thus, if
the circle be composed of gold, tin, and acid, the
positive Electricity will pass in the order in which we
have here enumerated them, and from the acid will be
transmitted back again to the gold. The stream of
negative Electricity, will of course follow an order
exactly the reverse of that which has now been stated.
Thus it appears that each metal is positive with rela-
tion to all those that succeed it in the series; negative
with relation to those which precede it. It follows also,
as a necessary consequence, that the oxidizing fluid,
which receives Electricity from the metal that is ox-
dated by it, and transmits it to the metal upon which it
has no chemical action, must be considered as posi-
tive with regard to the former, and negative with
regard to the latter.

(110.) The powers of the different circles that may be
formed by various triple combinations of this kind, of
effect, are very different in degree; the greatest being that
in which two metals, the most remote from each
other in the scale, are employed, together with the
fluid which acts with the greatest chemical energy on
the most oxidable of these metals. It is an indis-
pen sable condition for the production of Galvanic
effects, that a chemical action be excited between the
fluid and one of the metals with which it is in contact.
Thus silver and gold evolve no Galvanic influence
when in contact with pure water, which is incapable
of acting chemically upon either of the metals; but
when they are connected with water containing nitric
acid, or any other fluid decomposable by silver, they
form an active Galvanic arrangement.

(111.) The conducting powers of charcoal, and its Galvanic
efficacy when employed as a component part of Gal-
vanic combinations, were discovered by Dr. Wells. Sir H.
Davy afterwards found that charcoal might be
used in the Voltaic circuit, instead of a metallic wire,
for decomposing water; carbonic acid being formed
by the combination of the oxygen with the charcoal
at one pole, and carburet of hydrogen at the other
pole. In this experiment, the quantity of gas given
out by the former is very inconsiderable, in conse-
quence of its rapid absorption by the water. Sir H.
Davy also formed a pile of zinc and charcoal, which
acted with considerable energy.

(112.) The fact already stated, that the combination
of two metallic bodies with fluids, is productive
of Galvanic influence, only in so far as it furnishes two
conducting surfaces of different degrees of oxidability,
led Sir H. Davy to suspect that a similar agency
would be developed if single metallic plates could be
connected together by different fluids, in such a man-
ner that one of their surfaces only should undergo
oxidation. After many trials he at length discovered
that active arrangements might be formed, not only
when oxidations, but likewise when other chemical
changes were going on in some part of the circle.

(113.) If the ordinary Galvanic combinations, in Galvanic
which two perfect conductors are joined with one
Circle of imperfect conductor, be considered as forming one
class of combinations: the second class will consist
of those in which one perfect conductor is combined
with two imperfect conductors. Of these last, Sir H.
Davy distinguishes three different kinds.

(114.) The first and most feeble is composed First kind,
of single metallic plates arranged in such a man-
ner that two of their surfaces are in contact with
different fluids, one capable, and the other incapable
of

Galvanism

oxidating the metal. Tin, zinc, and some other easily oxidable metals act most powerfully in this kind of combinations. If pieces of polished tin, about an inch square and one-twentieth of an inch thick, be connected with woollen cloths of the same size, moistened some in water, and some in dilute nitric acid, in the following order, tin, acid, water, and so on, till twenty series are put together, a feeble Galvanic battery will be formed, capable of acting weakly on the organs of sulphuration, and of slowly producing the common appearances in water; the wire from the oxidating surface of the plates evolving hydrogen, and the wire from the non-oxidating surface evolving oxygen. When batteries of this kind are placed perpendicularly in the form of a pile, the cloth moistened with acid should be placed underneath the one which is moistened with water; for as the acid is specifically heavier than the water, little or no mixture of the fluid will then take place. When zinc is employed, it is necessary, on account of its rapid oxidation in water containing atmospheric air, to use three cloths; the first moistened with a weak solution of sulphuret of potash, which is possessed of no power of action upon zinc, and which prevents it from acting upon the water; the second moistened with a solution of sulphate of potash, of greater specific gravity than the solution of sulphuret; and the third wetted with an oxidating fluid specifically heavier than either of the solutions. In this case, if the order be as follows, zinc, oxidating solution, solution of sulphate of potash, solution of sulphuret of potash, very little mixture of the fluids, or chemical action between them will take place; and an alternation of twelve series of this kind, forms a battery capable of producing sensible effects.

(115.) The second kind of Galvanic combinations with single plates, is formed when plates composed of a metallic substance, capable of acting upon sulphureted hydrogen, or upon sulphurets dissolved in water, are formed into series, with portions of a solution of sulphuret of potash, and water, in such a manner that one side of every plate is in contact with water, whilst the other side is covered with a solution of sulphuret. Under these circumstances, when the alternation is regular, and the number of series sufficiently great, Galvanic power is evolved; and water, placed in the circuit, with silver wires, is acted upon; oxide being deposited on the wire connected with the side of the plate undergoing chemical alteration, whilst hydrogen is evolved from the side in contact with water.

Silver, copper, and lead, are each capable of forming this combination. Plates made from any of these metals may be arranged with cloths moistened, some in water, and others in solution of sulphuret of potash, in the following order, metal, cloth moistened in sulphuret of potash, cloth moistened in water, and so on. Eight series will produce sensible effects; and the wire from the top of the pile produces oxide. Copper is more active in this kind of batteries than silver; and silver more active than lead.

(116.) The third and most powerful kind of Galvanic batteries constructed with fluids and single metals, is formed when metallic substances, oxidable in acids, and capable of acting on solutions of sulphurets, are connected, as plates, with oxidating fluids, and solutions of sulphuret of potash, in such a manner that the opposite sides of every plate may be undergoing different chemical changes; the mode of alternation being regular. The same metals which act in the second form may be used in the third; and the order of their powers is similar. The pile may be erected in the same manner as the pile with zinc under the first head; the cloths moistened with acid being separated from those moistened with solution of sulphuret, by a third cloth soaked in solution of sulphate of potash. Three plates of copper, or silver, arranged in this manner, in the proper order, produce sensible effects; and twelve or thirteen are capable of giving weak shocks, and of rapidly decomposing water: the wire connected with the oxidating end of the apparatus evolving hydrogen; and the wire attached to the end acting on the sulphuret evolving oxygen.

(117.) In all the single metallic piles constructed increased with cloths the action is very transient: but greater power by permanency may be given to their effects, by a disposition of the plates and fluid similar to the trough of Cruickshanks, with the partitions of the cells, composed alternately of oxidating and non-oxidating plates, and the cells filled alternately with the different solutions, according to the kind of combination employed: these fluids being connected in pairs with each other by slips of moistened cloth, carried over the non-conducting plates.*

(118.) Sir H. Davy has summed up the general results of these experiments in the following words: result.

"The metals having the strongest attraction for oxygen, are the metals which form the positive pole," (the composite battery being here understood;) "in all cases in which the fluid menstrua act chemically by affording oxygen; but when the fluid menstra afford sulphur to the metals, the metals having the strongest attraction for sulphur under the existing circumstances, determine the positive pole. Thus, in a series of copper and iron, introduced into a porcelain trough, the cells of which are filled with water or with acid solutions, the iron is positive, and the copper negative; but when the cells are filled with solution of sulphur and potash, the copper is positive and the iron negative. In all combinations in which one metal is concerned, the surface opposite the acid is negative, and that in contact with solution of alkali and sulphur, or of alkali, is positive."†

(119.) Dr. Young also has laid down a general formula for determining the direction of the Electric currents in all Galvanic combinations, which may often be found useful in practice. "We may represent," he says, "the effects of all Galvanic combinations, by considering the oxidation as producing positive Electricity in the acting liquid, and the sulphuration as producing negative Electricity, and by imagining that this Electricity is always communicated to the best conductor of the other substances concerned, so as to produce a circulation in the direction thus determined. For example, when two wires of zinc and silver, touching each other, are separately immersed in an acid; the acid, becoming positively Electrical, imparts its Electricity to the silver, and hence it flows back into the zinc. When the ends of a piece of charcoal are dipped into water and into an acid, connected together in a small tube, the acid, becoming positive, sends its superfluous Electricity

Galvanism through the charcoal into the water. If a wire of copper be dipped into water and a solution of alkaline sulphuret, connected with each other, the sulphuret, becoming negative, will draw the positive Electricity from the copper on which it acts. In all these cases the direction of the current is truly determined, as may be shown by composing a battery of a number of alternations of this kind, and either examining the state of its different parts by Electrical tests, or connecting wires with its extremities, which, when immersed into a portion of water, will exhibit the production of oxygen gas where they emit the Electric fluid, and of hydrogen where they receive it.**

Galvanic combinations without metals. Gautherot asserted that he had succeeded in forming a pile of which charcoal and plumago were the conducting elements.† Lagrange announced that by placing upon each other alternate layers of muscle and of brain, from a human body, with pieces of moistened cloth or leather interposed, he formed a pile which produced Galvanic effects.‡ Dr. Baconio, of Milan, composed a Galvanic pile entirely of vegetable substances. The substances he employed were discs of red beet root, two inches in diameter; and discs of walnut tree, of the same size, divested of their resin by digestion in a solution of cream of tartar in vinegar. With this pile he produced Galvanic effects on a frog, taking a leaf of scurry-grass as an exciter.§

Circles with Nerve and Muscle. (120.) Attempts have often been made to form Galvanic combinations without metal. Gautherot succeeded in exciting very considerable muscular contractions in frogs, without the intervention of any metallic substance; sometimes by bringing into contact the nerve of one animal with the muscle of another, and at other times by employing the nerves and the muscles of the same animal. In some of his experiments the most powerful contractions were excited, by bringing the parts of a warm and of a cold blooded animal into contact with each other.

Thus on introducing into one of the ears of an ox recently killed a finger of one hand moistened with a solution of salt, and holding in the other hand a prepared frog; when the denuded spine of the frog was made to touch the tongue of the ox, convulsions were produced in the limb of the frog. In like manner, if a prepared frog be held by one hand moistened with solution of salt, and the crural nerves be applied to the tip of the experimenter’s tongue, convulsions will be excited.

Many of these experiments were made in presence of the Members of a Commission appointed by the French National Institute, for the purpose of inquiring into the subject; and they were afterwards repeated in London at the Anatomical Theatre in Great Windmill-street.

Animal Electricity. (121.) The inference which Aldini drew from these facts was, that a proper animal Electricity was inherent in the body, not requiring the assistance of any external agent for its development. But the more probable supposition is, as Dr. Bostock has remarked, that the parts of the body in these experiments act in a manner analogous to the pile which was constructed by Sir H. Davy, in which Electricity was developed by the action of two different fluids upon carbon. There are, however, many circumstances wanting to render this analogy complete.*

(123.) In the conformation of several fishes, as the Torpedo, Gymnotus Electricus, and several others already noticed in the Treatise on Electricity, nature has constructed organs appropriated to the excitation of Electricity. These organs have a striking resemblance to the plates of the Galvanic battery; we know nothing, however, of the immediate arrangement from which they derive Electric properties. The effect of the shock they produce, resembles in all respects that of a weak charge of a very large Electric jar; and is therefore exceedingly analogous to that of the Voltaic pile. We have already seen that the shock given by a battery is in proportion to the number of plates of which the series is composed; now, in each of these fishes, there are at least 150,000 cells, a number which will sufficiently account for the magnitude of the effect in giving shocks, compatible with a very low state of Electric intensity. It is presumable, according to Volta, that the small layers or pellicles found in the Electric organs, placed one above the other in the columns, are formed of alternate structures belonging to different classes of conductors, and arranged in such a way as that the heterogeneous parts may be separated by a humid layer of more imperfect conducting power.

2. Comparison between different batteries of the ordinary construction.

(124.) Reverting to the more ordinary forms of the Galvanic apparatus, several circumstances with regard to their comparative powers remain to be noticed.

The principal inconvenience attending the pile of Volta, is that it requires considerable time to put together, and adjust it properly; and that it must frequently be taken to pieces and cleaned, on account of the oxidation of the zinc by the action of the fluid employed: operations which become very troublesome when the number of plates is considerable. The soldering together of each pair of zinc and copper plates, is an improvement upon the plan of simply laying them on each other; a better and more extensive contact between the metals being thereby secured. But still the pile is troublesome to put in action; from the fluid being liable to be pressed out of the discs of cloth by the weight of the plates, and frequently running over the edges, and destroying the insulation of the fluid.

The pile has been more in use among the continental philosophers than among those of this country: where the trough, invented by Mr. Cruickshanks, of Woolwich, has almost entirely superseded it. As the fluid can be very readily poured out of the cells, and replaced when wanted, it requires considerably less time to put it in action. The following directions for constructing it are given by Mr. Singer.

(125.) The zinc plates are made by casting that metal in an iron or brass mould; they may be about an eighth of an inch thick. The copper need not exceed twelve or fourteen ounces to a square foot, and may be soldered to the zinc at one edge only, the other three being secured by cement in the trough. The trough must

(126.) The objections to which the Wedgwood ware troughs are liable, are that, besides being expensive, they occupy a great deal of room, and are easily broken.

(127.) A more commodious form for the Voltaic battery is that in which troughs, with a number of partitions, made entirely of Wedgwood ware, are intended to contain the fluid, into which the plates are let down when the instrument is employed. Having already described the construction of this kind of battery, we shall only observe that the most convenient sizes for the plates are from two to six inches square. When a high power is required, a great number of these batteries may be combined together by connecting them in proper order, endwise, with slips of copper: taking care to connect the zinc end of one battery with the copper end of the next, so that the plates shall all tend in one direction.

(128.) The objections to which the Wedgwood ware troughs are liable, are that, besides being expensive, they occupy a great deal of room, and are easily broken. Part III.

(129.) The power of the instrument, as we have already noticed, is greatly increased by the addition of copper to each side of the zinc. Mr. John Hart, of Glasgow, availed himself of this circumstance, in constructing a battery in which the inconvenience above stated is entirely avoided. It occurred to him, that by adding sides and bottoms to the double copper plates, they would themselves form cells for containing the acidulous liquid, and the use of troughs be thus altogether dispensed with. The cells are formed by cutting the copper in the form represented by fig. 14; they are then folded up, as seen in fig. 15, and the seams grooved. A drop of tin is run into each lower corner to render the cells perfectly tight, and at the same time to increase the positive state of the copper. Fig. 16 represents the zinc plate cast in the usual manner, and having a piece of screwed brass wire cast into the top of it in order to suspend it by. Fig. 17 is a section of the battery, showing how the copper tail of the first cell is connected with the zinc plate of the second, and so on. This connection is rendered perfect by joining them with a drop of solder. The zinc plates are kept firm in their place by three small pieces of wood. The whole are then fixed (by means of screw-nuts fitted on to the brass wires) to a bar of baked wood, previously well varnished. When the battery is to be used, it is to be lifted off the frame, and dipped into a wooden trough lined with lead, into which the acid has been poured, or it may be placed into the leaden trough, and the liquid poured into it, till the cells are full. It is then to be placed on the frame, and the rest charged in succession. When the battery is small, two may be suspended on one frame. When used for shocks, they may be arranged with the positive and negative poles together, and joined with wire to complete the circuit; but when employed for deflagration, the batteries ought to be placed alongside of each other, with all the positive poles at one end, and the negative at the other, and the poles of the same name joined: this arrangement will increase the surface while the number is the same.

(130.) A battery of this construction made by Mr. Condle, with ten triads, when compared with one upon the plan of Dr. Wollaston, made by Mr. Newman, with the same number of triads, but of double the surface, was found to decompose the same quantity of water in less time than the latter, thus indicating a very considerable superiority of power: a result which can be attributed to nothing but its superior means of insulation.*

(131.) In making experiments in which numerous repetitions of contact between wires are required, Mr. Faraday recommends, if these wires be of copper, to rub the ends over with a little nitrate of mercury; an amalgam is thus formed on the surface of the
Galvanism. copper, which does not oxidate or become dirty, as copper itself does, but remains bright, and fit for Voltaic contact for a long time.*

3. Results of various analyses of the Voltaic pile.

(132.) Our attention has hitherto been directed to the effects resulting from the conjoint operation of the Galvanic apparatus, of which all the adjoining parts, constituting the compound circles, are in extensive contact. But in order to obtain correct views of the theory of Galvanic action, it is necessary to ascertain the precise relation which each part of the apparatus bears to the effects produced; or the function that it performs in the process which results from the combination employed. The investigations of M. de Luc were directed to this important inquiry. He began by considering the Voltaic pile, consisting of its three constituent parts of zinc, copper,† and moistened cloth, following each other in successive alternations, as divisible into ternary groups, under three different aspects. First, zinc, wet cloth, and copper; secondly, copper, zinc, and wet cloth; and thirdly, wet cloth, copper, and zinc. In order to discover which of these ternary associations constituted the efficient part of the apparatus, he united them respectively into piles, in each of which the different groups were separated from each other by some conductor, which could not be supposed materially to influence the effects. For this purpose M. de Luc employed small tripods, formed of brass wire so bent as to touch the plates, between which the tripod was placed, only at the three points of support. Thus was the pile dissected, as he terms it, by three different modes, so as to compose three different instruments. To each extremity of these piles a delicate electrometer was attached; and the opposite poles were also connected by the interrupted wire passing through water, so that both the Electrical and chemical effects could be measured at the same time: care was also taken that each pile should, in other respects, be insulated. The following are the principal results of the experiments conducted with this apparatus.

First dissection.

(133.) He first examined the phenomena presented by the first dissection of the pile, in which the groups were arranged with the fluid between the two metals, while the surfaces of the metals, which in the ordinary pile are in contact, were separated by the brass tripods. He found that the pile, when dissected in this way, acts in the same manner, both as to the Electrical and chemical effects, as if all its parts were continuous, except that its power is rather diminished by the separation of the metals.

Second dissection.

(134.) When dissected according to the second mode, in which the two metals were placed together; and the wet cloth was in contact with the zinc, but separated from the next plate of copper by the brass tripod; the extremities of the pile indicated to the electrometer the same states of positive and negative as in the ordinary pile; but no shock was experienced when the circuit was attempted to be made through the human body. No decomposition of water took place when the wires of the interrupted circuit were placed in water; although from the cessation of all Electrical indications, it was evident that the Electricity was conducted through them.

(135.) In the third dissection of the pile, the ternary groups consisting of the zinc and copper in mutual contact, the moistened cloths being in contact with the copper, and the groups being separated, as before, by the brass tripods, it was found that no effect, either Electrical or chemical, was perceptible.

(136.) In these experiments, the cloths were moistened with water only; but a second set of experiments were next performed, in which a strong solution of muriate of soda was employed instead of water. With the continuous pile, no difference was observed with regard to the effects upon the electrometer by this substitution; but a more powerful sensation was produced when the salt was used. A new shock was experienced every time either of the hands was brought into contact with the apparatus, or removed from it; but no sensation was experienced as long as they remained in contact. When the interrupted circuit was applied between the extremities of the pile, the shock was felt, but in a less degree; and the chemical effects were suspended, while the contact of the body was preserved: evidently showing that the body is about an equally good conductor with water.

The pile with the cloths soaked with brine, was now dissected in the same three ways as before. In the first dissection, that is, with the moistened cloths between the plates, the same Electric effects were exhibited by the electrometer, the same shock was felt; and the same chemical effects were produced, only in rather a less degree than with the continuous pile formed with muriate of soda. The second and third dissections of the pile produced exactly the same effect, as when the same dissections were employed with pure water.*

(137.) The general conclusion which M. de Luc deduced from these comparative experiments is, that the Electrical and the chemical effects originate from different parts of the pile, or from different groups, considered in relation to the parts contiguous to them. The Electrical effects appear to arise simply from the combination of the two metals, each pair being separated by a fluid conductor; while for the chemical effects ternary groups are necessary, consisting of the two metals with a fluid between them. This distinction between these two sets of properties, or modes of action, is supposed to be proved by the different effects of the pile in its three states of dissection. In its first state, which may be regarded as equivalent to the continuous pile, it exhibits both the Electrical and the chemical action: for here the two metals are in contact with each other, either directly, or by the intervention of the brass frames, which is the condition requisite for the Electrical effects; and they are also separated by wet cloth, which is the condition requisite for the chemical effects. In the pile dissected in the second manner, there are the binary groups, that is the metals in contact, for producing the Electrical effects; but as there is no fluid between them, we obtain no chemical effect. In the third dissection, neither of the conditions just stated are preserved, and no effects result: the metals have not the wet

---

† In the original experiments of De Luc, silver is used instead of copper; but we have preferred mentioning the latter metal for the sake of preserving uniformity with preceding statements.

* Nicholson's Journal, xxvi. 113—130.
Oxidation required for the Chemical power.

138. The observation of the differences of effect which took place when a saline solution was employed instead of pure water, led M. de Luc to examine what connection existed between the chemical action of the instrument and the oxidation of the zinc. With this view he formed a pile of pewter and silver; the pewter being chosen for the experiment, because it has an Electrical relation with silver, and is oxidizable by muriatic acid, at the same time that it is not much affected by pure water. In the first instance water was interposed between the plates; the extremities of the piles, as indicated by the electrometer, became Electric, the pewter side negative, and the silver positive; but there was no shock, nor any decomposition of water in the interrupted circuit. A pile was then formed of such a number of zinc and pewter plates, that its Electrical energy might be the same with the pewter pile; but here there was both the shock produced and the decomposition of water. The pile of pewter and silver was then fitted up with muriatic acid; and in this case, when the pewter plates became oxidated, the shock and the decomposition of water were both produced. Hence he concludes, that when the metal is not oxidated, no electrical effect is produced on the water in the interrupted circuit. When the oxidation is produced by means of pure water, there is no shock, although the chemical effects take place; and lastly, when either of these effects are produced, the current of Electricity is retarded in its passage across the water in the interrupted circuit.

139. We have also to notice, in this place, the curious properties of an instrument which resembles the Voltaic pile in the successive and regular alternations of dissimilar metals, and of imperfect conductors, of which it is composed; but which differs from it in the latter consisting of dry, instead of fluid substances. This instrument was invented by De Luc, while he was engaged in the train of investigation of which we have given the results; and in order to distinguish it from the Voltaic pile, he gave to it the name of the Electric column. He was led to its construction, by the trials he made to ascertain how far a liquid was essential to the operation of the pile; and by finding that Electrical effects were still produced when the pile was mounted with pieces of cloth not moistened at all; although these effects were in that case weaker than if the cloths were wetted. He then commenced a series of experiments, in which he substituted layers of different animal and vegetable substances for the wetted cloths, interposed between the metals. He found writing paper to be the most convenient of all the materials which he tried. A column constructed with the two metals arranged in pairs, with disc of paper between each pair, was found to give the same electrical indications as the common Voltaic pile; the end of the column which is bounded by the zinc plate being in the state of positive Electricity; and that bounded by the copper plate, in the negative state. But, however numerous the plates, it produced no chemical effects; nor could any oxidation of the surface of the zinc plates be perceived to have taken place, even when the instrument had been for a long time in action.

140. In order to obtain any considerable effect from this instrument, it is necessary that it should contain a very considerable number of plates. As the thinnest surface of copper is adequate to the purpose answered by that metal, a trial was made with what is called Dutch gilt paper, which consists of thin copper leaf, laid upon paper, together with tinned iron plates. Eight hundred groups thus composed, and regularly arranged, were included in a glass tube; and formed an instrument which affected the electrometer more powerfully than a Voltaic battery of an equal number of plates; but yet, notwithstanding, produced no chemical effects whatsoever. Plates of zinc were afterwards employed instead of the tinned iron, as being both more convenient and efficacious.

141. Mr. Singer, who has had extensive experience in the construction of these columns, in all the variations of which they are susceptible, gives the following directions for making them. Of the materials to be employed he gives the preference to thin pieces of flattened zinc, alternated with writing, or smooth cartridge paper, and silver leaf. The silver leaf is first laid on paper, so as to form silver paper, which is afterwards cut into small round plates by means of a hollow punch. An equal number of plates are to be cut from these flattened pieces of zinc, and from common writing or cartridge paper. The plates are then to be arranged in the order of zinc paper, silvered paper with the silvered side upwards; then zinc, paper, and so on; the silver being in contact with the zinc throughout; and each adjacent pairs of the metals separated by two discs of paper from each other. An extensive arrangement of this kind may be supported by being placed between three slender glass rods, covered with sealing-wax, and secured in a triangle by being cemented at each end into three equidistant holes in a round piece of wood: or the plates may be introduced into a glass tube previously well dried, and having its ends covered with sealing-wax, and capped with brass; one of the brass caps may be cemented on, before the plates are introduced into the tube, and the other afterwards. Each cap should have a screw passing through its centre, and terminating in a hook outside. This screw will serve to press the plates closer together, and to secure a perfect metallic contact with the extremities of the column.

142. By placing two of these upright columns side by side, but with their poles in opposite directions, and connecting their upper ends, the whole apparatus becomes equivalent to a column of double the length, of which the two lower extremities become the efficient poles. If each of these extremities be insulated, and made to terminate in a small bell; and a brass ball be suspended as a pendulum by a silk thread, so as to hang midway between the bells, and at a very...
small distance from each of them, the alternate attractions and repulsions between the ball and each of the balls will cause the former to oscillate continually, and to strike the balls so as to produce a perpetual ringing. This mechanical contrivance was the invention of Mr. Forster, who constructed a series of 1500 groups, and by its continued action kept up the vibrations of the pendulum for a very long time. Mr. Singer had an apparatus of this kind, containing only 1200 groups, which during fourteen months had never ceased to ring, excepting when removed from one room to another. There was, however, an interval of more than six months, in which it was never disturbed, and during which time its motion never ceased. M. de Luc stated that he had a pendulum which had constantly vibrated between two bells for more than two years, and which still continued in motion at the time of his report.* There appears, however, to be some connection between the activity of the instrument and the state of the atmosphere; for although the motion may always continue, it is much more rapid at one time than at another, and is subject to much occasional irregularity. This connection was perceived by De Luc soon after he had constructed the apparatus, and he made a number of accurate observations respecting it, from which he inferred that the cause which affected the movements of the machine, was the variable Electric condition of the atmosphere. He contrived an instrument, on this principle, which he terms an Aerial Electroscope, adapted to the purpose of giving indications of the different states of atmospheric Electricity.†

(143.) The power of the Electric column, as indicated by the oscillations of its pendulum, was observed by De Luc to increase when the sun shines upon it; an observation which was confirmed by Mr. Hausmann.‡ This effect, he conceived, did not arise from the heat of the sun's rays; because he had found that a column which had been put together after all the pieces had been thoroughly dried by a fire, had entirely lost its power, but again became efficacious, after it had been taken to pieces, and its parts had remained all night exposed to the air, from which the paper imbibed moisture, and was once again mounted. Mr. Singer, however, observes that a moderate heat really increases the power of the column; for that his apparatus, which is kept in a room where there is usually no fire, pulsat most slowly in winter; but as soon as a fire is lighted in the room, its movements are much more rapid, and the indications afforded by the electrometer much more positive.

(144.) It appears, from the above experiment of De Luc, that the presence of a certain quantity of moisture is essential to the action of the instrument. If the paper be perfectly dry, it is a non-conductor, and intercepts all Electric action of the column; but this perfect dryness cannot be obtained unless by exposing the paper to a heat nearly sufficient to scorch it. In its driest natural state Mr. Singer always found paper sufficiently a conductor, even when, by exposing the paper discs to the heat of the sun, they have been so dried as to warp considerably. When the paper is sufficiently dry, the action of the column continues without diminution; and on taking such an apparatus to pieces after two years and a half, no trace of oxidation could be perceived on the zinc plates. Mr. Singer is persuaded that the action of a well constructed column will be permanent; and states that he had several which had been made nearly three years, and which continued as active as at first. He observes, however, that care should be taken not to allow the two ends of the column to be connected by a conducting substance for any length of time; for, after such continued communication, if it be applied to an electrometer, it will not have power to affect it for some time. It is therefore necessary, when a column is laid by, to place it upon two sticks of sealing-wax, so as to keep its brass caps at the distance of about half an inch from the table, or other conducting surface, on which it is laid. If a column which appears to have lost its action by lying by, be insulated in this way for a few days, it will usually recover its full power.*

(145.) The most extensive series made by Mr. Singer Column or consisted of 90,000 groups of silver, zinc, and double 20,000 discs of writing paper; and possessed very considerable power. Pith-ball electrometers, with balls of one-fifth of an inch in diameter, and threads of four inches long, diverged to the distance of above two inches, when connected with its opposite extremity. An electrometer connected with the centre was not affected. When either extremity of the column was connected with the ground, the electrometer attached to that extremity closed, and the central electrometer opened with the same Electricity; while that connected with the opposite extremity had its original divergence considerably increased; but the motion of the Electricity was so slow, that some minutes were required to produce the full effect. By connecting one extremity of the series with a fine iron wire, and bringing the end of this near the other extremity, a slight layer of varnish being interposed, a succession of bright sparks was produced, especially when the point of the wire was drawn lightly over the varnished surface. A very thin jar, containing fifty square inches of coated surface, charged by ten minutes contact with the column, had power to fuse one inch of platinum wire one 5000th of an inch in diameter. It conveyed a disagreeable shock, felt distinctly in the elbows and shoulders, and by some individuals across the breast. The charge from this jar could perforate thick drawing-paper, but not a card. It had not the slightest chemical action. Saline compounds, tinged with the most delicate vegetable colours, were exposed under the most favourable circumstances to its action, and in some instances for many days, but no chemical change could be observed.

5. Of the different forms of the Dry Pile of Zamboni.

(146.) An apparatus somewhat analogous to that of De Pile of Luc, was constructed by Hachette and Desormes with Hachette pairs of metallic plates, separated by a simple layer of farinaceous paste, mixed with murinate of soda. To this instrument they gave the very inappropriate name of *Dry Pile,* since its action is still more evidently owing to the moisture contained in the intervening body, than even that of the Electric column of De Luc. In proportion as the moisture of the paste is evaporated, the action of the instrument diminishes; while

GALVANISM.
Galvanism.

On the other hand, this action is resumed when the layer of paste has recovered its moisture, by attracting it from the atmosphere. Like the Electric column, it charges the condenser by a simple contact; and it preserves this property for whole months and years; but it does not excite shock, nor taste, nor chemical action.

(147.) Professor Zamboni also of Verona, constructed a species of pile, of which the Electrical effects were said to be very durable. It was composed of discs of paper, gilt or silvered on one of their sides, and covered on the other with a layer of pulverized black oxide of manganese, mixed with honey. A similar pile has also been constructed with the omission of the honey.* This instrument exhibits signs of the Electrical influence in the same manner as the pile of paste; but not any chemical action, nor taste, nor shock. The Electrical attractions and repulsions which it produces are very considerable in their degree; for if two of these piles be placed at a distance of four or five inches from each other, and a metallic needle be properly suspended between them, it will be alternately attracted by the two piles, so as to move between them like a pendulum. When Zamboni's pile is confined for a short time in a limited portion of air, the oxygen of the air is absorbed by it, and after this has happened the action of the pile ceases. When the oscillations of the pendulum have stopped, on admitting a fresh supply of atmospheric air, without moving the apparatus, the pendulum was instantly attracted to the positive pole, and the oscillations renewed in the same manner at first. These oscillations were not found to be affected by atmospheric changes, as those of the Electric column.†

(148.) In a Memoir relative to the dry Voltaic pile, Zamboni states that its energy ceases to diminish after two years; such, at least, he finds to be the case during an experience of twelve years. The diminution in the two first years varies according to the manner in which the pile is constructed. The pile is more energetic in summer than in winter, both with regard to the intensity produced, and the promptitude with which it is manifested. The tinned paper, called silvered paper, with black oxide of manganese, develops an Electric force very superior to that obtained from paper covered with a thin leaf of copper, as in what is called Dutch gold paper. By using a dry pile of one thousand pairs, the plates being about two inches in diameter, Zamboni obtained by the condenser sparks of an inch in length; so that with such a pile, the Electric battery might be retained constantly charged to a state of tension, which might be heightened at pleasure, by increasing the number of plates. He is of opinion that a pile of 50,000 pairs of plates, of the usual diameter, of leaves of tinned paper, would be a constant source of Electricity, of which the tension would equal that of a strong common Electrical machine.*

6. Of the Secondary Piles of Ritter.

While attempts were making to construct Voltaic instruments composed entirely of dry substances, Ritter, of Munich, invented a construction, which, indeed, had not the power of developing Electricity by its own action, but was capable of receiving a charge from the Voltaic pile, so as thereby to acquire for a time all the properties of the pile. These have been denominated the Secondary Piles of Ritter. They consist simply of a column formed of discs of copper, and moistened card, placed alternately. When a pile of this description is once charged, it loses its Electricity very slowly, when there is no direct communication between its two poles. But if this communication be made by a good conductor, a discharge will immediately take place of the Electricity accumulated in the exterior plates, which, as in the Leyden jar, will operate by an instantaneous shock. To this effect a new state of equilibrium will succeed, and the discharges may be repeated a considerablenumber of times, but of course with continued diminution of power, until they at length cease to be sensible.

(150.) This apparatus produces, with diminished intensity, the decomposition of water, and the other physical, chemical, and physiological effects obtained from the ordinary pile.†

PART IV.

THEORY OF GALVANISM.

(151.) Having given an account of the principal phenomena which relate to this science, as they present themselves to observation, without any reference to the theoretical views of the experimentalists who discovered them, or to the hypotheses which they may tend either to support or to confute: we have now to consider what are the general laws to which they are reducible, and what explanation these laws will enable us to give of the various circumstances attending these phenomena.

(152.) The proofs of the identity of the agencies producing Galvanic and Electrical phenomena, may easily be collected from the facts we have already detailed. All the effects which the Electric battery is capable of producing, may, as we have seen, be also produced by the Voltaic battery. The shock and convulsive muscular actions which accompany its discharge through the human body; the vivid spark and loud report which mark the transit of Electricity through the air; the ignition and deflagration of combustible bodies; the inflammation of gunpowder, phosphorus, and mixtures of hydrogen and oxygen gases, are effects common to both these instruments. All those bodies which are conductors of Electricity, are also conductors of Galvanism; as the metals, charcoal, and carbons which contain oxygen as one of their elements. The Galvanic, as well as the Electric shock, is propagated through a number of persons without any perceptible interval of time. We have already noticed some of these principal features of difference, while describing the several effects of Galvanism; and have pointed out many particulars, in which they even present a striking contrast with the ordinary operations of Electricity. We are now, therefore, prepared for pursuing out generalization of facts to a further extent; and for entering into an inquiry into the nature of these different modifications of effect, and the sources from which they proceed.

1. Modifications of Galvanic Power.

(154.) There are many physical powers, in regard to which it is necessary, for the proper estimation of their effects, to distinguish two different modes of efficiency: the one of absolute quantity; the other of intensity. The first has reference to the totality of effect which the power in question is capable of producing, from first to last, when the whole of that power is exerted, and actually expended in the production of its proper effect. The second of these terms is expressive of the degree of effect produced with relation to circumstances which limit the operation of the power in certain ways, so as to allow only of its partial exertion. Heat, or caloric, is a power, the operations of which cannot be understood or appreciated unless this distinction between its quantity and its intensity be kept in view. The quantity of absolute heat which a given body contains would be measured by the quantity that could be abstracted from it by surrounding bodies, which were themselves absolutely deprived of heat; or which it would lose by radiation, under circumstances in which it could receive no heat in return. The intensity of the heat residing in a body, is the tendency it has to quit that body, and either pass into those other bodies which are in contact with the first, or diffuse itself in space by radiation. This quality of intensity in heat is expressed by the term temperature; which, when applied to a heated body, may be defined the actual disposition of that body to part with its heat. It is well known that in bodies of different kinds, the temperatures may be in very different ratios to the absolute quantities of heat. Two bodies, however different may be their absolute quantities of heat, are said to be of the

* Philosophical Transactions for 1809, p. 36.
Galvanism.

same temperature, or, in other words, their heat to be
of the same intensity, when the dispositions in each
to impart heat to the other are precisely equal; that
is, in which the tendencies of the heat to escape from
each are the same, and the radiations exactly balance
one another.

Temperature or intensity of heat, depends
upon the nature of the substances in which it
resides, and its attraction for that substance, as well as
upon the absolute quantity of heat; and is, therefore,
subjected to a very different law. The ratio between
the absolute quantity of heat which a body contains, and
its temperature, is expressed by the term capacity for heat.

(155.) A distinction precisely similar must be made
with regard to the operations of Electricity. The
prime conductor of a common Electrical machine,
when communicating with the ground, is in a neutral
state, and exhibits no signs of Electricity. If it be
insulated, and the machine set to work, a certain
quantity of that power will be communicated to it;
which power will affect bodies in the vicinity, and
will at the same time possess a tendency to fly off
from the conductor. It is this tendency to produce
certain effects on other bodies, and to quit the body
which contains it, that is termed intensity; and
although it be true, that when all the circumstances
relative to the conductor and the surrounding bodies
are the same, the intensity will increase in a certain
ratio with the absolute quantity of Electricity that
has been given to the conductor by the machine, yet
if those circumstances vary, the same ratio is not
preserved. If, for example, the form of the conductor
be altered, by drawing out one part into a point, the
intensity of the Electricity at that part will be
increased in a high degree, while the absolute
quantity in the conductor remains the same as before.
On the contrary, if, while the general form of the
conductor remains the same, its surface be increased,
the same quantity of Electricity will be diffused over
a more extended space, and will exist in a state of
diminished intensity. The term intensity with respect
to Electricity, corresponds, therefore, to temperature
as regards heat; and expresses in both cases the
tendency of the agent to quit the body which
contains it. We have a striking illustration of the
difference between quantity and intensity in the Leyden
jar; the coatings of which are capable of receiving,
and of retaining a very large quantity of Electricity,
in consequence of the law of induction. Hence,
although the quantity be great, the intensity is very
small; and the instrument may in this sense be con-
sidered as having a great capacity for Electricity.

(156.) Besides quantity and intensity, there is also a
third regulating condition to be taken into account in
estimating the effective agency both of heat and of
Electricity; namely, the conducting power. The time
which a given body will take to have its temperature
changed from one degree to another, when subjected
to the operation of a heating or cooling cause, will
depend not merely on its capacity for heat, but also
on the facility with which heat is transmitted from
particle to particle. The quickness of dissipation,
or of absorption, will be much promoted by the ready
passage of the heat to every part of the body which
undergoes a change of temperature; or, in other
words, it will be regulated by the degree of conduct-
ing power possessed by that substance. A body
charged with Electricity will, in like manner, act with
greater quickness or slowness in producing Electrical
effects, in proportion to the facility with which the
Electricity can be transferred along its parts; a facility
which is the result of its conducting power, and which
may be expressed by the general term of velocity.

For the production of different effects by Galvanic combinations, different modifications of
the Electric power with respect to quantity, intensity,
and velocity are required. Thus, the increase of
temperature, the ignition and deflagration of metals, and
all Electro-Magnetic effects, are in proportion to the
quantity of transmitted Electricity: the affection of the
condenser and of the electrometer, and the charge
communicated to the Leyden jar: the deflection of
the charge from the conductor to the other are precisely
equal; that which a given body will take to have itstemperature,
is expressed by the term capacity for heat.

The effects in the calorimotor, affords no chemical effects in the
interrupted circuit. On the contrary, it is the imper-
fection in the conducting power, that is, in the
velocity of the current, that is the source of the
incapacity of the Electric column of De Luc, or the
other forms of the dry piles, such as those of Zamboni,
for producing any sensible chemical changes in
fluids which are interposed in the circuit.

2. Sources of Galvanic Power.

(158.) The preceding observations apply only to the
evolution of power in the case of
heat. The quantity and intensity of power in
Electricity, on the other hand, depend solely on its
intensity: the shock and other physiological effects
are the results principally of intensity, but partly also
of quantity: the power of effecting chemical decom-
positions requires, in addition to quantity and intensity,
a certain degree of velocity also, for its production. It
is in want of the production of a sufficient quantity
of Electricity in a given time, that the common Elec-
trical machine fails, under ordinary circumstances, in
producing chemical decompositions. When this is
obviated, as in Dr. Wollaston's apparatus, we find it
rendered effectual in producing chemical action. It is
from deficient intensity, on the other hand, that a
single pair of plates, even when of considerable size, as
in the calorimotor, affords no chemical effects in the
interrupted circuit. On the contrary, it is the imper-
fection in the conducting power, that is, in the
velocity of the current, that is the source of the
incapacity of the Electric column of De Luc, or the
other forms of the dry piles, such as those of Zamboni,
for producing any sensible chemical changes in
fluids which are interposed in the circuit.

Part IV.
Galvanism. From the point whence it is evolved it tends to diffuse itself equally in all directions. The converse of this is often observed in processes attended with the absorption of heat, as happens with frigorific mixtures, which we find attracting heat from the surrounding bodies on every side indiscriminately. While in the former examples the heat appeared to be generated, it appears in this to be destroyed, at least for the time.

Electrical phenomena exhibit merely a transfer of power.

(159.) Nothing of this kind has been ever observed to take place with regard to Electricity: no instance occurs of its absolute production or absorption; no evidence of the actual increase or diminution of its quantity in any system of bodies. The phenomena indicate, in every case, merely a transfer of the agent from one body to another. If one body acquires positive Electricity, it is always at the expense of the Electricity of some adjoining body, which becomes to the same extent negative. The Electricity withdrawn from any one body is never lost, or rendered latent, but is invariably transferred to some other body, where its positive action is excited. The excess is always accompanied by a corresponding and equal deficiency; when the equilibrium is restored, and the balance struck, an exact compensation is found to have taken place; nothing has either been lost or gained, and the system of bodies resumes its natural or perfectly neutral state.

(160.) In the enunciation of this remarkable law, we have used, for the sake of greater simplicity, a language conformable to the Franklinian hypothesis of a unity of Electric power; but the facts remain essentially the same when interpreted by the more fashionable hypothesis of the existence of two species of Electric agencies, the vitreous and the resinous. For if we regard the neutral state, in which no Electric power is manifested, as consisting of the combination of the twoElectricities, which are active only when separate: then the production of Electrical power can arise only from the separation or decomposition of the combined powers; and it will follow as a necessary consequence, that we never can obtain the one without the other. If the cause, whatever it be, which disturbs the Electric equilibrium, direct the vitreous Electricity to one side, the resinous Electricity will invariably be found on the other. Thus the friction of the two surfaces, which, in the common Electrical machine, transfers the vitreous Electricity to the conductor, determines the transfer of an equal quantity of resinous Electricity to the cushion, or, by means of a conducting chain, to the ground. The same thing happens in the contact of dissimilar metals, or the action of a chemical menstruum on the substance it dissolves. If vitreous Electricity be accumulated in the one body, resinous Electricity will be received by the other; and if by any means these two quantities of opposite Electricity could be reunited, they would exactly balance one another.

(161.) The distinction we have been endeavouring to establish between heat and Electricity, with respect to the circumstances of their evolution, has frequently been overlooked by those who have attempted to frame theories for the explanation of the phenomena of Galvanism, and who have inadvertently applied to the latter those laws and conditions which obtain only in the former. From the consideration of the effects resulting from a change in the capacity of bodies for heat, it is natural, indeed, to conceive that some corresponding effects with regard to the evolution of Electricity may, in like manner, be the consequence of a change in the capacity of bodies for Electricity, as we have already shown, the effects themselves present no real analogy, and cannot therefore be explained on the same principle. Heat may be transferred, or may be abstracted from one body, and accumulated in another, and it may also be evolved, or absorbed; that is, converted from latent to sensible, or from sensible to latent: but Electricity admits of transfer only; it can neither be generated nor destroyed: no change of capacity in any one body, or system of bodies, has ever given rise to its appearance or disappearance under any existing circumstances.

(162.) We may satisfy ourselves that a change which might take place in the total capacity of a body for Electricity, is in no case the source of the power which produces Electrical phenomena, by tracing the consequences which would result from such a supposition. Let us suppose that the chemical action of an acid upon a metal were accompanied by a diminution of the capacity of the compound produced for positive Electricity. Let us take, for example, a metallic cup, in a neutral state with regard to Electricity; and let it be perfectly insulated by being suspended by silk threads. While in this situation, let it be filled with dilute acid, also in a neutral state of Electricity. The hypothesis we are examining is, that after a chemical action has taken place between the acid and the metal, the capacity of the compound for positive Electricity is diminished: the consequence must be that positive Electricity will be developed, or be rendered active. The whole mass of cup and acid must, therefore, exhibit signs of positive Electricity; that is, it will repel other positively electrified bodies, and so forth. But in no case has such an effect ever been observed to take place. The hypothesis which implies a consequence so contrary to fact, must therefore itself be erroneous; and we must seek in the phenomena themselves, some other principle of generalization by which they may be explained.

(163.) Although the two bodies in the above experiment do not exhibit any signs of Electricity, when examined in conjunction, they afford, when examined after separation, very decisive indications of being in different Electrical states; the acid will be found to have acquired a positive, and the metal a negative Electricity.*

(164.) Similar phenomena occur in a still more remarkable degree when two heterogeneous metals, such as zinc and copper, are brought into contact. The earliest experiments, in which the production of Electricity was found to be the result of the contact of different metals, were made by Bennett; and were published in his New Experiments on Electricity, in 1789.† Other experiments were made by Cavallo, on the Electricity produced by the contact, or collision of a piece of metal, let fall out of the hand upon an insulated metallic plate; and were published in his Electricity, in 1795.‡ But the more complete investigation of this subject was made by Volta, and detailed in various scientific Journals in the year 1801.§

* Becquerel, Annales de Chimie, xcv. and xxvi.
† P. 86—102.
‡ Vol. iii.
§ Nicholson's Journal, 4to, v. 78, 341; also vo. i. of the 8vo series, p. 135; and Philosophical Transactions for 1801.
Galvanism. The series of experiments by which these important results are established, was repeated by Volta, and verified in presence of a Commission of the Members of the French Institute. The following is the outline of the principal experiments, for a more detailed account of which, the reader is referred to the report of the Commissioners drawn up by Biot. *

(165.) The apparatus employed by Volta for these experiments, consisted of two discs, the one of zinc, the other of copper, rather more than two inches in diameter, ground perfectly plane, not varnished, and having in their centres insulating handles perpendicular to their surfaces, by means of which the plates could be brought into contact, without being actually touched with the hand. With this precaution the discs were made to approach till they touched one another; they were then separated, by keeping them parallel while they were drawn back. The Electricity they possessed after this separation was then examined by means of the condenser; and that the effects might be rendered more distinct, the Electricity produced by a number of successive contacts, (taking care to restore the discs to the state of Electrical intelect before each contact,) was accumulated in the same condenser. It was invariably found that the copper disc charged the condenser negatively and the zinc with positive Electricity. Thus these two metals, insulated, and in their natural state, are brought by their simple contact into different Electrical states; the zinc acquiring an excess of positive Electricity, and the copper the complementary quantity of negative Electricity.

(166.) This experiment may be varied in the following manner: Instead of making one of the plates of the condenser communicate, as is usual, with the ground, leave them both insulated upon the electrometer; but every time that the discs are separated after contact, touch with each of them, and always with the same, each of the plates of the condenser. After several contacts of this kind, separate the plates, and each of them will be found charged with that species of Electricity belonging to the plate with which it was touched. All these experiments require great care and attention to ensure correct results. The electrometer and the insulated disc of the condenser should be very perfectly insulated, and the manipulations very carefully conducted. †

(167.) If it be asked, What is the cause of these phenomena? we fear it must be confessed that no satisfactory solution of the question has as yet been given. They do not accord with any of the previously known laws of Electrical equilibrium, and appear to be totally at variance with every preconceived notion we might have entertained of the results of any disturbance of that equilibrium. We must, therefore, for the present content ourselves with admitting that some unknown cause exists, which upon the contact of zinc and copper, determines the transfer of the positive and negative Electricity respectively to the two surfaces which are brought in apposition, and which continues to maintain this relative difference of Electrical states as long as the contact is continued, and as often as it is renewed.

(168.) The two Electricity must be retained on the surfaces of the two metals which are in contact in a manner in some respects analogous to the Electrical condition of the two coatings of a Leyden jar. Each respectively is prevented from exhibiting Electrical effects by the inducing influence of the Electricity contained in the other. But if a communication be made between them, the equilibrium is immediately restored. But in the case of the zinc and copper no reason has been assigned for the difficulty which opposes the direct transit of the Electricity through the surfaces of contact.

(169.) Another question of great importance next presents itself. Are the positive and negative Electricity, collected at the two contiguous surfaces, so concentrated in those surfaces as not to produce any sensible Electrical effects at a distance from the surface? Or does the greater vicinity of the one or the other determine some degree of Electrical polarity in the joined metals? If such were found to be the case, the intensity of the sensible Electricity would, it is evident, be extremely low, compared with the total quantity retained; for the same reason, that the coatings of the Leyden jar exhibit but a feeble degree of Electrical intensity after each contact, has endeavoured to establish the fact that some degree of Electricity is perceptible in the different metals, even when they continue conjoined. For this purpose he formed a thin metallic rod by joining two pieces, the one of zinc, the other of copper, and soldering them end to end; then taking between the fingers the extremity which was composed of zinc, he touched with the copper extremity the upper plate of a condenser, which was also of copper, while the under plate of the condenser communicated with the ground. After the contact, the plate which had been touched, was found to be electrified negatively. In order that the Electricity thus produced by a single contact may be very apparent, the condenser must be much larger than that of the electrometer, and its condensing power considerable.

(170.) This experiment was repeated in a reverse order. That extremity of the rod, which was of copper, was now taken between the fingers, and the upper plate of the condenser, which, as before, was of copper, was touched with the zinc extremity of the rod. On removing it, and examining the plate of the condenser, it was found not to have acquired any Electricity whatsoever. If the rod had consisted of zinc alone, it would have acquired positive Electricity from the copper plate of the condenser by its contact with it, and the condenser would have been rendered negative. But the addition of the piece of copper to the remote end of the zinc rod, was sufficient to prevent this effect from taking place, by having already communicated a positive charge to the zinc. These experiments, therefore, appeared to show that the force which determines a transfer of positive Electricity from the copper to the zinc on one side, may be balanced by a similar force acting on the opposite side of the zinc. In the first experiment, in which the two pieces of copper were on the same side of the zinc, this force was allowed to exert itself, and the Electricity which it disengaged was spread over the plate of the condenser. But in the second experiment, in which the zinc was situated nearer to the hand, the force was exercised equally on the two sides of the zinc, and therefore did not develop any Electricity.*

Galvanism.

(171.) To the force which thus effects a transfer of a certain quantity of Electricity from one body to another which is in contact with it, Volta has given the name of Electromotive force. He ascribes to this force the property of producing a continual transit of Electricity in the same constant direction, (that is to say, of positive Electricity in one direction, and of negative Electricity in the other) so that Electri-

city can find an exit from the body which receives it, and can be supplied on the other hand to the body which imports it. As long as these conditions are fulfilled, he conceives that a constant and rapid current of Electricity will be maintained. He regards this law as the fundamental principle of Galvanism; of which all its phenomena are direct consequences. The following is the outline of his theory, as explained and elucidated by Biot.

Its different degrees.

(172.) All the metals, and a great number of nonmetallic substances, act on their natural Electricity in the manner which we have seen that zinc and copper do, when they are brought into mutual contact; and it is considered extremely probable that this property extends in different degrees to every body in nature. Among all the combinations that may take place, there will be some wherein the development of Electricity will be more powerful, and others wherein it will be feeble and even insensible. In the first class we must place pure water, saline solutions, and liquid acids, brought into contact, either with each otheror with metallic substances, if they are considered as extremely probable, that this property will be admitted to exist, and if it can be accounted for by the repetition of these circles in the Voltaic pile, compound Galvanic batteries, is a consequence which must naturally flow from the theory we are considering. The force which directs the Electricity from the copper to the zinc, and transfers it by means of the interposed liquid to the next surface of copper, will receive an addition to its intensity by the second plate of zinc, which is in contact with the copper on its opposite side, and the Electricity will be transferred to the subsequent pair of plates by means of the next intervening stratum of fluid with increased energy; so that when the circuit is completed, the whole amount of the force which determines the velocity of its circulation, and the quantity which circulates, will be the sum of the separate Electromotive forces, arising from the contact of each independent pair of the dissimilar metals.

(174.) But it is otherwise with regard to liquids. Their Electromotive powers, when in contact with each other, or with metallic substances, are, if they exist at all, so feeble as to be scarcely sensible. For the purpose of comparison with the phenomena attending the contact of metals, the following experi-
ments were made. A glass tube open at one end, was closed at the other by a stopper of copper, having a thin plate of the same metal stretching from it into the interior of the tube for some extent. The tube was then filled with the liquid intended to be examined, such as water, or saline or acid solutions; and thus composed an arrangement similar to the rod in the former experiments, formed by joining two pieces of zinc and copper; and applicable in the same way to the condensing electrometer. But when the trials were made in a similar manner, by touching with the finger the liquid in the tube, and applying the copper extremity of the tube to the plate of the condenser, no signs of Electricity could be obtained. It is thence inferred, that the Electromotive force, exerted by the immediate contact of the metals and the liquids, is absolutely imperceptible.*

This absence of Electromotive power enables liquids to transmit the reciprocal action between the copper and the zinc, without giving rise to any counteracting force. Thus, if, while the zinc and copper are united by a fluid, capable of conducting the Electricity which is impelled by that force, be interposed between these two metals at any other part, the positive Electricity which had been determined to the zinc, will now be conveyed away, and transferred back again to the copper. The same Electromotive force still continuing to operate will again send it onwards to the zinc, and the fluid will again restore it to the copper, and so on in a perpetual circle. Such is the explanation of the phenomena of the simple Galvanic circle, on the hypothesis of Volta.

(175.) The accumulation of Electromotive power by the repetition of these circles in the Voltaic pile, and other forms of compound Galvanic batteries, is a consequence which must naturally flow from the theory we are considering. The force which directs the Electricity from the copper to the zinc, and transfers it by means of the interposed liquid to the next surface of copper, will receive an addition to its intensity by the second plate of zinc, which is in contact with the copper on its opposite side, and the Electricity will be transferred to the subsequent pair of plates by means of the next intervening stratum of fluid with increased energy; so that when the circuit is completed, the whole amount of the force which determines the velocity of its circulation, and the quantity which circulates, will be the sum of the separate Electromotive forces, arising from the contact of each independent pair of the dissimilar metals.

(176.) If this rapid and perpetual current of Electricity is admitted to exist, and if it can be accounted for by the above theory, then all the other phenomena of Galvanism will receive a ready explanation. The electrical effects which we have described as resulting from the action of the Voltaic battery, and which are appreciable by the electrometer, are evidently the result of the increased intensity of the poles, which the accumulation of force in the same direction gives to the Electricity, when its circulation is prevented by the insulation of the apparatus. When the Voltaic pile is completely insulated, its two poles indicate opposite states of Electricity, and the middle part is in a neutral state. If one pole be made to commu-

* Biot, Traité de Physique, p. 475.
Galvanism. The intensity of Electricity will be regulated almost entirely by the conducting power of the liquid part of the circle. The effective quantity of Electricity will be regulated almost entirely by the conducting power of the liquid, and it is in consequence of this latter view of the subject, an accurate comparison was instituted by Biot, with the aid of the condensing Electrometer, of the charges obtained from piles of the same number of plates, constructed with moistened conductors of different kinds; and it was found that water, weak acids, the greater number of saline solutions, the substances in general whose conductibility is powerful, give, as nearly as can be judged, the same quantities of free Electricity, that is, Electricity of the same intensity, and give it also by a contact to our senses instantaneous. We may even, with most of these conductors, increase or diminish extremely the extent of their surfaces, without producing any sensible variation in the charge of the condenser, owing to the facility, almost infinite, which their surfaces present to the transmission of the Electrical currents. But this tends to prove that, in every case, they only act the part of conductors, and that the contact of the elements of the pile, and not their chemical action, is the determining cause of the production of the Electricity.

(180.) But it is further maintained, that even the absolute quantity of Electricity evolved, is not in proportion to the chemical action; for sulphuric acid acts as powerfully on zinc as the nitric or muriatic acids, but is less active in exciting the chemical powers of the battery, which, we have seen, depend on the quantity of Electricity. In like manner, the alkalies, which exert but a very inconsiderable chemical action on the metals, excite its powers in a greater degree than many saline fluids, of which the chemical energies are much greater.

(181.) Against this theory, which is generally denominated the Electric theory of Galvanism, in contrast to the Chemical theory, many formidable objections may be urged. The truth of the fundamental proposition on which the whole of it rests; namely, that while two dissimilar metals remain in contact, they must both be retained at the surfaces of contact, by the law of induction, and can neither be ejected, nor separated, in accordance with the pole of the battery, which, we have seen, depend on the quantity of Electricity. In like manner, the alkalies, which exert but a very inconsiderable chemical action on the metals, excite its powers in a greater degree than many saline fluids, of which the chemical energies are much greater.

(182.) Secondly, the proposition that positive Electricity has a tendency to quit a plate of zinc, and negative Electricity to quit a plate of copper, while these two metals are kept in contact, cannot by any means be inferred from what takes place after the separation of these metals. Whatever displacement of the two Electricity may attend the approximation of contact of the metals; they must both be retained at the surfaces of contact, by the law of induction, and can have no tendency to quit those surfaces until the

---

‡ Singer, Elements, p. 431.
The quantity of contact. All that the contact of the metals can effect is to produce a new condition of Electric equilibrium; this equilibrium, once established, will continue until a change of circumstances destroys this condition, by giving rise to tendencies to new states, in which Electric intensities are manifested, and may be estimated by the electrometer. But in the Galvanic circle, and in all the forms of Galvanic apparatus, the plates still remain in contact, and therefore the reasonings derived from the phenomena which appear on their being separated, are in no way applicable to them. The experiments that have been advanced with a view to prove that Electricity is evolved, in an active state, while the metals are in contact, (see 169) are of too delicate a nature, and too much exposed to causes of fallacy, to justify our placing upon them that degree of reliance, which experiments intended to serve as the foundation of the whole theory should possess. But even admitting their results to be correctly stated, they are in themselves by no means conclusive of the existence of an Electromotive force of the nature ascribed to the metals.

(183.) Thirdly, since the contact of the two metals is assigned as the sole source of the Electricity of the Galvanic apparatus, it must follow as a necessary consequence, that the quantity of Electricity developed will be proportionate to the extent of the surfaces of contact. The intensity of that Electricity, it may be admitted, will be the same, whatever be the extent of surface; but the absolute quantity must evidently increase with the increase of the number of particles in contact. But the results of experiments with different modes of combination of the metals do not accord with this conclusion. The effects of the Voltaic battery are the same, whether the zinc and copper plates be soldered together throughout their whole extent, or be only united by their edges, or even by a thin slip of metal. A metallic wire is sufficient to form the communication between the metals requisite for carrying on the Electric influence from each pair of plates to the next in the series. In De Luc’s first dissection of the pile, the zinc and copper plates were connected merely by the extremity of the three brass wires which formed the feet of the tripods, (sec. 133;) the surface effecting the contact being inconsiderably less than when the metals were put together without any interposed wires; and yet the effects of the pile were in both cases almost exactly the same.

(184.) The only answer that can be given to this objection, is that so enormous a quantity of Electricity is set in motion by the contact of a very minute surface of the dissimilar metals, as to be sufficient, in all cases, for the production of the observed effects, even when the contact is limited to the extremity of a wire; and that the actual quantity which is circulated depends solely on the conducting powers of the fluids which complete the circuit. This argument would lead us then to the following inference, that in the case of a single pair of plates of great size, as in the Calorimotor, in which the circuit is completed by means of a very slender wire, which we know will, under these circumstances, become intensely ignited, and thus manifest the passage through it of a prodigious quantity of Electricity, the whole of this Electricity is set and maintained in motion, by a force developed at the point where the extremity of the connecting wire touches the metal which is of a different nature from itself. The manifest extravagance of such a supposition throws additional discredit on the theory which requires it.

(185.) Fourthly, it is assumed in the Electric theory of 4. But to Galvanism, that the conducting power of the fluid part of the circles regulates the quantity of circulating Electricity. But experience shows that this circulating Electricity is always exactly in proportion to the energy of the oxidizing process, which is going on at the surface of the most oxidizable metal. It would be impossible, therefore, to reconcile this general fact with the above assumption, unless it were proved that the conducting powers of all the liquids tried, were exactly in the same proportion to their oxidizing power. Such a singular coincidence, it must be admitted, is possible; but it must also be observed, that it is exceedingly improbable, and appears to be contradicted by a multitude of facts. Pure water, which is a conductor of Electricity, although an imperfect one, is of itself incapable of forming an effective Galvanic instrument, when interposed between the metals in the usual orders of arrangement. The presence of atmospheric air, or other gas containing oxygen, or of a saline body is indispensable to the action of the Voltaic pile. Thus if pure water alone be employed, the pile will act as long as it is surrounded by the air of the atmosphere, which finds its way to the surface of the metal through the medium of the water; but the action ceases when the pile is placed in an exhausted receiver, or in any of those gases that are incapable of supporting oxidation. On the readmission of atmospheric air, the action soon recommences; and the power of the instrument is still further increased by an atmosphere of oxygenous gas; or by adding to the water various saline substances, in a proportion too minute to produce any considerable change in its conducting power. The nitric acid, though a worse conductor of Electricity than the sulphuric, is more active in promoting the energy of the apparatus.

(186.) Another coincidence, equally unexplained by the Electric hypothesis, but no less remarkable than the former, is that the power of Galvanic combinations is uniformly proportional to the disposition of one of the metals composing them to be oxidized by the interposed fluid.

(187.) That the chemical action of the fluid, employed upon one of the metals, is an essential element quantity of oxygen consumed. And the energy in producing the continued activity of the pile, is further supported by the rapid absorption of oxygen, which takes place from the air surrounding the apparatus. This may be rendered apparent, by placing a vertical pile upon a support surrounded by water, and covering it with a cylindrical jar of glass, which also dips into the water at its base. In a few minutes, the water will be seen to rise into the interior of the jar, especially if we form a communication between the two poles of the pile by metallic wires, so as to direct the current of Electricity through them; when no communication is formed, the absorption still goes on, but with much greater slowness. In every case, at the end of a certain time, the absorption ceases, and the air remaining in the jar presents no more traces of oxygen. When the pile has thus become surrounded with an atmosphere of azote, its energy ap
subject. Voltaic instrument, in the production of the Electri-we have just seen, will be exactly the reverse of the
degree of Electromotive action when applied to cer-
mercuric contact, as in the case of the heterogeneous
action.

Rºarches (191.) In order to investigate the precise influ-
ence of the metals on the electrical properties of the
solution, Mr. Becquerel has lately instituted an experi-
mental series of interesting and highly important
experiments. His first object was to ascertain what the
Electrical states induced, when an acid or a
alkaline solution, was placed on the copper plate of
the condenser; the solution was then touched with a
plates of zinc, but so as not to come in contact with
the copper; the lower plate of the condenser was
next touched with the finger; and after a lapse of
twenty seconds, the upper plate was removed.
The electrometer attached to the condenser im-
diately indicated that the copper capsule had received
positive Electricity. The experiment was reversed by
using a capsule of zinc filled with either solution;
and the lower plate of the condenser was touched
with a plate of zinc, to destroy the Electromotive
action between the capsule and the plate; and a plate
of copper, held between the fingers, was immersed in
the solution. On raising the upper conducting plate,
the electrometer showed that the zinc capsule had
become negative.

(192) It is proved, then, by these two experiments,
that when zinc and copper are separated by an acid,
or an alkaline solution, and are not otherwise in con-
tact, the copper becomes positive, and the zinc nega-
tive. This result shows that the important law
assigned by Volta to the action of the metals, (sec.
173.) namely, that when a pile is formed entirely of
metals, the Electrical conditions of the two extreme
metals is the same as if they were in direct contact,
is not applicable to the case in which an acid or alka-
line liquid is interposed between the two metals; for,
according to this law, the zinc should be positive,
and the copper negative, which is just the contrary of
the result actually obtained.

(193) Mr. Becquerel also examined what takes
place on the contact of a metal with a saline solution;
and copper, for instance, with a solution of muriate of
soda; and found that, in these circumstances, the
copper became negative, and the solution positive.

(194) If we still consider these several Electrical
changes effected by the action of the fluids on the
respective metals with which they are in contact, as
the results of an Electromotive force; then it will be
obvious that such a force will entirely cooperate with
the supposed Electromotive force arising from the mutual
contact of the metals, in producing a circuit of Elec-
tricity in the very direction in which we observe it
to take place in the Voltaic battery, (sec. 4.)

Law of

(195.) But an obvious distinction will here suggest
itself, between the Electrical changes resulting from
more contact, as in the case of the heterogeneous
metals, and those which accompany the contact of a
metal with a fluid, exerting a chemical action upon it.
If the dry crystals of an acid be brought into contact
with a plate of metal, and then separated, the metal
is always rendered positive, and the acid negative.†
In this case, no chemical combination has taken place.
But if the acid, instead of being in a dry crystalline
form, be in a liquid state, and capable of acting
chemically on the metal, such as oxidizing it, and
dissolving the oxide so formed, the Electrical result, as
we have just seen, will be exactly the reverse of the
former; the acid will have become negative, and the
metal negative. If the liquid in the Voltaic battery,
therefore, assist in propelling the Electricity in the
direction conformable to these latter results, as is
really the case; is not this a proof that it does so in
consequence of its chemical action, and not from any
force derivable, like that of the metals, from mere

Fluids may also exert an Electromotive
action.

(190.) The only possible way of reconciling these
facts with the theory of Electromotion, is to admit
that fluids, as well as solids, are capable of exerting a
degree of Electromotive action when applied to cer-
tain metals, or other solid substances. Let this princi-
ple be once established, and its operation must also
be sensible in the ordinary forms of Galvanic combina-
tions. If it be admitted that some portion of the
effect of the Voltaic pile may be ascribed to such a
power; we may next inquire whether it may not be
sufficient to produce the greater part, nay even the
whole of the effect?

Researches of Becqu-
erel on this
subject.

(191.) In order to investigate the precise influence
of the fluids interposed between the plates of the
Voltaic instrument, in the production of the Electrical
phenomena, Mr. Becquerel has lately instituted a
series of interesting and highly important
experiments. His first object was to ascertain what are the
Electrical states induced, when an acid or alkaline solution
is placed between two dissimilar metals. For this pur-
pose a copper capsule, filled with either an acid or
alkaline solution, was placed on the copper plate of
the condenser; the solution was then touched with a

T. Davy, Elements of Chemical Philosophy, p. 59.

† Davy, Elements of Chemical Philosophy, p. 59.

‡ Annales de Chimie, tom. xxvi
Galvanism. contact, since such a force would have operated in the contrary direction?

(196.) But if any considerable portion of the Electrical effect can be actually traced to the chemical action of the liquid upon the metal, may we not venture further, and inquire whether this chemical action be not competent to produce the whole of the effects? If this can be shown, it will follow that the Electromotive action of the metals on each other is unnecessary for the explanation of the phenomena, and may be altogether discarded as an useless and unwarranted hypothesis. Thus will the chemical theory, as it is called, be established on the ruins of the Electrical.

(197.) Let us, in pursuance of these views, follow up the consequences of the principle we have now unfolded, and compare its results with observation. Let us assume, what, indeed, has been proved by Becquerel to be a fact, that the usual liquids employed in the Voltaic pile and battery, namely, acid, alkaline, and saline solutions, evolve, by their chemical action on the most oxidable of the metals with which they are in contact, a quantity of Electricity, or, (to use what will perhaps be esteemed more correct language,) produce a separation of the two Electricities, determining the negative Electricity in the direction of the metal which is oxidated, and the positive Electricity in the direction of the liquid which oxidates it. This process will continue to take place as long as the chemical action continues; the two Electricities will be unable to unite, so as to neutralize each other, at the surface where they were separated, in consequence of the peculiar circumstances that accompany the change of composition which takes place in the chemical elements on both sides, and in consequence of the continual removal of the resulting compound from the metallic surface, and its diffusion through other parts of the liquid. The positive Electricity, then, which the liquid has acquired, will be transferred to the copper plate of the next pair, and immediately communicated by it to the zinc plate with which it is associated. This second plate of zinc, having thus acquired a larger share of positive Electricity than its natural share, is capable of imparting a larger portion to the liquid, which, in consequence of its chemical action, tends powerfully to abstract it from the zinc, and to impart a corresponding quantity of negative Electricity in return. This increased quantity is again transmitted to the next pair of plates, and is capable of maintaining a still further intensity of action, and so on throughout the whole series. The intensity of the Electricity will be increased by every successive passage through a new oxidating surface, and the power of the battery will be proportionate to the number of alternations; but the absolute quantity of circulating Electricity will depend upon the extent of surface in which the chemical action takes place, and also upon the energy of that action. All the facts, therefore, which are referable to this source of difference, are applicable upon this theory as completely as upon that of Volta.

(198.) The chemical theory of Galvanism thus sets aside all effects resulting from the Electrical relations of the metals, as not being applicable to the circumstances of the experiment, and takes into account only the evolution of Electricity by the chemical action of the liquid upon the zinc: the copper plate being regarded as acting no other part than that of conducting the Electricity so evolved from the fluid to the zinc. The necessity of a substance capable of performing the function of a conductor, is presupposed between the liquid and the zinc, in the Galvanic circle, is the reason why a second metal, not acted upon by the liquid, is required in order to complete the circuit; for if the same metal were placed on the side of the fluid opposite to that in which the Electro-chemical action takes place, the same action would be repeated at that surface, and being exerted in a direction opposite to the former would counteract and neutralize its effects. The results of De Luc's analysis of the Voltaic pile are exactly conformable to the chemical theory; since the effects were found to be proportionate to the chemical action of the liquid upon the zinc; and to the extent of contact between them: while no effect whatever was produced when this contact, and the consequent chemical action, were prevented from taking place, (sec. 137.)

(199.) One material advantage which the chemical theory possesses over that of Volta, is that it relieves us from the difficulty of supposing that a perpetual effect may be produced by a power which is not expended in its production. The chemical action between the elements of the pile gives rise to a change of composition, and to a new distribution of Electric energies. Electrical effects are the consequence of these changes: they appear only when these changes take place; they are in all cases in exact proportion to the amount of the chemical change; and they cease when these changes no longer occur, from the power which produced them being expended.

(200.) That different fluids possess different powers of conducting Electricity, is a fact concerning which no doubt can be entertained. The transmission of the Electricity through the successive portions of fluid in the battery will necessarily be much influenced, both as to quantity and velocity, by these differences in their conducting powers. When this circumstance is taken into account, it will probably enable us to explain many minor anomalies, which present themselves in instituting a comparison between the powers of different batteries. But it is unnecessary to enlarge upon these points, as they will readily suggest themselves on a little consideration in every particular instance.

(201.) From the outline of the two leading theories of Galvanism which we have now given, it will be seen that they each assign different parts of the Galvanic circle as giving origin to the Electric power which is brought into action. The Electric theory considers the points at which the two metals are in contact as the primary source of that power; the chemical theory ascribes it to the metallic surface which is in contact with the oxidating fluid. The former regards the fluid, the latter considers the less oxidizable metal, as merely conducting the Electricity so evolved; in the one case from the zinc to the copper, in the other case from the fluid to the zinc. The efficient ternary association according to the former theory is that of copper, zinc, acid; according to the latter, it is zinc, acid, copper.

(202.) The foundations of the chemical theory were first laid by Fabroni, in a paper published at Florence in 1799, in which he enters into an inquiry whether the phenomena of Galvanism may not originate from.
Galvanism.

the action of chemical affinities, of which Electricity may be one of the concomitant effects. But Dr. Wollaston was the first who decidedly pronounced that the oxidation of the metal in the pile is the primary cause of its Electrical effects. This he thinks may be inferred from the following experiments, which exhibit the Galvanic process reduced to its most simple state.

1. If a piece of zinc and a piece of silver have each one extremity immersed in the same vessel, containing very diluted sulphuric or muriatic acids, the zinc is dissolved and yields hydrogen gas, by the decomposition of the water of the acid; in this case, silver, not being acted upon, has no power of decomposing water; but, whenever the zinc and silver are made to touch, or any metallic communication is made between them, hydrogen gas is also formed at the surface of the silver. Any other metal besides zinc, which by assistance of the acid employed is capable of decomposing water, will succeed equally, if the other wire consist of a metal on which the acid has no effect.

2. If zinc, iron, or copper, are employed with gold, in dilute nitric acid, nitrous gas is formed, in the same manner, and under the same circumstances, as the hydrogen gas in the former experiment.

3. Experiments analogous to the former, and equally simple, may also be made with many metallic solutions. If, for instance, the solution contain copper, it will be precipitated by a piece of iron, and appear on its surface. Upon silver, merely immersed in the same solution, no such effect is produced; but as soon as the two metals are brought into contact, the silver receives a coating of copper. Dr. Wollaston adds, we have no reason to suppose that the contact of the silver imparts any new power; but merely that it serves as a conductor of Electricity, and thereby occasions the formation of hydrogen gas.†

Attempts have often been made to reconcile these two theories, by supposing that the causes assigned both by the one and by the other, are jointly in operation, and concur in producing the observed phenomena. Sir H. Davy conceived that the Electricity evoked by the mutual contact of the metals, might be the first step in the series of Electrical changes; and that the effect, so begun, was continued and increased by the chemical actions taking place between the oxidable metal and the fluid, which tended to restore the equilibrium of Electricity between the adjacent plates of successive pairs. He also thought that the law of induction was in operation among the different strata of the pile, and contributed to increase the intense Electrical state of each, in every successive alternation of the ternary elements. Induction, it is well known, takes place only when the transmission of Electricity is prevented by the interposition of a non-conducting medium; and the liquid portion of the pile, having but imperfect conducting powers, might thus, as Sir H. Davy supposed, give occasion, in Electrodynamics of such low intensity, to a degree of Electrical induction. Thus every copper plate being itself negative, produces by induction an increase of positive Electricity upon the opposite zinc plate; and every zinc plate, an increase of negative Electricity on the opposite copper plate; the intensity increasing with the number, and the quantity with the extent of the series. It has been objected to this explanation of the action of the pile, that the effects of induction are most conspicuous when the interposed substance has the least conducting power; while in the Voltaic pile, on the contrary, the greater the conducting power of the fluid, the more powerful are its effects. Comparative insulation of the parts of the pile, even by liquids, is by no means an essential requisite for the action of the instrument. Some curious experiments on this subject have been made by Mr. Singer, which it would take too much space to detail, but to which we beg leave to refer our readers.† Mr. Children, by applying to his large battery an arrangement which reduced the whole to a single pair of plates of zinc and copper, each presenting a surface of 1344 square feet, found that when they were suspended quite out of contact with any liquid, they produced no sensible effect on a connecting wire of platina, the 5000th of an inch in diameter; although the same wire would have been instantly ignited by a single pair of such plates, one inch square, immersed in a diluted acid. The ratio of the areas of the plates in the two experiments was as 1 to 48384; yet no traces of Electricity by induction were discovered.

(203.) A variety of theoretical views have been other entertained by different philosophers on the subject of theoretical the excitation of Galvanic Electricity, and on the mode in which it is transmitted along the series of alternations composing the battery, and accumulated at its poles. But it would far exceed the limits within which we must confine ourselves, to enter into so extensive a field of speculation, or even to attempt giving such an outline of these theories as could be rendered intelligible in so small a space. It must be admitted, indeed, that notwithstanding the laborious researches of so many experimentalists in this department of science, many important questions with respect to the origin of Galvanic power, still remain unresolved.

(204.) Having discussed the principal theories that relate to the origin of Galvanic power, there still remains another branch of inquiry; namely, into the mode in which the different phenomena, we have described as the effects of that power, are produced.

(205.) The operation of the Electric currents, set in motion by the Voltaic apparatus, in the ignorance of metallic conductors, and in producing various physiological effects by their passage through animal bodies, is in general sufficiently intelligible from its analogy with corresponding effects produced by ordinary Electricity. The same observation applies also to the Electro-Magnetic results which are obtained by Voltaic Electricity. The theories of all these phenomena have no particular relation with Galvanism, but are comprehended in the general theory of Electricity, which we have elsewhere considered.

(206.) We ought, perhaps, to except from this...
GALVANISM

Dr. Roget's experiment, which was made in the year 1807, by the Writer of this Paper, in conjunction with Mr. Sylvester. The ends of two platina wires, communicating with the poles of a powerful battery, were introduced into two separate vessels of water, which were made to communicate by a tube, bent in the form of a syphon, and filled with a solution of muriate of soda. The whole length of the circuit of fluid between the two wires was forty-six inches. Microscopes were applied to the ends of the wires, for the purpose of enabling the two observers to ascertain the precise moment when the gases made their appearance at the respective wires. No sensible interval of time could be perceived between the appearance of the oxygen gas at the positive, and of the hydrogen gas at the negative wire, when the communications with the battery were established.

(206.) The transfer of material and ponderable substances, such as those which constitute the elements of water, with even a moderate velocity, might be expected to produce visible currents in the fluid through which they passed; for their motion, whatever be the moving force which produced it, must be accompanied by a certain momentum, and must displace the particles of the fluid through which they pass, and which oppose their passage. But no indication of any current or displacement of the fluid can be detected. When the fluid contains globules of dust, which by their movements would point out such currents if they existed, all appears tranquil and unchanged, even when subjected to minute inspection in the field of a microscope. Mr. Wilkinson on applying a magnifying power of about 300,000 times with a solar microscope, could not detect any current.* Professor A. de la Rive, of Geneva, made the same observation by employing a microscope of Amici.† It is evident that if, instead of assuming the decomposition to take place in the particles of water in immediate contact with the positive wire, it were supposed to take place in any other part of the line of circuit, the same difficulty would occur in explaining the transfer of one or other, or of both the elements.

(909.) So great has been the difficulty of explaining these phenomena of transfer, that in the opinion of some chemists it has been deemed entirely subversive of the doctrine of the composition of water. Conformably with this view, water was considered as a simple substance, consisting of the ponderable bases both of oxygen and of hydrogen gas, the former being composed of water united to positive Electricity, the latter, of water combined with negative Electricity. This theory was first advanced by Professor Ritter of Jena, and was embraced by several other philosophers; it was again brought forward by Dr. Gibbs, of Bath, in a Paper which was read to the Royal Society, but not published.

(210.) Another solution of the difficulty was at tempted by Monge, on the supposition that when one of the elements of water is liberated by the influence of Electricity, the other combines with the adjoining particles of water, forming water with excess, either of hydrogen or of oxygen; these new compounds are supposed to pass in a continued stream to the opposite wires, where they again part with the superabundant ingredient, which appears in its natural form. This hypothesis was maintained in a detailed memoir by Fourcroy.‡

(211) Dr. Bostock has proposed an hypothesis which is remarkable for its ingenuity, and its accordance with a variety of facts relating to this subject. He supposes that a strong attraction exists between Electricity and hydrogen. The Electricity which passes from the positive wire into the water, and decomposes it, whereby its oxygen is liberated, unites with the hydrogen, and carries it invisibly to the negative wire; the superior attraction of which for Electricity, again occasions the separation of the hydrogen, and its appearance in the gaseous state.§ But this theory would require, as we shall presently see, to be greatly modified in order to reconcile it with more complicated cases of transfer.

(212.) In a Paper which was read to the Manchester Dr. Roget's Philosophical Society in 1807, but not published, Dr. explanation Roget suggested the following mode of explaining the phenomena. "Instead of supposing Electricity to

* Elements of Galvanism, ii. 386.
† Annales de Chimie et de Physique pour 1825.
‡ See Report made to the French National Institute by Cavoir.
§ Nicholson's Journal, iii. 9. See also Thomson's Annals of Philosophy, iii. 85.
have an affinity for hydrogen, let us suppose it repulsive of that element. We may conceive the agency of Electricity to extend throughout the whole of the fluid line connecting the two wires. The hydrogen existing in every particle of the water in this line, will have a tendency to move from the negative towards the positive wire. These particles of hydrogen may be considered abstractedly as forming a row of particles; while those of oxygen compose another row. While the particles in the former row are moving together, by the agency of the Electricity, in a direction towards the negative wire, all those which have not yet reached it, will merely have to pass in succession from one particle of oxygen to the next, among those in the latter row. They will not appear in the form of gas, because the instant each particle has quitted the particle of oxygen with which it was associated, it finds another to combine with; and this process will continue, till it has arrived at the end of the line, when finding no oxygen to unite itself with, it will make its appearance in the form of a bubble of gas. In like manner, the first particle of hydrogen in the series, by its abandoning the first particle of oxygen to replace it, occasions the oxygen to appear at that point in the form of gas. We have thus the two gases formed at each end, not from the same individual particle of water, but from the two which happen at that moment to be in contact with the wires. The production of the two gases will take place at the same instant in both places; each particle having only to move one step, that is, from one particle to the adjoining one, instead of having to traverse the whole extent of the line: and no current will be perceptible in the fluid. The current of hydrogen which sets in one direction, will necessarily be accompanied, by a corresponding current of oxygen in the contrary direction. If this theory be correct, the operation of gravity in favouring the descending current of the heavier element, namely, oxygen, might be rendered sensible; and that this is actually the case, is confirmed by an observation of Mr. Sylvester, who found that when the wire which gives out oxygen is placed below that which gives out hydrogen, the effect is sensibly greater, than when the positions are reversed. A similar view of the subject has been taken by Dr. Henry, and by Grothus.

(213.) That visible motions are sometimes produced in fluid conductors when transmitting the Electric current, has been shown by Sir H. Davy; who noticed very singular convulsive agitations into which mercury is thrown, when placed within the circuit of a powerful Voltiac battery discharged through water. These motions, which frequently are of a violent and capricious kind, have attracted, more particularly the attention of Mr. Herschel, who has made them the subject of an interesting research, of which he has lately given an account in a Paper read to the Royal Society.

(214.) But none of the theories we have been considering are adequate to explain the phenomena of the transfer of the elements of saline bodies, of which we have already given an account, (sec. 56–60.) They more especially fail when applied to the cases in which these elements are made to traverse other fluids, (sec. 61.)

(215.) Some interesting researches on this subject have lately been made by Professor A. de la Rive. By dividing the interior of a vessel into three compartments, by means of partitions of bladder, which prevented the mixture of the liquids contained in each compartment, but did not intercept the passage of the Electric currents, he ascertained from the changes of colour in blue vegetable tests added to a solution of muriate of soda, with which all the compartments were filled, that the decomposition of the salt took place only in those parts which were in immediate contact with the metallic wires. However long the experiment was continued, no alteration took place in the liquid occupying the middle compartment. Hence he infers, that the whole mass of the solution does not, as was supposed, divide itself into two portions, the one positive and the other negative.

(216.) Mr. Porret had already observed, that if a vessel be divided by a membranous partition into two compartments, of which the one was filled with water, and the other contained a very small quantity; and if the positive wire be inserted in the former, and the negative wire in the latter, the water will be impelled from the first compartment into the second, through the partition; and will at length rise to a higher level in the latter than in the former. Mr. de la Rive, repeated these experiments, found that this result is obtained only when distilled, or river water, which has but a small conducting power, is used; but if a sufficiently concentrated saline solution is employed, no effect of impulsion is perceptible. On varying the experiments by employing a greater number of compartments, to which tubes were respectively joined, so as to indicate, by the height at which the fluids stood in them, the changes of volume taking place in each particular portion of the solution, he deduced the conclusion that their decomposition was effected only in those parts that were in immediate contact with the metallic surfaces, which communicated and received the Electricity, that is at the positive and negative poles. This result was also confirmed by placing at the same time several different solutions in the circuit. If, for instance, a solution of muriate of ammonia occupy the two extreme compartments, while the intermediate one is filled with solution of sulphate of zinc, the elements of the former alone will be developed, on the respective poles; on the other hand the elements of the sulphate of zinc, will make their appearance separately, when this order is reversed, by placing this solution in the extreme compartments, and that of muriate of ammonia in the middle one.

(217.) The experiments in which totally different saline solutions are placed at the two ends of the circuit, and in which it is found that the positive acids are accumulated at the positive, and the negative bases at the negative wire, prove that there is an actual transfer of these elements through the whole line of circuit. It appears then, that the two Electric currents which traverse the fluid, decompose the first particles with which they meet,

Galvanism.

and carry along with them, respectively, the particular elements for which they have an affinity, and again deposit these elements on arriving at the metallic surface, which they enter in proceeding on their course towards the pole of the battery to which they are tending.

(215.) Thus, in explaining on this hypothesis the Galvanic decomposition of water, it may be assumed that the Electric current which issues from the positive pole, seizes upon the particle of hydrogen belonging to the contiguous particle of water, and carries it on till it reaches the negative pole, where, meeting with a solid conductor, which is impervious to the hydrogen, the Electricity abandons it on entering into the metal. The current of negative Electricity acts in the same way upon the oxygen, and effects its transfer from the negative to the positive pole. The same processes are effected with regard to the acids and bases of salts; and when one element is carried by the Electric current through a fluid for which it has an affinity, the result will depend on the balance of affinities; if that which it has for Electricity should prevail, it continues its course in conjunction with it; but if its affinity for the element of the liquid happens to predominate, it quits the Electricity and remains behind. We find the latter case occur whenever an insoluble compound is the result of such an affinity, as in the examples given in sec. 63.

(219.) M. de la Rive ascertained by the application of a very delicate galvanometer, that Electric currents were established in the fluid between the two wires; and that they occupied a considerable extent in the fluid, and were most intense in the direct line joining the two poles, and especially in the vicinity of those poles. The extent of diffusion of these currents was uniformly in proportion as the fluid was a more imperfect conductor of Electricity; so that it would appear that each current, on emanating from its respective pole, and meeting with a substance which opposed an obstacle to its free passage, was obliged to deviate from the course for which it has an affinity, to describe a curve in passing to the opposite pole. The experiments of Mr. Herschel above referred to tend to throw great light on this curious subject.

(220.) This diffusion of the currents throughout the whole liquid was rendered still more manifest, by separating the vessel which contained it into two compartments, by a lamina of platina. Although the plate of metal was situated perpendicularly to the line joining the two wires, and was nearly an inch in diameter; and although each of the wires was at a distance of only three inches from the plate, yet there appeared on each of its sides, and over its whole surface, a very considerable disengagement of gas; and the saline solution, which was coloured blue, received a red and green tinge, in every part which was contiguous to the surface of the plate. By interposing a greater number of plates, the decompositions were effected in much greater quantity; for they took place at each of the surfaces through which the Electric currents were thus made to pass. The effect was much diminished, as indeed might be expected, if the different portions of fluid were allowed to communicate round the edges of the metallic partitions; as a considerable part of the Electric currents found their way by this circuitous route, which they seemed to take in preference to the more direct passage through the plates. From a number of experiments in which M. de la Rive succeeded in forming a comparative estimate of the intensities of the currents under different circumstances, by means of a magnetic galvanometer, he ascertained, that the intensity of the Electric current is impaired according to the number of metallic plates which are interposed in its passage. The diminution of intensity is next to nothing when the current is very energetic, and proceeds from a pile composed of a great number of plates; but it becomes more and more sensible, according as the original intensity of the current is less considerable. When, in two comparative experiments, in which the current had passed through an unequal number of plates, the intensity has been rendered equal, that current which had previously passed through the greater number of plates, will pass through every succeeding plate with less diminution of intensity than the other. When different metals were used in these experiments, it was found that the more readily the metal was acted upon by the liquid conductors, the less was the diminution of intensity produced by the passage of the Electric currents through them.

(221.) By the aid of the conclusions deduced from these interesting researches, M. de la Rive is enabled to account, in a very satisfactory manner, for the differences of effect, particularly in regard to chemical decomposition which accompany the multiplication of pieces in the Voltaic pile. The Electric current is disposed to pass with greater readiness through imperfect conductors, which present a degree of resistance when it has previously traversed a great number of metallic plates. The phenomena correspond with those which would take place, if we could imagine that there were two distinct portions of Electric currents, the one capable of passing indiscriminately through all sorts of conductors, good or bad; the other capable of passing through good conductors alone. The passage of the currents through a great number of plates effects a separation of these two portions, the plates retaining that which cannot pass through bad conductors, and giving passage to the other portion alone. The Electricity elicited by a pile consisting of a small number of plates, not having been thus filtered, (if the expression may be allowed,) only a part of it will pass through an imperfect conductor which is presented to it, and the other part will be arrested; but if a good conductor be presented to it, the whole of the Electricity finds a ready passage, and the effects it will produce will be much greater. Electricity of the former kind will only be capable of producing chemical decompositions, and of passing through organized bodies; but, in the latter case, it is adequate to the production of all the calorific and Magnetic effects. These important modifications in the action of Electric currents, obtained by different means, suggest a remarkable analogy with the modifications of Light and of Heat, under circumstances somewhat parallel.
HISTORY OF GALVANISM.

Galvanism. (222.) The full account which we have given of the principal facts belonging to the science of Galvanism, and of the most plausible theories devised for their explanation, may be regarded as comprising an exposition of the present state of our knowledge, and this department of Physics, and will supersede the necessity of our entering into any copious historical details as to the researches and opinions of its early cultivators. Little interest can attach to speculations in which truth is so much involved in error as to be with difficulty recognised; or to laborious investigations, undertaken with a view of ascertaining facts which we have since been able to arrive at by a much shorter process. Still less need we dwell upon abortive attempts to establish theories, which our more enlarged acquaintance with the subject enables us easily to refute. Much instruction, it is true, may often be reaped from a revision of the steps by which important principles were deduced; but for this purpose it would be necessary to enter into a minuteness of detail incompatible with the objects, and far exceeding the limits of this Treatise. We must content ourselves, therefore, with presenting a very brief outline of the History of Galvanism.*

(223.) This science owes its origin to an accidental observation made in the year 1791, in the laboratory of Galvani, Professor of Anatomy at Bologna. His wife, being in a declining state of health, employed as a restorative a soup made of frogs. Several of these animals deprived of their skin happened to be lying on a table, near an Electrical machine. While the machine was in action, one of Galvani's pupils happened to touch, with the point of a scalpel, the crural nerve of one of the frogs that was nearest to the prime conductor; when it was observed, that upon each contact, the muscles of the limb were thrown into strong convulsions. This curious fact attracted the notice of the Professor's lady, who communicated it to her husband. He repeated the experiment, and varied it in different ways; he then perceived that the convulsions took place only at the time that a spark was drawn from the prime conductor, while the nerve of the frog was, at the same moment, touched by a substance which was a good conductor of Electricity. This newly observed fact, appearing to confirm his hypothesis in a very remarkable manner, inspired him with new ardour for prosecuting the inquiry. He found that contractions could be excited in the limbs of frogs by the Electricity of the atmosphere; and in the course of his investigations on his subject, he was led to the discovery that an effect of the same kind was produced, independently of the Electricity of surrounding bodies, merely by establishing a communication by means of metals between the nerves and muscles. He drew from his experiments the general conclusion that these different animal parts possessed an inherent Electricity, forming an apparatus analogous to the Leyden jar, which might be discharged by the application of proper conductors.

(225.) Soon after the publication of Galvani's work,* Researches in which these discoveries are detailed, there appeared of Valli, some letters of Valli† on the same subject; and in the year 1793, Dr. Fowler published his Essay on Fowler, Animal Electricity, in which he discusses with great ability the question whether the phenomena of Galvanism are referable to Electricity; and is led, in consequence of the imperfect state of the science at the time he wrote, to form the opinion that they are the results of distinct agents. He made a great number of observations on the effects of Galvanism in different animals, and on different parts of animals. He repeated the experiments of Sulzer, already noticed, (sec. 85;,) and the same subject was further prosecuted by Professor Robison.

(226.) Professor Volta, of Pavia, in a letter to Volta, Cavallo, published in the Philosophical Transactions for 1793, entered into a train of highly original observations and experiments. He successfully refuted Galvani's hypothesis concerning the analogy of the animal body to the Leyden jar; and laid the first foundations of that theory, which has since found so many advocates; namely, that the phenomena arise from the development of small quantities of Electricity by the mutual contact of two different metals, and that the animal organs are affected in consequence of their being highly susceptible of this Electrical influence.

(227.) Dr. Wells's Paper on this subject, in the Philosophical Transactions for 1795, is deserving of notice, as establishing his claim to the discovery of the fact, that charcoal may be employed, together with one of the metals, in exciting the Galvanic influence; and that it is also a conductor of that influence. Dr. Wells arrives at the correct conclusion, that Galvanism

Part V.

* The best work on this subject is that of Dr. Bostock, published in 1818, and entitled An Account of the History and Present State of Galvanism. It is executed with great accuracy and ability, and we have been much indebted to it in drawing up the following summary.

† Historie de l'Academie Royale des Sciences pour 1700, p. 40.
Galvanism, in identical with Electricity; from the consideration that the same bodies are equally conductors of both. It is singular that Humboldt, who engaged about the same period in a very extensive series of investigations on the irritability of the muscular fibre, as a test of which he employed the galvanic power, should have adopted an opinion opposite to that of Dr. Wells on this subject, and as we now know, contrary to the truth. He may, however, be considered as the discoverer of the very important fact, that contractions may be excited in the muscles of an animal, by placing them simply in contact with the nerves in certain situations; a fact which was afterwards pointed out more fully by Aldini; (sec. 121.)

The discovery of the galvanic pile, which forms so important an era in the history of the science, is Volta's discovery. (230.) The discovery of the galvanic pile, which was made by Volta in 1800, and was the fortunate discovery of Trommsdorff, as to the efficacy of large plates in producing combustion of thin metallic leaves, (sec. 25.) Experiments on the combustion of French metals were performed about the same time by Fourcroy, Vauquelin, and Thenard.* The comparison between the effects of Electricity and Galvanism was further pursued by Van Marum, in conjunction with Van Marum, Professor Pfaff, of Keil, in which they employed the and Pfaff, great Teylerian machine at Haarlem.

(232.) The next step in the progress of our knowledge of the effects of the voltaic apparatus, was the discovery of Trommsdorff, to the efficacy of large plates in producing combustion of thin metallic leaves, (sec. 25.) Experiments on the combustion of French metals were performed about the same time by Fourcroy, Vauquelin, and Thenard.* The comparison between the effects of Electricity and Galvanism was further pursued by Van Marum, in conjunction with Van Marum, Professor Pfaff, of Keil, in which they employed the and Pfaff, great Teylerian machine at Haarlem.

(233.) The labours of subsequent experimentalists were chiefly directed to the establishment of various points which had previously been subjects of doubt and controversy; to the improvement of the apparatus, and to discussions concerning the nature of galvanic action, and its relation to chemical affinity. They have furnished materials for a great number of memoirs contained in a variety of scientific journals, of which it would be impossible to attempt a review, or even an enumeration in this place. During this period, the attention of philosophers was again drawn to the effects of Galvanism upon the animal body, and various experiments, already referred to, (sec. 95, 96,) were made in 1803, by Aldini, Professor of Natural Philosophy at Bologna, and nephew of Galvani, and were repeated by other naturalists in different countries in Europe. Attempts were also made to introduce the employment of Galvanism in medicine, especially in those diseases for which common Electricity had been found useful; but the expectations of advantage from its application have been very generally disappointed, and it had again fallen into disuse as a medical agent, until its recent employment by Dr. Philp, (sec. 102.)

(234.) The most important step that was made at Hisinger this time in the history of Galvanic action, resulted from the labours of Hisinger and Berzelius, an account of which is given in detail.

* Annales de Chimie, xxxix. 103.
Galvanism, which was published in the first volume of Gehlen's Journal, in 1803. They ascertained, by a number of series of experiments, the transfer of the elements of water and of neutral salts to the respective poles of the battery. This law was verified and extended by Sir H. Davy in the masterly train of investigation, of which we have already given a detailed account, (sec. 55—70,) and which affords so beautiful and perfect a model of a truly philosophical inquiry. While Sir H. Davy was engaged in these researches, De Luc occupied himself with the analysis of the pile, and in examining the various circunstances and conditions from which its power is derived. We have already given an account of the results of his labours, (sec. 132–138.) In the course of the inquiries to which he was led by these experiments, he invented the instrument called the Electric column, of which we have described the properties, (sec. 139.) A claim of priority of invention with regard to his instrument was made by Hachette, in favour of himself and Desormes, stating that they had formed a dry pile so long back as the year 1803. Two objections may be made to this claim; the first, that De Luc's pile had been published some time before that of Hachette; and the second, that the two instruments are not analogous, the latter being by no means entitled to the appellation of a dry pile, (sec. 146.)

Mr. Children, in 1809, formed a very large and powerful battery upon the principle of Volta's Couronne de tasses, (sec. 7,) which produced very considerable effects, and afforded instruction as to the ratio between the quantities and the intensities of the Electricity produced by instruments of this kind. A still more powerful battery was constructed by the same gentleman in 1813; and about the same time that at the Royal Institution was made, (sec. 14.)

Dr. Wollaston's ingenious elementary battery, which forms a remarkable contrast with these gigantic instruments, was constructed by him in 1815. A still larger battery than any of the preceding was formed by Mr. Children in the same year. Dr. Hare's first form of the Calorimotor, so named from its extraordinary calorific power, was constructed in 1819;* his improved apparatus, described in sec. 12, was constructed in 1821: that of Mr. Pepys, made for the London Institution, in 1823.

Of late years the attention of the philosophic world has been in a great measure drawn away from the immediate consideration of the theory of Galvanism, by the study of those effects which establish its relation with the magnetic properties of iron, and which have constituted a distinct branch of the science, under the title of Electro-Magnetism. Yet the cultivation of this new science has not been without advantage to the progress of knowledge in respect to Galvanism, as it has furnished us with an admirable test of its agency in cases where its presence could not otherwise have been rendered sensible; see sec. 44.

The invention of the Galvanometer derived from this principle, has conferred a signal benefit to the science, by affording the means of more extended investigations on the laws which govern its phenomena. It was by the aid of this instrument that De la Rive conducted those researches of which we have given an account. The inquiries of Sir H. Davy on the subject of Electro-Magnetism, have also, as we have already seen, (sec. 33—36,) led to the discovery of many curious circumstances with regard to the conducting powers of metals. The principal researches of importance, as far as respects the theory of Galvanism that have lately been undertaken, are those of Becquerel, on the Electricity evolved by the contact of metals with liquids, in which he availed himself of the Electro-Magnetic galvanometer, as well as of the more ordinary form of the condensing electroscope; an instrument which he considerably improved. These researches throw considerable light on the origin of the Electrical power in the Voltaic apparatus.

But by far the most important application of this science, is that which Sir H. Davy has lately made of it for preventing the corrosion of the copper sheathing of ships by sea water. An account of this admirable invention was read before the Royal Society in January, 1824; and published in the Philosophical Transactions for the same year.

(147–148.) Construction and effects of Zamboni's piles.

(149.) Construction of Ritter's piles.

PART IV.

THEORIES OF GALVANISM.

(152.) Proofs of the identity of Galvanism and Electricity, as to the kinds of effect.

(153.) Distinctions in which they differ.

1. Modifications of Galvanic power.

(154.) Distinction between quantity and intensity.

(155.) The effects also depend upon the degree of conducting power.

(156.) Modifications of Electric power with respect to quantity, intensity, and velocity.

(157.) Modifications of Electric power with respect to quantity, intensity, and velocity.

2. Sources of Galvanic power.

(158.) Evolution of power in the case of heat.

(159–161.) Electrical phenomena exhibit only a transfer of power.

(162.) No change in the total capacity of a body for Electricity ever takes place.

(163.) Electricity from the contact of metals.

(164.) Experiments of Volta on this subject.

(165.) The cause of this transfer is unknown.

(166.) Electricity manifested during the contact of the metals.

1. Electromotive force.

2. Its different degrees.

3. Law of its action in different metals deduced by Volta.

4. The Electromotive force exerted by liquids is insensible.

6. Explanation of their various effects.

7. Influence of the conducting power of the fluid part.

8. The intensity of the Electricity is not increased by it.

9. The quantity of Electricity obtained is not in proportion to the Chemical action.

10. Objections to the Electric theory.

11. An action is assumed without any expenditure of power.

12. This action is contrary to the laws of Electric induction.

13. The quantity of Electricity is not in proportion to the extent of contact.

14. But to the energy of oxidation.

15. To the quantity of oxygen consumed.

16. Batteries can be constructed with one metal only.

17. Electromotive action of fluid.

18. Researches of Becquerel on this subject.

19. Law of Volta inapplicable to fluids.

20. The Electricity from Chemical action is of an opposite kind to that from mere contact.

22. The two theories contrasted.

23. Dr. Wollaston's experiments in support of the Chemical theory.

24. Other theoretical views.

4. Theory of the decomposition of water.

5. Batteries can be constructed with one metal only.

6. No current visible in the fluid.

7. Theory of Richter and Gibbs as to the composition of water.

8. Theory of Monge and Fourcroy.

9. Dr. Hestock's theory.

10. Dr. Roget's explanation.

11. Motions exhibited by mercury.

12. Researches of Professor A. de la Rive.

13. Mr. Perrot's experiments repeated by De la Rive.

15. Situation of Electric currents in the fluid.

17. De la Rive's explanation of the effects attending an increase of the number of plates.

PART V.

HISTORY OF GALVANISM.

(223.) Origin of the science.

(237.) Galvanism applied by Sir H. Davy to the preservation of the copper sheathing of ships.
HEAT.

INTRODUCTION.

It might prove an amusing, and in some degree possibly an instructive task, were we to prefix to this Article a review of the opinions of ancient philosophers, and even of those in times comparatively modern, who have bent their genius to inquiries upon Heat; but reasons, which to us appear sufficiently cogent, have compelled us to abandon such an undertaking. The writings of the ancients on this and every physical subject abound in speculations neither founded upon, nor confirmed by, experiment; and if, passing over a long interval of time, we wish to learn what the extent of knowledge on this subject may have been at a period from which the steady advance of physical science may be dated, have we but to turn to the Novum Organum of Bacon for a very complete Treatise upon Heat. Complete we term it, with reference to the knowledge of that day; for as no one ever brought greater mental powers to bear upon the question, and none had before him possessed equally just views of the mode in which these powers might be most advantageously directed; and as he himself has selected his Inquisitio de forma Calidii, "exempli gratia," we feel that we can have done the philosophical world of that day no injustice by our selection. The limits, however, within which an Article of this sort must be confined, compel us to pass by historical disquisitions in general, in order that we may give as full and clear an account as possible of those researches which are to be treasured up in our minds, and constitute the present knowledge on this subject. We do this the more willingly, from a conviction that such a history is a matter of curiosity, rather than of utility.

For the sake of precision, it may be advisable that we say something in explanation of the terms employed in this Article. Heat is a vague and general word referring to our bodily sensations, and in that sense universally understood; but what is the cause existent in matter which produces those sensations upon the organization of our frame? For convenience in language, this cause, producing the sensation or effect of heat, has been termed Caloric. But if, again, it be asked what is Caloric? we confess ourselves unable to afford a satisfactory answer. Suppositions and theories are not wanting; but certainty has not yet been attained. By some, Caloric is thought to be a fluid; existing and material, though of such tenuity and imponderability, as to escape our observation as such, and to become manifest to us only by its effects upon our sensations, and upon all the ponderable forms of matter. By another party it is supposed that Caloric is not material, but is a property or principle of motion, which, by exciting a certain species of vibration among the particles of bodies, causes the sensation and effects of Heat. These difficulties will suggest to our readers the analogous case of the questionable existence of an electric fluid. (See Electricity, Introduction.) The plan we purpose to pursue in this Article, will, we trust, set us free from any practical difficulty arising out of this theoretical uncertainty. We shall find it convenient to speak of Caloric as if it were a substance, though imperceptible and imponderable; of its addition to, and abstraction from, all other bodies: for this mode, even when made use of in calculation, need not imply the admission of any theory, if we remember that it is but employed for the purpose of illustration. The arguments by which these opposite theories are supported will be brought together for comparison in the last chapter.

The word Temperature will also frequently occur. Heat expresses vaguely an effect or operation of Caloric. To Temperature we assign a more definite meaning; considering it the comparative measure of the effects of Caloric in bodies referred to sensation. Thus, if we feel one body to be hotter than another, we say that its temperature is apparently greater; and if we obtain any instrument for measuring the apparent temperatures of the two bodies, free from the fallacies to which our sensations are liable, we consider that we have the true ratio of the temperature of the bodies. It may seem an odd illustration, but we think it a familiar one, to compare temperature to the hand of a clock which tells us what the time is, according to that engine, but does not tell us over how many hours more the moving force will enable the clock to impel the hand; so temperature is an indication of a present external state of the body examined, which does not pretend to teach us the total Caloric existent in the body, nor even the quantity existing in a given portion of it.

It may be desirable that we should explain why the appearance of this Article will differ considerably from that form under which it has been usually presented by the scientific writers of this country. With them the doctrines of Heat have formed a part, and that not an inconsiderable one, in the systematic Treatises on Chemistry; and it is to those Treatises only that the English reader can at present apply for information on the doctrines of Caloric. Of these Treatises no country has produced better; but if we rightly estimate the limits due to physical and chemical science respectively, we cannot place the science which treats of Caloric as a mere appendage or preliminary step to the Treatise on Chemistry. We call it a branch of General Physics, and claim for it a rank corresponding to that of Electricity, Physical Optics, or Magnetism. The chemists have in this country been the able teachers of the doctrines of Heat; witness the Treatises of Thomson and Murray; but we are inclined to think that a separation of the two subjects will conducing to
Heat.

The extent of this Article will not surprise any one acquainted with the subject, who shall consider the number of treatises usually separated, but which here form parts of one uniform whole. Chemistry is relieved from all that relates to the integrant molecules of bodies, and from every consideration which does not depend upon pure Chemical affinity.

All tables of general application and reference, are thrown together at the end of the Article in an Appendix. In the description of experiments, it might have produced a greater appearance of uniformity if we had reduced all the Thermometric indications to some one scale, as that of Fahrenheit or Celsius; but, on the other hand, the whole numbers frequently employed during those researches would have been altered to decimals or fractions, and a sort of evidence arising out of the ready comparability of their appearance would have been lost. Thus, in most cases, they are left in the original numbers of the writers.

It remains that we should present a tabular form or scheme of this Article: with regard to its execution, no one can be more sensible than the writer of it, how much more polished and complete his analysis might have been, had more time been afforded for the task. Punctuality, as far as attainable, is however essential in an undertaking like the present, and the time allotted for the completion of each article must depend upon the promised order of its appearance. In examining the memoirs, strict impartiality has been observed; for this, with the addition of our unworthy thanks, forms all the tribute we can pay to the labour and genius of those distinguished philosophers who composed them. And if the name or the praise of any one such, shall have been inadvertently omitted, it will be to us an additional cause of regret with regard to this Article.

Heat.

§ 1. Dilatation of Bodies by Heat.

GENERAL PRINCIPLES.

Expansion. (1.) It may be stated as a general fact, that all substances experience an enlargement of their volume, by an increase of temperature. The apparent exceptions to this law can scarcely be considered such as to destroy its generality, although they do present irregularities in its application, which were highly injudicious to overlook. Such is the contraction of water by increments of temperature below 40° Fahrenheit. The expansion of some metals at the instant of congelation to this law can scarcely be considered such as to destroy after fusion, is, apparently, connected with the tendency of their particles to arrange themselves in crystalline form; and the contraction of the clay balls in Wedgwood's pyrometer has been shown to depend upon an actual diminution in their substance, by the liberation of water which previously had existed in a state of intimate combination with the aluminous matter of which they are formed.

(2.) For a given change of temperature, different substances undergo different degrees of expansion. In solids, the quantitative expansion is not considerable; in liquids, it is greater; and in aeriform fluids it is much the greatest of all. A question may naturally here occur to the reader, whether in the same substance, be it metal, liquid, or gas, equal increments of temperature, but at different temperatures, produce equal expansive effects. It will be seen hereafter that this, though a fundamental inquiry, is one of the most perplexing ones which could have been advanced. The affirmative can only be answered of aeriform fluids. With regard to the solids and liquids, even if this property be found to belong to them, through some portion of the scale of temperature, it is fully proved, that their dilatations are highly unequal and irregular near to those fixed points of temperature at which they change their physical condition, and from solids become liquids, or from liquids pass on to the state of gaseous matter.

(3.) It has been usual to give a familiar exhibition of the dilatation of a solid from heat, by having an iron bar exactly fitting into a metal ring; the bar, on being made red hot, will no longer enter within the ring. The expansion of a liquid is seen in the bulb and stem of a thermometer; or should this illustration not be familiar, let fig. 1 represent a glass flask filled with cold water, linseed oil, or other liquid, at the ordinary temperature of the atmosphere. Let A be a point marked upon the neck at the surface of the liquid. On placing this flask over a lamp, or before a fire, the liquid will acquire an increase of temperature, and by its dilatation will rise above the point A. The same property in aerial fluids is also easily exhibited; let fig. 2 represent a common phial with a glass tube passing through the cork, or cemented into the neck of the phial so as to be air tight. The tube may reach to within one-fourth of an inch of the bottom of the phial, so as to dip below the surface of a little coloured liquor of any kind filling one-fourth of the bottle. Now hold this little instrument before the fire, or plunge it into hot water, the air that is in the phial will expand and force up the coloured liquor into the tube. This instrument, if graduated, is in fact an air thermometer. Fig. 3 represents one of more convenient form, but in Fig. 3 the principle the same.

The Thermometer.

(4.) Could we but estimate the expansion of the Thermometer.
iron bar in the first case, or the dilatation of the liquid in the second, or of the air in the third; and could we be satisfied that these various bodies underwent equal dilatations for equal accessions of temperature, we should then be in possession of instruments for measuring the temperatures of all bodies. Such in fact are our instruments, and such our means of experiment; but with certain cautions and corrections which it will be our duty to point out. Hence these instruments are called THERMOMETERS.

(5.) By a careful admeasurement of the dimensions of bodies after they have been exposed to considerable changes of temperature, and suffered again to return to their original state, it is found that their volume is unaltered. But in the case of liquids, it requires some care, in order that they may sustain no actual loss by evaporation.

(6.) For very slight variations of temperature, air thermometers may with advantage be employed, from their great sensibility. Among fluids, alcohol and mercury are most commonly made use of; the former for estimating very low temperatures, at which mercury becomes frozen; but the latter is more rapid in its variations, and has its scale of temperature particularly well adapted to experiments lying between our ordinary atmospheric temperatures, and a heat about thrice as great as that of boiling water.

(7.) We are now in a condition to proceed to the construction of some instrument of this sort for the estimation of temperatures. For example sake, let us take the mercurial thermometer. Our first requisite is to obtain mercury in a state of uniform expansive power, and this is in some measure dependent on its purity; to fulfil this condition, the metal is first strained through leather, by which all dirt is removed; and then submitted to distillation, in order to obtain it pure, from small quantities of lead and other metals with which it is frequently adulterated in commerce, or found alloyed in its native state.

It would be by no means difficult, but might be rather tedious, to state all the precautions to be
Heat.

observed in making a good thermometer. We shall therefore content ourselves with mentioning some of the most material properties that such an instrument ought to possess; thus avoiding much of the practical manipulation, because we are convinced that it is much better for the experimentalist to purchase, if not the complete instrument, at least the tube ready filled, in order that he may carefully attend to its graduation. Under this impression it may be sufficient to state, that a thermometer tube, as represented in fig. 4, is made from a tube of thick glass of small but uniform capacity throughout, by closing one end, which is then heated and blown into a bulb by forcing in air from the mouth, or from a bottle of caoutchouc affixed to the other extremity. The mercury is introduced into the tube thus formed, first by heating the bulb over a lamp, for the expulsion of air; the open end is then dipped into pure mercury, and as the bulb cools the contraction of the air remaining within will allow the atmospheric pressure to drive up a quantity of mercury through the tube into the bulb. This operation is then repeated; but in the second heating, the bulb and tube may be filled with the vapour of mercury throughout, so that upon again dipping the extremity, the instrument may be almost, if not completely, filled. It is obvious, that as the volume of space in the tube is very small compared with the volume of the bulb, a small dilatation of the mercury in the bulb will be very apparent in the tube. The expansions of the fluid in the bulb are measured then by the elongations of the delicate column of mercury in the tube; and as the diameter of this column is supposed uniform, the length of the column serves for the measure of temperature. Hence the necessity of uniformity in the capacity of the tube; for if that condition be not fulfilled, a given quantity of mercury propelled from the bulb by a given change of temperature, will not have the same apparent magnitude in the stem, and therefore if estimated by measure will produce an incorrect result. As this condition of perfect uniformity is not always attainable, it is sometimes desirable to make graduations upon the stem, in order to obviate this source of inaccuracy. After the thermometer tube has thus been filled, a certain quantity of mercury is expelled by heat; the upper end of the stem is hermetically sealed, and, upon cooling, a vacuum is left in the upper part of the tube, by which the mercury meets with no obstruction in its dilatations from a body of air enclosed within the stem. Such obstruction would be, in fact, inconsiderable; but a still more cogent reason for this precaution is found in the great inconvenience frequently experienced from the separation of the mercury in the stem into small portions with the air intermingled, an evil that it is not always easy to remove. A thermometer may be examined as to this particular by placing the bulb uppermost; unless the bore of the tube is extremely minute, the mercury will immediately fall down so as to fill the stem quite to the bottom, if no air has been left in the tube.

(8.) It is found that a quantity of water, in which ice or snow is undergoing liquefaction, remains of one invariable temperature at all times; and that every accession of caloric to the water is employed in the fusion of more ice, so that the water can experience no risé of temperature as long as any particle of the ice remains. Hence one fixed point may be determined upon all thermometers by plunging them into such a bath, and marking this point upon the stem, or on the scale, as melting point of ice. (9.) Again, it is found that under a given pressure boiling of the atmosphere, measured by the barometer, pure distilled water enters into ebullition at a temperature quite as invariable; some regard being had to the nature of the vessel in which it is placed, of which more hereafter. For if the heat communicated to the water be increased, no increase of temperature ensues; the only effect being that of driving off a greater quantity of steam in a given time. If then, the barometer standing at some altitude fixed upon by general consent, we place a number of thermometer tubes in boiling water, and mark the point to which the mercury rises in the stem of each, we have obtained another fixed point of temperature, well adapted for facilitating the comparison of observations made in distant countries by independent experimentalists. Such instruments constructed by each upon these general principles.

In different thermometers it is obvious that the distances between these two points will be dissimilar, being in each case determined by the ratio existing between the volume of mercury in the bulb and the diameter of the tube.

(10.) In the present state of our question we are considering the temperature as measured by the dilatation of a volume of mercury, or other fluid, confined within a glass vessel. And to make this estimate with accuracy, it is obvious that all the mercury should be exposed to the action of the heated fluid; or, in other words, that the bulb should be quite immersed, and also that part of the stem which contains mercury. In obtaining the freezing point for the graduation of the instrument this is not difficult, because any portion of the stem may be immersed in the mixture of ice and water; but in ascertaining the boiling point of water, the difficulty seems greater, with an additional one superadded. For let us suppose the barometer at the proper height for this operation; it is true we may plunge the tube of the thermometer into a vessel in which water is boiling, to whatever scale of unequal height may be requisite to cover the mercury, but upon careful trial we shall find that the mass of boiling water in reality differs in temperature at different depths. This is easily explained; for as the formation of vapour, which constitutes the process of ebullition, takes place at the bottom of the vessel, and as this vapour is thus subject to the pressure of the incumbent mass of water, in addition to the true atmospheric pressure, it follows that it is steam of a temperature more elevated than that at which water just boils in that given state of the atmosphere. The thermometer stem will, therefore, unduly affect the thermometer which meets with it. It is known, however, that the temperature at which steam issues from the surface of a mass of boiling water under the standard barometric pressure, is exactly the temperature of boiling water. Hence is obtained an accurate mode for the adjustment of thermometers. It requires only that all that part of the instrument which contains mercury should be plunged in steam of this regulated nature; and as the condensation of the vapour upon the glass stem renders the exact view of the mercury a matter of difficulty, and is a source of error, the following simple but convenient apparatus is recommended in the general instructions of the Royal Society, for the graduation of the boiling point.
Hence the two thermometers, when exposed to the same temperature, will mark the same number of degrees, and therefore be capable of comparison or reference the one to the other.

(12.) Several divisions have been proposed for the thermometric scale, on the interval between melting ice and boiling water; and whatever system be adopted, it is usual to extend the graduations beyond both these points in each direction. The original invention of the thermometer (in the XVIth century) seems to be a disputed point between a Dutchman of the name of Drebble; Sanctorius, an Italian physician; and the celebrated Galileo. It would appear, however, that the thermometers of all these were of a most limited application; for as they adopted no fixed point of general comparison, the experiments of the one could not be referred to the instrument of the other; each had but his own researches recorded in some terms of the length of his own thermometer stem, and if by accident the instrument were broken all future comparison was lost for ever. It is to Newton that we are indebted for extrication from this state of confusion, as regards the estimation of temperature. He perceived the necessity of some fixed point upon the scale of every thermometer, which might be referred to some unchangeable natural phenomenon, for the purpose of simultaneous verification; and for this reason adopted a ratio between the fluid in the bulb and that in the tube, calling the former 10000, but finally suggested the application of the two points now in use, the melting of ice and the boiling of water.

(13.) We proceed then to the next practical step in the construction of the thermometer, the graduation of the stem. The methods for this purpose depend upon two principles widely differing from each other. In the one, the problem is considered simply the division of a glass tube into spaces of strictly equal capacity, without any reference to the bulb, which may not exist at the time of the graduation, or to the freezing and boiling points, which are independent, and may be a subsequent addition.

(14.) ‘Where the tube is of sufficiently large diameter for mercury to be poured into it, the following process is extremely simple and accurate. Let a few bubbles of glass be blown of different sizes, fig. 6, open at both ends; and, of course, as the bubble in the plate is of the full size, having but a minute orifice at each end, made by drawing out the tube heated with the blowpipe and then breaking it evenly off. A bubble is selected, large or small, as the tube may require, and filled by dipping it into a vessel of mercury, and closing each end with the finger and thumb. Thus one measure of mercury may be transferred to the tube, the space it occupies marked with a diamond, and the operation repeated as often as necessary. The absolute capacity of these divisions may easily be calculated if required, by weighing the bubble alone, then the bubble and mercury; and having thus obtained the weight of the mercury filling one division, and knowing either the weight of a cubic inch of mercury, or its specific gravity, compared with water, and the weight of a cubic inch of that fluid, the absolute capacity of the bubble is found. There is also a convenient method of this sort described in Professor Thomson’s valuable article on Decomposition, in the Supplement to the Encyclopaedia Britannica.

(15.) It is evident, however, that such methods are.
not applicable to the capillary apertures of common thermometer tubes. These are seldom graduated upon this principle; and therefore we omit, for the sake of brevity, M. Gay Lussac's accurate method of dividing such a tube into portions of equal capacity. The reason of this process of graduation being little employed is obvious; namely, that after the tube has been thus divided, it is a mere chance whether both or even one of the points for adjustment fall exactly upon any line of division, after the bulb has been blown and the instrument filled. With a thermometer thus constructed it is necessary to find exactly the freezing and boiling points upon its scale, that is in terms of its degrees, be they what they may, and then by calculation to reduce all the indications of such an instrument to the scale of some other known system of notation, such as that of Fahrenheit, Celsius, &c. For complete information on this head we must refer to M. Biot, (1. p. 46.)

(16.) The mode of division more commonly employed for the stem or scale of the thermometer is this. After the freezing and boiling points have been determined, the intermediate space is divided into any number of equal parts by repeated bisection, or by a dividing engine; this number being determined by the scale we may choose to adopt.

Fahrenheit's. In Fahrenheit's scale, that of Fahrenheit, which places 180° between the melting point of ice and the boiling point of water. The former is marked 32°, which was estimated by degrees of the same magnitude, counted from the greatest degree of cold which Fahrenheit could produce; this he called 0. The advantage of this scale consists in the degree being of very convenient magnitude for common purposes, neither too large nor too small. The disadvantage which strikes us most forcibly in calculation, consists in the zero point being placed arbitrarily with reference to our present knowledge. In this respect those scales which place zero at the melting point of ice, seem to us to possess a decided advantage.

Reaumur's. In Reaumur's thermometer melting ice is 0, boiling water 80°. "The peculiarity of this scale seems to have arisen from the principle upon which it was constructed. He supposed the liquid in the bulb (weak spirits of wine) equal to 1000 parts at the temperature of freezing water, and the increase of volume to be 80 parts when heated to the point at which water boils. Hence the latter temperature was denoted by this number." De Lisle's. De Lisle's thermometer was founded on the contraction of mercury in cooling from the boiling to the freezing point of water. Taking the original volume at 10000, the contractions were supposed 150. The scale commenced, therefore, at the boiling point of water, and proceeded to the freezing point, through 150 degrees.

Celsius's. The division proposed by Celsius, a Swede, has been adopted in France, by the name of the Centigrade scale. Zero is placed at melting ice, and 100° at the point of boiling water. This scale is particularly convenient for calculation, but has some disadvantage in the great size of each degree, from which it is frequently necessary to employ fractional or decimal parts.

Murray's. Mr. Murray proposed the adoption of a scale of which the freezing point of mercury should be 0°, and the boiling point of the same metal 1000°. In this scale each degree would be more than half as large as one of Fahrenheit's, and the appearance of the scheme of mercury are uniform throughout, which it will be shown hereafter is not the case through so great an extent of scale.

(18.) In the Appendix, Tables 1, 2, and 3, serve for the reduction of degrees upon one scale to those of another, for the three divisions most in use. The following formulae are also convenient for the same purpose:

\[ C^o = \frac{F^o - 32}{1.8} \]

\[ F^o = C^o \times 1.8 + 32 \]

\[ R^o = \frac{F^o}{3} + 32 \]

\[ C^o = \frac{R^o}{0.8} \]

\[ R^o = C^o \times 0.8 \]

(19.) The method of graduation by continued bisection, or by equal numerical division, though made use of almost invariable, takes for granted that the tube is uniform in capacity throughout. Thermometers thus constructed have certainly a great advantage, in the facility of reading their indications at once from the graduated scale, without an intermediate calculation; but in matters of great delicacy the source of inaccuracy just adverted to must not be overlooked. Our able countryman, Mr. Troughton, makes use of a method in the construction of thermometers which combines the advantages of both the systems we have mentioned. We regret much that he has never made it public other than by verbal communication. The tube is selected with care, and filled in the usual manner; the freezing and boiling points are then ascertained and marked upon the stem; the process for obtaining degrees of absolutely equal capacity, is founded upon the principle of changing the position of a given column of mercury to different parts of the tube. After all, this method seemed to require considerable manual dexterity, which M. Gay Lussac's, depending on the same principle, did not. But the result of Mr. Troughton produces by far the most convenient thermometer.

(20.) Let us now suppose that we have got a mercury thermometer constructed as well as possible in all points hitherto mentioned, and let it be plunged into a heated fluid. What does the position of the mercury in the instrument tell us? A numerical result according to some conventional notation, which in its comparative reference to other instruments is quite intelligible. Founded, it is true, upon the dilatation of mercury; but not indicating to us precisely the temperature in terms of the dilatation of mercury, but in terms of that dilatation as it takes place in glass which is also dilatable by heat, though in a much less degree. The expression of the thermometer then is the excess of the dilatation of mercury over that of glass, for a given augmentation of temperature.

The apparent dilatation of mercury in glass thus obtained is \( 1 \times \frac{F}{F'} \) of its initial volume, proceeding from the temperature of melting ice to that of boiling water; and hence, it is evident, the apparent dilatation for one degree upon any given thermometric scale, may easily
be calculated: thus for 1° Centigrade, it is \( \frac{1}{6480} \) and for 1° of Fahrenheit it is \( \frac{1}{11664} \).

The real dilatation of mercury from the temperature of melting ice to that of boiling water is \( \frac{1}{6480} \) of its initial volume, according to the latest researches of Dulong and Petit.

The indications of the thermometer are altogether independent of the quantity of absolute dilatation; for were it double or triple of the quantity stated, so that it did but follow the same proportion at all temperatures, the numerical indications of the thermometer would always be the same, under the same circumstances; only if the dimensions of the instrument were constant, the dilatation from the point of melting ice to boiling water would be twice or thrice as great, and of course each degree would be enlarged in the same proportion.

For this reason, the differences in the kinds of glass employed for thermometers do not affect their indications, for these are but comparative; and it will be seen hereafter that the dilatations of mercury are exactly proportional to those of glass, or of other solids which do not fuse but at high temperatures, within the limits of melting ice and boiling water. Hence the unequal dilatation of different sorts of glass will only alter the absolute distance of the freezing and boiling points, and of course change slightly the magnitude of each intermediate degree. The only change thus effected is in the apparent dilatation of the mercury; and this change does not affect the relative indications of thermometers. The same reasoning applies also to those constructed with any other liquids, so that the dilatations, however absolutely unequal, be in constant proportions throughout the interval at which the instrument is to be made use of.

(21.) In order that the indications of a thermometer (accurate in other respects) should be perfectly just, it is requisite that the whole of the mercury should obtain one uniform temperature; the instrument, in short, should be entirely plunged into the fluid to be examined. It is true, the difference thus produced is in most cases inconsiderable; in consequence of the minute quantity of the mercury contained in the stem as compared with that in the bulb. Still, this consideration is sometimes important, and it is convenient to be able to apply a calculated correction, when from any cause we may be unable to immerse the mercury completely.

Let us first consider the case of a thermometer, in which it is required to mark the melting point of ice; but under such circumstances that we are only able to immerse the bulb in the mixture of ice and water used for the bath. Here it is evident the mercury will stand too high in the tube, because all that is above the bulb will remain at the temperature of the apartment.

Let \( l \) be the length of this column, see fig. 7, and suppose \( x \) the true length that the column would be, if reduced to the temperature of melting ice. Let the temperature of the column of mercury in the tube be \( f' \) above the true freezing point of water, where \( t \) refers to degrees of any scale we may be employing, so that they be counted from the point before mentioned; and let \( \frac{1}{\delta} \) represent the apparent dilatation of mercury in glass for each degree of the thermometer we are using, the volume of mercury at freezing temperature being unity. By the effect of an increment of temperature of \( t^\circ \) upon the mercurial column \( x \), its length will become \( x + \frac{t}{\delta} \). But this length also = \( l \), therefore, \( x + \frac{t}{\delta} x = x \cdot \left(1 + \frac{t}{\delta}\right) = l \)

and \( x = \frac{l}{1 + \frac{t}{\delta}} = l - \frac{lt}{\delta + t} \)

Which formula is general for all scales, and it is evident that \( l \) and \( \delta \) are quantities mutually dependent upon each other; for the value of \( l \) in every particular case depends upon the number of degrees into which the space upon the scale between freezing and boiling is divided; and this consideration also affects the value of \( \delta \), which is only invariable with reference to the whole extent of that interval.

For Fahrenheit's thermometer \( \delta = 11664 \),

And the formula becomes \( x = l - \frac{lt}{11664 + t} \)

For the Centigrade scale \( \delta = 6480 \),

And therefore \( x = l - \frac{lt}{6480 + t} \) and so of any others.

The first term is the length \( l \), and the second is the length to be subtracted for placing the true point of melting ice upon the scale.

(22.) Let us proceed to a similar calculation for determining the true boiling point to be marked on the stem of a thermometer, when only the bulb and a part or none of the stem can be immersed.

Let \( l \) be the length of the mercurial column not immersed, see fig. 8. Let \( x \) be the length of the same column at the freezing temperature of water; and let \( x' \) be the unknown length it would assume, if entirely immersed. Let \( t \) be the number of degrees expressing how much the temperature of the column in question is below the point of ebullition of water; \( \Delta \) the number of such degrees between freezing and boiling upon the thermometer employed; and \( \frac{1}{\delta} \) the dilatation for each such degree, as in the last problem.

Here, \( x' = x + \frac{n}{\delta} x = x \cdot \left(1 + \frac{n}{\delta}\right) \)

for by the hypothesis \( x \) becomes \( x' \) by passing from the freezing to the boiling temperature.

Also, \( t = \frac{n - \Delta}{\delta} \) for \( x \) by dilating to the temperature \( n - t \) becomes \( l \).

Hence dividing one equation by the other.

\[ \frac{x'}{l} = \frac{1 + \frac{n}{\delta}}{\frac{n - \Delta}{\delta}} = \frac{\delta - n}{\delta + n - t} \]

or, \( x' = \frac{\delta l - \Delta n}{\delta + n - t} = l + \frac{lt}{\delta + n - t} \)

Which equation is general; the first term of the value of \( x' \) being the length \( l \), and the second the quantity by which \( l \) is to be increased for the position of the true boiling point upon the scale.

If now we wish, as before, to apply this to the scale of Fahrenheit, we must substitute 11664 for \( \delta \), and
180 for \( n \), and \( t \) will be measured in degrees of that scale.

Hence, \( x = l + \frac{lt}{11844 - t} \)

and similarly for the centesimal scale, \( x' = l + \frac{lt}{6580 - t} \)

The importance of these corrections, when accuracy is required, were first pointed out by Mr. Cavendish. When \( t \) becomes 0 the second term vanishes, for in this case \( x = l \), that is, all the mercury is at boiling heat. All that has been said of the mercurial thermometer may be applied to those constructed of other liquids, and the laws of their dilatations may be found from the tables for making the requisite substitutions.

(23.) The thermometer of spirit of wine may be employed for the lowest temperatures that we can arrive at, for this liquid has not yet been frozen; but the low position of its boiling point restricts its application to a range of temperature much more limited than that of the mercurial one. The latter is, however, useless below \( -39^\circ \) Fahrenheit, which is the point of congelation of the metal; but it may be employed at temperatures considerably elevated, viz. to beyond \( 600^\circ \) Fahrenheit.

Thermometers made of liquids, if the stem be perfectly free from air, may, however, be exposed to temperatures considerably above the boiling points of the fluids contained in them.

Fig. 9. (24.) It is evident that if \( A \) and \( B \), fig. 9, represent two narrow plates of different metals of unequal expansibility by heat; and that these are fastened together with rivets, as in the figure, or even soldered throughout, upon any change of temperature, the system will assume a curvilinear form. Such is the principle of the compensation balance applied to chronometers, and such the principle of a very sensible thermometer invented by M. Breguet. The compound plate is formed of platina and silver, and a thin strip some inches in length is coiled round into the form of a cylindrical spiral. One end is fixed, and the other carries a light needle for an index, which traverses a graduated circle. The sensibility of this instrument is extremely great, and the absolute quantity of heat which it requires to affect it extremely small, in consequence of the delicacy of the metallic plates. Fig. 10 is a sketch of this instrument, but with the spiral all in one plane, like the hair-spring of a watch; by which the instrument is rendered much more portable. \( A \) is the fixed end of the spiral; \( B \) is the index needle pointing to the graduated circle, and affixed to the other end of the spiral. The sensibility of this instrument is perhaps greater than its accuracy, and the absolute value of its degree must be previously ascertained by careful comparison with a good mercurial thermometer.

(25.) In the estimation of very elevated temperatures Newton had recourse to calculation. His method, though not strictly accurate, gave results which were valuable approximations; but still it remained a desideratum to be able to measure the temperatures of furnaces, at the intense heats required in some manufactures. For this purpose different instruments have been contrived, in the greater part of which the estimation of the temperature is attempted by measuring the expansion of some metal through a known range of temperature, and thus obtaining by simple proportion the temperature corresponding to any other measured expansion. For this purpose platinum is best adapted from its refractory and unoxidable nature. But the expansions of metals being minute, the mechanical artifices employed, for rendering those expansions more apparent, introduce complication into the apparatus, and the whole principle is founded upon an assumption by no means proved as yet; that the expansion of metals is equal for equal increments of temperature, upon distant parts of the scale.

(26.) Engaged in the manufacture of porcelain, no one could feel the want of an instrument of this sort more sensibly than Mr. Wedgwood; hence he was led to contrive that pyrometer which has been more celebrated than any other. The heat required for the absolute fusion of the finer kinds of clay made use of in the manufacture of porcelain is most intense, and scarcely to be attained by the most powerful furnaces; it is found also that after this clay has been well dried and hardened by exposure to moderate heat, it undergoes a gradual contraction by the application of higher temperatures, and on this property Mr. Wedgwood's pyrometer depends. It is stated that the absolute contraction produced in very pure clay by the most intense heat, considerably exceeds the fourth part of its original volume; and this contraction is permanent, even after the clay has become cold. The pyrometer consists of a gauge composed of two straight pieces of brass, each twenty-four inches long, divided into inches and tenths, and fixed upon a brass plate so as to converge; the distance between the bar being \( \frac{1}{4} \) of an inch at one extremity, and \( \frac{1}{8} \) at the other. The clay is well washed and tempered, and formed by a mold into small cylinders flattened on one side, and of such magnitude as to exactly fit the larger end of the scale after having been heated to redness. The clay cylinders are then exposed to the temperature which it is desirable to estimate; that of a furnace, for instance; and their permanent contraction enabling them to slide further within the graduated scales, is thus measured for obtaining the comparison of temperature. (2)

Wedgegood endeavoured to reduce the indications of this instrument to the scale of Fahrenheit's thermometer by an intermediate comparison. He considered the zero of his instrument commenced at \( 1077^\circ \) degrees of Fahrenheit, and that the opposite extremity of his scale was equal at \( 32000^\circ \) Fahrenheit. He divided the interval 240\( ^\circ \), estimating each of these at about \( 130^\circ \) Fahrenheit. But the most elevated temperature that he actually measured was that of a small air furnace, which he made \( 169^\circ \) on his scale, or 21877\( ^\circ \) Fahrenheit, and 30\( ^\circ \) of his scale above the fusing point of cast iron. Great doubts, however, exist as to the accuracy of this instrument. Mr. Wedgwood himself was aware, that it was difficult to obtain corresponding results from clays of even the same apparent composition. It has been rendered very probable that the construction is dependent upon a portion of water being driven off by these intense heats, which before existed in a state of chemical combination with the alumina; and it has been shown that a long continued exposure to a much inferior temperature will produce as great a contraction in one of these cylinders, as if it had been submitted to a more intense degree of heat. And it has further been suggested by Guyton, that from an error in the mode of connecting his own scale with

Pyrometer.
Heat.

that of Fahrenheit, Mr. Wedgwood's temperatures are
much over rated.

Guyton has examined these results, and proposed
another pyrometer, depending upon the expansion of
metal. (b.) Another is described by Mr. Ellicot. (c.)
Others by Galton, (d.) Ramsden, (e.) Crichton, (f.)
Regnier, (g.) Biot (h.) We are, therefore, on the whole
compelled to acknowledge, that a good instrument for
estimating very high temperatures is yet a desideratum
in science, and should be glad to hear of some trial
being made of a method suggested by Dr. Ure, in his
very useful edition of Nicholson's Chemical Dictionary.

(27.) For meteorological purposes, especially, it is
desirable to possess a thermometer which should reg-
ister every change of temperature which may take
place in the absence of the observer. Little success
has hitherto attended the efforts that have been made
to construct such an instrument; but very tolerable
ones have been produced for showing the maximum
and minimum of temperature to which the instrument
has been exposed.

Fig. 11. Fig. 11 represents an instrument of this sort, in
which the tubes are made rather large in the drawing
for the purpose of illustration. A is a spirit thermo-
meter, having a small bit of glass a within the spirit,
and just sliding freely within the tube. To whatever
degree of cold the instrument may be exposed, the spirit
will contract, and the extremity of its column will move
towards the bulb. In so moving, the glass index will
retrograde with the spirit within which it will remain,
but upon a rise of temperature the spirit again advances
in the tube. Now the glass being within the spirit,
cohesion is equal in every direction, and therefore the
glass index will not advance, but will remain to show
the lowest point to which it has been forced.

B, the other tube, is a mercurial thermometer, having
in the vacant part of the tube a bit of steel wire, b,
which slides freely. Suppose the iron in contact with
the mercury, and that by an elevation of temperature
the mercury advances. The cohesion of its own par-
ticles will prevent the mercury from suffering the entry
of the iron, which a very slight force will drive along
the tube to some point at which it will remain, and thus
mark the maximum elevation of temperature which has
taken place. It must be obvious that a horizontal
position is essential in every direction, and therefore
the glass index will not advance, but will remain to show
the lowest point to which it has been forced.

Six's ther-
mometer.

Fig. 12.

(28.) The instrument just described is, however,
very apt to get out of order, and hence we greatly prefer
the register thermometer invented by Mr. Six. Fig. 12
represents the tube of this instrument without its scale.
The central tube is, in fact, the bulb, which is cylindrical
and filled with spirit of wine. The tube returns down
past a, and up by b, as seen in the figure. The dark
part of the tube below a and b is a column of mercury,
the expansions of which have nothing to do with the
indications of the instrument. At a and b are seen the
two indices, consisting of metal wires with delicate
fibres of glass affixed to preserve them from sliding
down the tube by their own weight, yet so as to allow
of motion by a slight force applied. Some part of the
index must consist of iron, in order that a magnet may
be applied to the exterior of the tube for the purposes
of adjustment. Let a and b be by this method brought
in contact with the surfaces of the mercury. Should an
elevation of temperature take place, the mercury will
force up the index b, which will remain to mark the
maximum of that elevation, after a subsequent depres-
sion. Should the temperature fall, the mercury will
force up the index a, which also will remain fixed as a
mark of the minimum temperature. Each leg of the
tube may have a graduated scale, adjusted by a good
common thermometer. This is a good instrument, but
not at all portable, and should, in fact, be fixed firmly
to one place to secure it from injury. (l.)

(29.) M. Gay Lussac has proposed the following
Gay Lussac's thermo-meter as applicable to the measurement of the
maxima and minima of temperature. "A, fig. 13, is a Fig. 13.
glass bulb terminated by a tube, at the extremity of
which is a capillary orifice of about the diameter of a
small pin. Let us suppose this bulb filled with salt
water or any other liquid, according to circumstances.
C D is a tube of considerable diameter, cemented
from F to D around the tube B H. This larger tube is
filled with mercury from F to E. In making use of
this instrument, let us suppose the bulb A, as well as the
tube C D, filled with salt water, at a temperature of 20°;
let mercury be poured into the tube C D, filling it
from F to E; this, in consequence of the smallness of
the orifice B, will not be able to penetrate into the
bulb. But should the temperature of the medium, in
which the instrument is placed, be diminished, there
will be a tendency to the formation of a vacuum in the
bulb; this the mercury will fill up, and form the drop A
at the bottom of the bulb. The complete effect having
been obtained, the mercury is removed from the tube
C D and that which has entered to which is driven
out by reversing the glass, and applying a slight heat.
This mercury received into the graduated tube G, fig.
14, will indicate the real depression of temperature Fig. 14.
below 20°, the point from which we are supposed to
have set out.

"But in order that we may know the value of the
degrees of the tube G, which we here suppose equal
and arbitrary, we must bring the instrument, arranged
as before described, from one known temperature to
another temperature which also is known, and measure
by the tube G the mercury thus forced into the bulb.
If it be desirable to make the degrees upon the tube
mental centigrade degrees, the tube G the mercury is raised marked, and the corre-
sponding portion of the tube must be divided into that
number of equal parts, which answers to the number
of degrees through which the change of temperature of
the apparatus was carried.

"This apparatus seems peculiarly adapted to make
us acquainted with the temperature of lakes and seas at
considerable depths." (m.)

(30.) The differential thermometer, as constructed Differen-
tial, by Mr. Leslie, is one of the most simple and elegant thermo-
struments ever devised. It will be evident from the
following description extracted from his work, that the
absolute temperature of the apartment in which it may
be placed, produces no effect whatever on this instru-
ment, and that its sole object is to estimate the differ-
ence of temperature between its two bulbs, under given
circumstances. It is, in short, an air thermometer of a
peculiar construction.

"Two glass tubes of unequal lengths, each termi-
nating in a hollow ball, and having their bores some-
what widened at the other ends, (a small portion of

VOI. IV.
sulphuric acid, tinged with carmine, being introduced into the ball of the longer tube,) are joined together by the flame of a blow-pipe, and afterwards bent into the shape of the letter U; the one flexure being made just below the joining, where the small cavity facilitates the adjustment of the instrument, which, by a little dexterity, is performed by forcing with the heat of the hand a few minute globules of air from the one ball into the other. The balls are blown as equal as the eye can judge, and from four-tenths to seven-tenths of an inch in diameter. The tubes are such, as are drawn for mercurial thermometers, only with wider bores. Fig. 15 represents this instrument; the actual value of its degrees must be ascertained by comparison with the mercurial thermometer, as the range of its scale is seldom made so as to extend from the freezing to the boiling point; so that degrees might be obtained by division."

(31.) The freezing point upon the mercurial thermometer has been supposed to undergo some slight variation, so as to appear too low upon the scale of those instruments which have been long made; and it is said, that in such cases the just indication was again recovered by breaking off the end of the stem, so as to admit atmospheric air. Our very accurate countryman, Troughton, examined several very old thermometers, without finding that they had undergone any such change. On this subject consult the following references: (p) (g) (s) (s) (r.)(s) (t.)(v.)(w.)

References from (1) to (31) inclusive:

Dilatation of Solids.

(32.) Before we proceed to a review of those researches, which have at various periods been made for the purpose of ascertaining the absolute laws of dilatation for various bodies, solids, liquids, and gases, we shall find it convenient to examine briefly the abstract mathematical designations for these dilatations, and in so doing, shall select some of the most important formulae from M. Biot's work.

Let \( \delta \) represent the dilatation of a solid for some unit of length, from the effect of some given increment of temperature; then may the dilatation for the unit of volume, by the same change of temperature, be represented by \( 3 \delta \); so that if the original volume of a mass or vessel be \( V \), the subsequent volume may be called \( V + V' \).

For let us suppose an homogeneous mass, \( V \), which by being dilated by heat becomes \( V' \), the form will be the same in both cases; but the volumes of similar figures are as the cubes of their homologous sides; that is as the cubes of their linear dimensions \( l, l' \) measured in the same direction.

Hence,

\[
\frac{V'}{V} = \frac{l'}{l} = \left(\frac{l'}{l}\right)^3
\]

If the linear dilatation \( l' - l \) be very small compared with \( l \), as is the case with all solids at temperatures distant from their fusing points, \( V - V' \), the dilatation of volume will also be very small, compared with \( V \), because of the factor \( l' - l \), which is its multiplier in the second member of the equation. So that by considering these dilatations so small that we need only regard the first power of the fractions representing them, which is almost always sufficiently exact, we see that they may be neglected in the factor \( l' + l' l + l' \), in which case \( l = l' \), and the factor in this case becomes \( 3 l' \). Thus the numerator and denominator become divisible by \( l' \),

whence

\[
\frac{V' - V}{V} = 3 \cdot \frac{l' - l}{l}
\]

If \( l' - l \) is the linear dilatation for the unit of length, and \( V' - V \) is the cubic dilatation for the unit of volume between the temperatures of the experiment; so that by calling the former \( \delta \), and the latter \( \Delta \), we have between these temperatures \( \Delta = 3 \delta \), that is to say, the cubic dilatation is triple the linear one very nearly.

(33.) From the above formula, the new volume of a body may be readily calculated,

\[
\frac{V'}{V} = V \left\{ 1 + \frac{3 \cdot \delta}{l} \right\}
\]

for as \( \frac{V' - V}{V} = 3 \cdot \frac{l' - l}{l} \)

or simply \( V' = V \left( 1 + \Delta \right) \)

(34.) Proceeding in the case of solids, and assuming that their linear dilatation \( l' - l \) is constantly propor-
Should the initial volume \( V \) be unknown, it may be deduced from these formula after we have obtained \( V' \) by observation; but it is equally just to adopt as counting from the freezing point: let \( V \) be the volume at the temperature, counted upwards from that point. If the linear dilatation for 1 degree = \( k \); the linear dilatation for \( t \) degrees will be \( k t \); consequently \( V' = V (1 + k t) \) or by making \( K = 3 k \)

\[
V' = V (1 + K t)
\]

(35.) Should the initial volume \( V \) be unknown, it may be deduced from these formulae after we have obtained \( V' \) by observation; but it is equally just to adopt as counting from the freezing point: let \( V \) be the volume at the temperature, counted upwards from that point. If the linear dilatation for 1 degree = \( k \); the linear dilatation for \( t \) degrees will be \( k t \); consequently \( V' = V (1 + k t) \) or by making \( K = 3 k \)

\[
V' = V (1 + K t)
\]

But all our present calculations are made on the supposition that the cubic dilatation \( K \) is so small, that we need only regard the first power of the fraction that expresses it. Continuing then here the same order of approximation; that is to say neglecting \( K \) in the denominator of the fraction \( \frac{k}{1 + k} \) because the numerator is already of the order \( K \), we obtain simply

\[
V' = V \left\{ 1 + K \left( \frac{t'}{t} - 1 \right) \right\}
\]

(36.) This approximation is, however, only applicable to the case of substances having very small dilatations. If otherwise, the higher powers of \( K \) must be employed. Returning to our equation,

\[
\frac{V' - V}{V} = \frac{\left( l' + l + l \right)}{l^3} - \frac{1}{l}
\]

and confining ourselves to the case of uniform dilatation

\[
\frac{l' - l}{l} = k t
\]

where \( k \) is the linear dilatation of an unit of length for one degree of the thermometer. By substituting this value of \( l' \) in our equation, and using \( k t \) for \( \frac{l' - l}{l} \) the linear dilatation,

we find

\[
\frac{V' - V}{V} = (3 + 3 k t + k^3 t^2) \cdot k t
\]

or calling \( 3 k = K \) as before,

\[
\frac{V' - V}{V} = K \left( \frac{t}{3} + \frac{K^3 t^2}{27} \right)
\]

whence

\[
V' = V \left\{ 1 + K t + \frac{K^3 t^2}{3} + \frac{K^3 t^2}{27} \right\}
\]

which formula is complete for substances of great dilatation.

The whole of the above reasoning has proceeded on the supposition, that in each solid the dilatation (be its absolute quantity what it may) is always proportionate to the increments of temperature, measured upon the air thermometer, the only one of invariant accuracy.
Heat.

estimated in divisions of the vessel in which the fluid is contained. Let $\delta$ be the cubic dilatation of the fluid in passing to $t$ degrees above the freezing point; then the new volume will be $V(1 + \delta)$; and let the dilated fluid occupy $V'$ divisions of the vessel in which the fluid is contained. But as the vessel also undergoes dilatation by the accession of temperature, each of its divisions will be augmented in capacity; that is to say, $V'$ at the temperature $t$ is greater than $V$ at the temperature of melting ice. Let $K$ be the cubic dilatation of the material of the vessel for one degree of the thermometer we are using, then will $V'$ divisions at the temperature $t$ be equal to $V' (1 + K t)$ of the divisions at the initial temperature. This then will be the true expression for the new volume of the gas, expressed in terms of the original divisions, hence

$$V(1 + \delta) = V' (1 + K t)$$

and

$$\delta = \frac{V' - V}{V} + \frac{V' K t}{V}$$

The first term $\frac{V' - V}{V}$ represents the cubic dilatation for a volume equal to unity, on the supposition that the vessel has no dilatation; and the second term $\frac{V' K t}{V}$ is the correction rendered necessary by the dilatation of the vessel.

By making such experiments in a graduated tube, $V$ and $V'$ are known, $K$ is ascertained from the tables of dilatation of solids; hence by substituting the values of $V, V', K,$ and $t$, in the result of any experiment, we obtain $\delta$, the absolute dilatation of the liquid or gas.

(43.) But there is, as we have already remarked, an important correction to be made in the case of aeriform fluids; for should the barometric pressure change during the experiment, the effect produced by the change of temperature $t$, will not be accurately measured in terms of $V$, and consequently an erroneous value will be found for $\delta$.

To obviate this source of inaccuracy let it be admitted that the barometer does change its indication during the experiment. Let $p$ be its altitude when the air is at the freezing temperature, and $p'$ its altitude when the air is examined at temperature $t$. It is easy by the formula in Art. 39 to reduce the volume of air to the standard pressure in both cases. For $V$ we have

$$\frac{V}{p} = \frac{p V}{p'}$$

and for $V'$ we have

$$\frac{V'}{p'} = \frac{p' V'}{p}$$

By substituting these values in the formula it becomes

$$\delta = \frac{p' V' - p V}{p V} + \frac{p' V' K t}{p V}$$

By the application of this general formula, the dilatation of a gas $\delta$ for the interval of temperature $t'$ is accurately found; and by varying the range of temperature to $2 t, 3 t, \ldots$ and comparing the dilatations deduced with the original value of $\delta$, the expansion of the fluid is ascertained to be uniform or otherwise. For the former case it is evident that the new values corresponding to $2 t, 3 t, \ldots$ must be exactly $2 \delta, 3 \delta, \ldots$. Such it has been proved by M. Gay Lussac is the case with regard to pure and dry gases; but it seems not to be strictly the case with any other substances in nature.

The mathematical reasoning applicable to vapours is of course the same; and the absolute results for both, will be seen when we come to M. Gay Lussac's researches.

(44.) We have remarked that the formula in Art. 42, is applicable to the dilatation of liquids; and the method is rendered an extremely convenient one, by making use of a graduated glass tube; but it must be remembered, in the first place, that the whole of the fluid is to be immersed in the heating medium; and in the next, that many liquids are apt to pass into the state of vapour and escape, by which means a source of error is introduced into the experiment. The latter may in some degree be guarded against by sealing the tube hermetically.

But the researches of De Luc, which were very extensive, point to us another source of inaccuracy, viz. that the atmospheric air mixed with the fluid originally introduced into the tube, is separated by an accession of temperature, and thus interferes with the results.

(45.) Another excellent method for obtaining the specific dilatation of liquids is that employed by Sir Charles Blagden and Mr. Gilpin, their researches having for the immediate object the specific gravity of the fluids.

The most convenient instrument for this purpose consists of a small glass flask, the neck of which may be accurately closed by a perforated glass stopper. The latter may be conveniently made out of a piece of thermometer tube.

Let this vessel be filled with the liquid to be examined, and the stopper inserted, the whole exterior being quite dry. It is evident that the flask will be filled with fluid, even to the orifice of the tube passing through the stopper. By knowing previously the weight of the flask and stopper alone, it is easy to find the precise weight of the vessel when filled with fluid, at the initial temperature of the experiment. Again, by communicating $t$ degrees of temperature to the flask and fluid by means of a bath, some will be forced through the tube and escape. The whole is then to be dried and again weighed. Let the first weight be $P$, and the second $P'$; but in finding the true value of $P$, care must be taken to allow for the air displaced by the introduction of the fluid. Let $V$ be the initial volume of fluid; now to find the volume which is due to the weight of fluid $P'$, if reduced to the initial temperature, we have

$$P : P' :: V : \frac{V P'}{P}$$

this last quantity is the volume of fluid which by an increment of $t$ degrees of temperature has filled the vessel. But if $\delta$ be the cubic dilatation between the temperatures of the experiment, this volume ought to change to

$$\frac{V P'}{P} (1 + \delta).$$

The capacity too of the flask, which originally was $V$, has changed to $V (1 + K t)$ where $K$ is the cubic dilatation of the material it is made of. But, as in the second state of the experiment, the liquid fills the vessel, these two quantities are equal; that is

$$\frac{V P'}{P} (1 + \delta) = V (1 + K t)$$

Whence

$$\delta = \frac{P - P'}{P'} + \frac{P K t}{P'}$$

by which $\delta$, the cubic dilatation, is ascertained.

(46.) The dilatation of liquids may be measured by another process, depending also upon the change of
Heat.

The quantity estimated by weight, which a given volume of the fluid undergoes by a given change of temperature. It is a known principle in hydrostatics, that a body plunged into any fluid experiences a loss of weight equal to the weight of the volume of fluid which it displaces. Let a mass of any metal, platinum for example, be affixed to a hair, and weighed in air at a pressure and temperature both given. Its absolute weight will, in this case, be diminished by the weight of the volume of air which it displaces; this loss is so inconsiderable, that let us for the present altogether neglect it, and suppose the weight obtained to be truly that of the platinum in vacuo. For similar reasons we may at present neglect the very slight alteration in apparent weight, which changes in the temperature and pressure of the atmosphere must, strictly speaking, produce. Let the mass of platinum be again weighed, but in water, and the difference between these two weights will give the weight of a mass of water equal in volume to the immersed platinum. But if this experiment be repeated, after the temperature of the water has been changed, the weight will not be the same; because though an equal volume of fluid, it has undergone a change in its density. From these data then the density or dilatation of the water, or any other fluid, may be deduced.

Let \( V \) be the volume of the heavy body at the initial temperature, \( P \) the loss of weight by immersion in the fluid at that temperature; which is, in fact, the weight of a volume \( V \) of the fluid. Let the temperature be elevated \( t \) degrees, and then let \( P' \) be the loss of weight which the body sustains; this will similarly be the weight of a volume of fluid equal in volume to the body. But the metal must also have changed its volume, for if the cubic dilatation of its substance be \( K \), its volume \( V \) will now have become \( V(1 + Kt) \); and this is the volume of liquid which has for its weight \( P' \). Consequently the unit of weight will then occupy a volume \( \frac{V(1 + Kt)}{P'} \), and the primitive mass of which the weight was \( P \), occupies a volume \( \frac{VP(1 + Kt)}{P'} \).

But this changed volume is expressed by \( V(1 + \delta) \), continuing \( \delta \) for the cubic dilatation of the liquid between the temperatures employed.

\[
\text{Hence } V(1 + \delta) = \frac{VP(1 + Kt)}{P'}
\]

and

\[
\delta = \frac{P - P'}{P'} + \frac{PKt}{P'}
\]

A formula analogous to that obtained for the process of weighing the same vessel filled at different temperatures.

Limitation. (47.) Let it be most particularly remembered, that all the preceding formulae investigated from Art. 32 to Art. 47, and applicable to solids, liquids, or gases, proceed upon the supposition that \( \delta \), the dilatation, is constantly the same for similar increments of temperature, even at different points of the thermometric scale. This assumption is not just, except in the case of gases or vapours; but the formulae are of constant utility for finding the values of \( \delta \) at different temperatures, and thus investigating the increment or decrement of absolute dilatation, estimated at different points upon the true thermometric scale.

(48.) The admission made in the last article of the uniform dilatation of elastic fluids, which we found upon the researches of M. Gay Lussac, confirmed by Dulong and Petit, leaves for our consideration the dilatation of liquids only, with the very desirable object before us of discovering some general expression which may, under certain modifications peculiar to each liquid, express the absolute dilatation corresponding to any increment of temperature taken upon any part of the thermometric scale.

The most satisfactory attempt upon this point has been made by M. Biot, who has constructed an empirical formula, which, compared with the experiments of De Luc, Blagden, Gilpin, and Dalton, presents some very good approximate results. For brevity sake, we are compelled here to exhibit the formula only; but this is the less to be regretted, as the method of its investigation, and the instances selected by the author for its application are rather extensive, and cannot have justice done to them by any abridgment which we can devise, (see b b, t. p. 210.)

In this formula, \( \delta = at + bt^{2} + ct^{3} \), where \( \delta \) is Biot's formula.

Experimental researches upon the Dilatations of Solids, Liquids, and Gases.

(49.) In speaking of the measures of temperature Absolute by the thermometer and pyrometer, we have, in fact, adverted to the researches of numerous and excellent experimentalists, who have attempted to investigate the absolute laws of the dilatation of bodies. Strongly recommending the original memoirs to those who may wish to prosecute such inquiries, we can only now reserve the results which they obtained to be thrown into a general table at the close of this article, and proceed to examine at greater length, though frequently with painful brevity, researches made by equally able philosophers, who, having lived at a subsequent period, enjoyed the advantages of accumulated and recorded experience, of which they have most ably availed themselves. The references to the experiments alluded to will be found at the end of this section; the first pause we make is in passing the name of De Luc, whose Recherches sur les Modifications de l'Atmosphère, &c. appeared at Geneva in 1772. His experiments upon the indications of thermometers filled with several sorts of liquids, enable us to obtain some idea of the relative expansions of these fluids in glass. The complaints which he makes of a bubble of air appearing after some time in his thermometers of oil, which he attributes to atmospheric air originally lurking in the pores of the fluid, we conceive may possibly have arisen from an actual decomposition of a minute portion of the oil, or even from vapourisation taking place to a slight extent, though at a comparatively low temperature. (k.)

(50.) Sir Charles Blagden's experiments had chiefly for their object the density of water and alcohol at different temperatures. Upon the experiments of Gilpin, Kirwan, and others, Dr. Thomas Young has founded an empirical formula for the dilatation of water, which seems of considerable practical conve-
In this expression, \( f \) represents the degrees of Fahrenheit's thermometer counted either way from 39\( ^\circ \), then generally the cubic dilatation of water from this value of \( f \) expressed \( \delta_a \) is very nearly

\[
\delta_a = 22 f^3 \times 1-0.002 f \
1000000000
\]

and also that the diminution of specific gravity for the same change of temperature is

\[
(0.0000022 f^3 - 0.00000000472 f^2)
\]

very nearly, so that the new specific gravity upon such a change becomes

\[
S_f = \{1 - 0.0000022 f^3 + 0.00000000472 f^2\}.
\]

The results calculated by these formulae agree very nearly with those obtained by experiment. (add.)

In the formula for cubic dilatation, it is obvious that the volume at 39\( ^\circ \) Fahrenheit is considered unity; and that it is in terms of this unit the results are obtained. Hence, if we know the original volume \( V \) of a mass of water at 39\( ^\circ \) Fahrenheit, its new volume \( V' \) for any other temperature is obtained from the equation \( V' = V (1 + \delta_t) \).

(51.) The next important step which seems to have been made in these inquiries, we owe to Mr. Dalton, whose words, as quoted from his paper in the Manchester Memoirs, are as follows: "Upon the whole, therefore, I see no sufficient reason why we may not conclude that all elastic fluids under the same pressure expand equally by heat; and that for any given expansion of mercury the corresponding expansion of air is proportionably something less, the higher the temperature." (p. 600.) This important fact was made public in the year 1801; and, by a singular coincidence, it seems to have been discovered by M. Gay Lussac about the same time, though Dalton’s experiments were some months prior in their appearance before the world. M. Gay Lussac states his object to have been the investigation of the expansion of air and gases for a given elevation of temperature, and to show that all pure aëroform fluids follow the same law in this particular. He mentions the researches of Amontons, (a,) Mignot, (b,) Ray, (c,) and Saussure, (d,) on the vapour of water only; those of Priestley, (e,) on other gases, also Monge, (f,) and Guyton, (i,) The apparatus that he made use of is then described, and the following are the results he obtained:

1. "That all gases, whatever be their density and the quantity of water which they hold in solution, and all vapours, undergo the same dilatations by the same changes of temperature.

2. "For the permanent gases the augmentation of volume which each of them receives from the point of melting ice to that of boiling water is equal \( \frac{3}{3} \) of the initial volume at zero, for the thermometer divided into 80 degrees; and to \( \frac{3}{4} \) of the same volume for the centigrade thermometer." (oc.) Or to \( \frac{3}{4} \) of the volume at 32\( ^\circ \) for Fahrenheit’s scale.

(52.) These numbers are correct; but by a typographical error in M. Gay Lussac’s Paper quoted above, the decimal point is omitted in both the denominators. His experiments proved, that one volume of air, gas, (or vapour not in contact with the fluid from which it was formed,) by being heated from melting ice to boiling water, became 1.875 in volume. Therefore the actual expansion is 0.875 of the original volume.
Heat. Instrument was filled with mercury and boiled, for the complete expulsion of the air; after cooling I weighed separately the mercury of the tube and that of the bulb, and thus obtained the ratio of their capacities. The liquid whose dilatation was to be measured was then introduced into the apparatus, and the extremity of the tube was closed at a lamp. Nothing more remains but to compare the march of this thermometer with that of the mercurial thermometer, and this I accomplished by plunging both into a water bath, of which the temperature might be varied at pleasure. I suppose the volume of each liquid at its boiling point to be represented by 1000, and I have estimated the volumes corresponding to inferior temperatures in proportional parts. Table 7 represents the contractions of volume obtained for each liquid.

The boiling points of each liquid are

<table>

</tr>
</tbody>
</table>

It may be remarked that these results in the table are not corrected for the contraction of the glass which augments them in a slight degree, because there is another cause tending to diminish them, which it is not easy to estimate; this is the vapour which fills the space left by the liquid, and also the thin film of fluid which moistens the interior surface of the tube. In order the better to observe the progress of dilatation, I have arranged another Table 8 in which the temperatures are ranged another Table 8 in which the temperature sinks by steps of five degrees, each setting out from the boiling point of each liquid, which is the zero of our scale: the corresponding contractions have been determined by taking the two nearest observations, and supposing their difference to be proportional to that of the temperatures. Besides, the contractions have also been calculated by M. Biot's formula
c = A t + B tº + C tº.

From this table it appears, first, that water dilates much less than alcohol and sulphuret of carbon, and both these less than ether. Secondly, that alcohol and sulphuret of carbon dilate equally, as it is only in the first fifteen degrees that there is a slight difference between their dilatations; and this may be attributed to the difficulty of maintaining an uniform temperature at great elevations. Throughout the remainder of the scale, which, for sulphuret of carbon, extends to 60° below its boiling point, or to 13° below freezing point of water, the accordance is perfect. Struck by this unexpected result, and not being able to refer it either to the density or to the very unequal volatility of the two liquids, I was anxious to convince myself that it did not depend upon the densities of their vapours.

Instead of weights I took equal volumes of each liquid at its boiling temperature, and sought what would be the volume of vapour produced under a pressure of 76 centimetres, and at a temperature of 100°. For this purpose I made use of the following data, furnished by direct experiment.

<table>

This result, that alcohol and sulphuret of carbon dilate equally and produce the same volume of vapour, is certainly very remarkable; it would seem to warrant the presumption, that there is an intimate relation between the dilatation of a liquid, and the expansion which it undergoes when reduced to the state of vapour. This ratio ought to be independent of the density and the volatility of the liquids; or, at least, ought not to depend upon these properties only, since in alcohol and sulphuret of carbon they differ so widely. Ether and water present no similar appearance; only we perceive that ether, which of the four liquids produces the least vapour, has the greatest dilatation; and that water, which produces the greatest volume of vapour, dilates the least. The contractions of the four liquids, compared together, are not proportional; and the contractions of the same liquid decrease gradually as we recede from their boiling points. (4.)

(55.) We now proceed to examine the first of two Dulong and Petit doctrines by MM. Dulong and Petit, connected with Petit's part of our subject. It was communicated to the French Institute in 1815. They first inquire, what is to be understood by the word temperature? and then, what is the true ratio between the thermometrical indications and the real quantities of heat added or subtracted in producing given changes of temperature?

The instruments at present in use depend upon the dilatations of substances by heat, and to be rigorously exact ought to satisfy two different conditions. The one of being constant in their indications under the same circumstances; and the other of being capable of strict comparison with each other, that is to say, having their motions in just uniformity with the changes of temperature. By care and well known methods, the former purpose may easily be attained.

With regard to the latter, however, there is much more difficulty; for it is necessary to establish a mode of division such that equal nominal parts upon the scale shall correspond to equal changes of temperature. To fulfill this object completely, it is not enough to ascertain the ratio between the dilatations in the thermometric substance, and the quantities of heat communicated to it; but we ought to be assured that the capacity of the substance for heat undergoes no change, or, at least, ought to be able to estimate that change if it take place. The extreme difficulty of determining exactly how the specific heat of a substance varies, especially at high temperatures, may be regarded as
one of the greatest obstacles to the direct solution of this question. Philosophers have, however, made some attempts to investigate this point: De Luc supposed that the capacity of water did not vary between 0° and 100° centigrade; so that by mixing equal weights of this fluid at different temperatures, the mixture would have as temperature the mean of that of the portion of fluid before mixture. Mr. Dalton proposed the mixture of equal volumes instead of equal masses; because he supposed that the capacity of the same mass augments with the temperature, in proportion to the volume acquired; or, in other words, that the capacity of bodies if referred to their volume is constant.

The method which MM. Dulong and Petit determined first to adopt, was to compare the indications of the mercurial thermometer with the dilatations of air or gas; for it seems proved by the experiments of Dalton and Gay Lussac, that all gases dilate exactly in the same degree under similar circumstances, and consequently it is inferred, that equal increments of volume, are produced by equal increments of temperature.

On this principle, M. Gay Lussac has satisfied himself that the march of the mercurial thermometer is accurate between the temperatures of melting ice and boiling water. It has generally been supposed also, that the dilatation of solids which are of difficult fusion is uniform; and the experiments of MM. Laplace and Lavoisier on metals, seemed to confirm that opinion.

"But," say MM. Dulong and Petit, "if substances so different as the metals and gases follow the same relative law in their dilatations, it becomes extremely probable that these dilatations may indicate the true temperatures; and this may be verified by a comparison with the corresponding quantities of heat."

Our authors then proceed to compare the dilatation of gases with the indications of the mercurial thermometer. It is impossible for us to give in this place a description of their apparatus, or a full detail of these excellent researches, we therefore pass by the numerical results, and quote the following general remarks.

"The results which we now publish, teach us that the dilatation of mercury in the thermometer follows a law which advances upon that of air; so that if we consider the latter as proper for the exact measure of temperatures, we must thence conclude, that the indications of the mercurial thermometer are too elevated at temperatures above the boiling point of water, and the numbers obtained in these experiments may afford the requisite corrections for such indications. These numbers increase with such regularity, that we may without sensible error determine the correction for intermediate temperatures from those comprised in the table."

For two such tables obtained by independent methods we must refer to the original memoir.

"The result of these experiments overthrows a doubt which has been raised, with regard to the law of the dilatation of gases. This law has not been expressed in the same manner by MM. Gay Lussac and Dalton, whose researches on this point appeared at the same time. The experiments of M. Gay Lussac tended to prove that the dilatations of gases referred to the mercurial thermometer, are for each degree one constant fraction of the volume at some fixed temperature. Mr. Dalton, on the contrary, supposed that the increment of volume for each equal change of temperature, is some constant fraction of the total volume at the temperature preceding the change. Mr. Dalton does not appear to have confirmed his supposition by direct experiments, but argues in favour of his hypothesis from the extreme simplicity to which it reduces certain apparently complicated laws, such as the law for the cooling of bodies, and that for the variation of the elastic force of vapours."

"We feel certain, however, that the former of these laws has not that simplicity of character which Mr. Dalton supposed, even on the admission of his own hypothesis."

"It is not, however, by reasonings of this sort that we can establish those laws which observation alone ought to furnish. The experiments we have made at high temperatures destroy the hypothesis of the English philosopher; for although these experiments decide nothing with certainty as to the true measure of temperatures, it is at least probable, that the march of the mercurial thermometer ought to be more rapid than that of the temperatures, because in all other liquids the dilatability augments in proportion as they are heated; while on the hypothesis which we now oppose, we should find that mercury on the contrary decreased rapidly in dilatability, according as it became heated; a result altogether opposed to the principles on which Mr. Dalton has founded his theory of the measure of temperatures."

(56.) The dilatations of solids at high temperatures forms the next subject of our memoir. The principle employed is that made use of by Borda long since. The absolute measures of the longitudinal dilatation are not attempted in the first instance by reference to a fixed scale, but by having compound bars formed of two different metals, exposed to the same changes of temperature, the differences of their expansions are ascertained with comparative ease and accuracy. Having formed an instrument of this sort from a bar of platinum and one of copper fixed together at one end, with a vernier at the other extremity, for ascertaining the difference of dilatation, they exposed it to temperatures of 200, 250, and 300 degrees, and made simultaneous observations upon the vernier and the mercurial thermometer.

By obtaining the value of one degree upon this metallic thermometer, from a division of the observed dilatation during about the first 100 degrees of heating, they found that by continuing that division, the point of 300° upon the mercurial thermometer would correspond to 310° upon the metallic thermometer. These experiments, which were frequently repeated with very accordant results, prove that, contrary to the generally received opinion, the progress of dilatation in metals is more rapid than that of the mercurial thermometer. Thus, supposing that the air thermometer, the mercurial thermometer, and the metallic thermometer, had been graduated as above described, when the former marked 300° in its scale the second would point to 310°, and the third to 320°.

It was highly desirable, but a matter of some difficulty, to make a similar comparison with regard to the dilatations of metal and glass, and for this purpose the copper bar was fixed to one of glass. The result of the experiments with this apparatus seemed to prove, that the excess of the dilatation of the copper beyond that of the glass, continued very nearly proportional to the indications of the mercurial thermometer up to the
**HEAT.**

The temperature of 300°. This result, so different from that obtained with scales of copper and platinum, did not seem capable of explanation, but by attributing to glass a law of dilatation still more rapid than that applying to the metals.

MM. Dulong and Petit then refer to some experiments made by De Luc with great ingenuity, very much in the same manner, and with similar results.

The course of the mercury in the common thermometer measures the excess of the dilatation of mercury over that of the glass; that is to say, the thermometric degrees measure the apparent dilatation of mercury in glass; similarly, a thermometer constructed of iron, and filled with mercury, would measure the apparent dilatation of mercury in iron. By comparing these two instruments, it appeared that the difference was considerable during the first 100 degrees, but that at 300° the difference of effect seemed to warrant the conclusion that the dilatation of glass did not remain constant at all temperatures, and that it increased more rapidly than that of iron.

It is extremely probable that the dilatation or increment of elasticity in gases remains constantly in proportion to the temperatures. This, however, remains to be proved hereafter. By admitting this principle, we perceive that the indications of the mercurial thermometer would be always superior to the true temperatures, and the more so the higher we proceed upon the scale; but philosophers may see, and probably with some surprise, how slowly these differences increase. This does not seem to depend upon the dilatations of mercury remaining very nearly proportional to the real increments of temperature, but upon this fact, that the law of dilatation in glass being combined with the effect of the same law in mercury, there results an almost exact compensation.

These researches also tend to show that metallic pyrometers indicate temperatures above the truth, because they are constructed on the supposition that the dilatation of metals is justly proportional to the increments of temperature, which is contrary to fact. (u.)

(57.) The part of the second memoir by MM. Dulong and Petit which concerns us at present, may be said to commence with a comparison of the indications of the mercurial and air thermometers. The previous state of the question as left by the researches of Dalton and Gay Lussac is examined; and the following table is given as the result of a much more extensive scale of experiments by the authors of this memoir, viz. through an interval of about 400 degrees upon the Centigrade scale.

From this it appears, that the indications of the mercurial thermometer may be considered strictly accurate.

Estimations of temperature for the first 100 degrees, but that above that temperature the mercurial thermometer is in excess gradually increasing, until at its apparent point of ebullition it is ten degrees above the truth.

The method by which these able experimentalists ascertained the boiling point of mercury, very ingeniously avoided some sources of inaccuracy which have attended former processes; the following, they justly say, is a remark of importance.

"In calculating the temperatures of an air thermometer by the augmentation of volume which a given mass of this fluid undergoes, under a constant pressure, the results are found to be strictly the same as those deduced from measuring the variations of its elasticity, maintaining the volume invariable. This result evidently proves that the law of Mariotte is perfectly exact for all temperatures.

"According to the valuable observation of M. Gay Lussac, all elastic fluids undergo the same dilatation in changing temperature from 0° to 100; (51,) and hence it was probable that the same uniformity might continue to more elevated temperatures, and that the numbers referring to air in the last table might serve for gases also. To leave no uncertainty in a matter of such consequence, we (MM. Dulong and Petit) made an experiment upon hydrogen gas, which, as is well known, differs most from other gases in some of its physical properties. The result was found to lay between the extremes of these obtained for common air. The latter were, at 300°, 2.0948 and 2.1027; and that for hydrogen 2.1003. Hence it seems an established principle, that all gases undergo absolutely the same degree of dilatation for equal changes of temperature."

(58.) The next object of this paper is to ascertain the absolute dilatation of mercury. From an examination of the methods made use of by preceding experimentalists, our authors determined to adopt an entirely new process. Their apparatus, though constructed upon a very elegant and simple principle, must have been a work of some difficulty. We have not here space for its full description, but we may state that it depended upon the known statistical law, that the weights of the two masses of fluid in the two legs of an inverted syphon, open at both ends, must be equal; and that, therefore, if the relative altitudes of two such columns be known, the density of the fluid in each may be calculated. Here the legs of the syphon contained mercury at different temperatures. These temperatures were estimated upon the air thermometer. From the different altitudes of the columns of mercury, their respective densities were calculated, which gave also the absolute dilatation of one portion of the fluid compared with the other portion. These results are given in a table, upon which the authors remark as follows:

HEAT.

By comparing the results of the two last tables, we readily perceive that the doubts concerning the course of the mercurial thermometer are not without foundation, and that the laws of dilatation for the instrument itself, and for the liquid contained in it, are materially different,—when we come to estimate a great interval of temperature. When the air thermometer would mark 300° upon its scale, mercury alone would indicate 314°.15, while the common thermometer would point only to 307°.64.

(59.) Upon the preceding data our authors next endeavour to find the absolute dilatation of any solid; because the experimental part of the problem resolves itself into the ascertaining the difference of dilatation between the solid itself and mercury. In the case of glass, for instance, it only requires to find the apparent dilatation of mercury when in glass. This is a question which has frequently engaged the attention of philosophers, and might have been copper, or platinum, reduced to some degree of certainty. The results of MM. Dulong and Petit are again presented in a tabular form.

The values of apparent dilatation to 200° and 300° as expressed in this table, are deduced from the preceding comparison of the scales of the mercurial and air thermometers. The two first columns need no explanation. The apparent dilatation of mercury in glass between 0° and 100° appears rather less than that assigned by MM. Lavoisier and Laplace, who state it at \( \pm 1.7\). The third column contains the dilatation of glass obtained as above mentioned. This dilatation is increasing, but from 0° to 100° it came out in the value before assigned by MM. Lavoisier and Laplace. Finally, the last column contains the degrees which would have been indicated by a thermometer formed by a bar of glass, the elongation of which should serve for a measure of temperature. It is evident from the discrepancy which takes place in reaching a temperature of 300°, how far the dilatation of glass is from being uniform.

It is worth stating, that no variations of result were obtained in these experiments when made with common glass tubes from different manufactories, whatever were their calibre or the thickness of the glass.

(60.) We must again refer to the original memoir for the elegant process by which the dilatations of other metals may be estimated and compared, giving, as before, the table of results for iron, copper, and platinum, the metals examined by our authors. The following table contains the mean dilatations of these three metals, taken at first between 0° and 100°, and then between 0° and 300°. No intermediate degree was attempted, the sole object being to assign the direction in which the different thermometric scales deviate from each other. To make these results more intelligible, there is appended to each dilatation the temperature which would be deduced from it, if we were to consider the expansion of the substance uniform. Such, in short, are the temperatures which would be indicated by thermometers constructed with each of these substances.

By comparing these results with those already obtained for glass, we find that the dilatability of solids, as referred to the air thermometer, is increasing, and unequally so for each of them. This fact, which a former memoir pointed out, is thus amply confirmed.

We believe ourselves in the preceding results to have attained as great a degree of precision as is consistent with measures so delicate; and of this fact some assurance may be obtained by comparing the numbers here given for the dilatations up to 100°, with those that have been published by MM. Lavoisier and Laplace. One remark may be added, that in the direct measure of the dilatations of solids, any error is tripled in passing from the linear expansion to the expansion of volume. The determinations here given produce the latter measure at once, so that any error which may be committed is not multiplied. (y)

(61.) Upon the whole, then, we seem to be entitled to conclude,
1. That the dilatations of all aeriform fluids, are not only equal for the same given changes of temperature, but are also equal for equal changes of temperature on different parts of the scale.

2. The same law does not hold for solids or liquids; but that generally the rate of expansion increases with the elevation of temperature, though several liquids have a point of maximum density below which a further depression of temperature produces expansion instead of contraction.

3. And, lastly, that the air thermometer is the only one of absolute accuracy, supposing no change to take place in the volume of the material from which it is formed. But that, in consequence of the mutual correction produced by the expansions of mercury and glass, the common mercurial thermometer may be considered as accurate between the interval of melting ice and boiling water.

(62.) As yet we have never adverted to the absolute force exerted during the dilatation of bodies; it would appear that the greater the absolute dilatation, the less is the force with which it takes place; thus the dilatation of the gasses may be overcome by the confinement of strong vessels; but in the case of liquids or solids the force of dilatation seems almost irresistible. The strongest rocks are rent by the expansive force of water freezing in their fissures; and strong cannon have been burst in a similar manner by water confined within them. The actual expansive force of solids in the process of heating has not, as far as we know, been made the subject of anything like accurate measurement; but a very elegant application of the force exerted in the converse operation of cooling was made in Paris by M. Molard. Some years ago it was discovered that the side walls of a large room filled with engines, at the Conservatoire des Arts et Métiers, were bulging outwards from the great internal pressure. Strong bars of iron were passed quite through the building; the extremity of each bar passing through the main outer wall. The ends of the bars were formed into screws, and fitted with nuts, which being screwed up closely to the wall might have served to prevent any further mischief. Still, however, the walls had to be brought into their original position to effect a complete cure; this was accomplished by heating each bar, a row of lamps being placed beneath it for the purpose; in this expanded state of the metal, the nuts were screwed up close to the wall again, and upon the removal of the lamps, the contraction of the bars actually brought together the walls of the building. The operation was repeated upon alternate bars, till the walls had been restored to their true vertical position.

It is usually supposed that the dilatation of homogeneous bodies is the same in every direction; the following, however, seems to be an exception to this law, but it is evident that the exception arises out of some peculiarity in that arrangement of the integral molecules which constitutes the crystalline structure. M. Fresnel observed, that the expansion of crystallized sulphate of lime by heat is greater in the direction perpendicular to the axis of the crystal, than in the direction of the axis itself. By the axis is here understood a right line bisecting the acute angle between the two optic axes. A similar phenomenon had been remarked by M. Mitscherlich, with regard to Iceland spar, but taking place in the contrary direction, and thus connecting the property with that of their double refraction, which is also of opposite character. The experiment is easily made by detaching two very thin laminae of seienite from a crystal, and then cementing the one upon the other, crossing their axes at right angles. The cement was such as to allow the surfaces to slide upon each other when warm, but upon cooling, as the dilatations had been unequal and in opposite directions, the compound lamina no longer could preserve a plane surface, but was bent in such directions as to prove the truth and generality of the law. (F.)

(63.) In concluding this chapter we can scarcely Applica- suppose any one whose patience shall have carried him thus far in our article, to need any memento of the numerous points of infinite practical importance which the questions here discussed either directly or indirectly embrace. Countless as have been the researches, and illustrious as were the talents of the philosophers who made them, it is only recently that we have learned, with any degree of certainty, what degree of confidence may be placed in the indications of a thermometer of any sort. And yet in how many of the arts do we seem to require its aid; and how few are the branches of philosophical research in which a knowledge of temperature is not essential to our calculations. It has long been learned from that most authoritative teacher, experience, that provision must be made for the expansion or contraction from changes of temperature, in the construction of iron bridges, and other extensive works in metal. In the iron pipes that are placed in the ground for the conveyance of water or gas, where the length is very considerable, it is necessary to have some points movable; so that by the end of one tube sliding a little within the other, the accidental changes due to temperature are provided for. The base of a trigonometrical survey requires to be measured with the utmost precision; and the expansions, or contractions of the rods employed, must be most carefully taken into the account. The pendulum-rod is subject to similar variations, and it is important that upon a knowledge of the dilatations of bodies, such a pendulum shall be constructed as may continue of invariable length under all changes of temperature. Such is the gridiron pendulum of Harrison; and such the mercurial pendulum of Graham; but neither the one nor the other can be constructed on scientific principles without a knowledge of the dilatations of the materials from which they are formed. In a thousand such inquiries the thermometer is our essential guide. To it the meteorologist daily looks, and by this he must correct the indications of other instruments; by it the chemist directs his operations, or measures their effects; and the astronomer calculates the inflection which the rays of light suffer in their passage through the atmosphere, from the degrees upon its scale.

The absolute dilatations of bodies as far as they are at present known, will be found from a table in the Appendix.

(64.) We may here briefly advert to a singular effect of heat discovered by Dr. Brewster, which we are unwilling to pass by, though the examination of it can only take place with the aid of optical science, in which the experiments may more properly appear. The following is Dr. Brewster's summary of the results:

1. Heat, in passing along a plate of glass, (by the process of spontaneous progress,) expands a part of the glass where the heat does not exist in a sensible state.
§ 2. Fusion and Solidification.

So far as either our means are adequate to the experiment, or our judgment can be correctly guided by analogy only, we are led to suppose that it may be considered as a universal law of nature, that by a sufficient elevation of temperature every substance which is originally solid might be reduced to the fluid state. It is true, that in practice we fall far short of this result, partly because the heat which we can produce by artificial means is of very limited extent, and partly from other properties in the constitution of bodies which interfere with such a consequence. It has, however, been found that every increase which has been made in our powers for the excitement of intense heat, whether by the pile of Volta, or by the gas blowpipe, has placed various substances in succession under the operation of this law, which before formed practical exceptions to it, and it can scarcely now be said than any absolutely infusible body is known to exist. Among the most infusible are some of those bodies which the present state of our knowledge calls simple or elementary; such are carbon, and some of the rarer metals; but it frequently happens that those which in that state are thus refractory, become easy of fusion when combined with other bodies. Thus pure lime is far more difficult of fusion than its carbonate. Those interfering pro-

...
Solidification of Fluids and Liquefaction of Gases and Vapours by Depression of Temperature.

(67.) Having considered the effects of elevation of temperature upon the physical state of matter, we must now advert to the converse operation of the depression of temperature; or, as we are in the habit of referring these changes to the ordinary scale of our feelings, and the medium temperature around us, the phrase in common use is the production of cold. Philosophically speaking, it is the same thing, whether we talk of the melting point of mercury or ice; or, as these are fluids at our ordinary temperatures, describe their point of congelation, by which we mean that degree upon the thermometric scale at which their solidification takes place, upon a proper reduction of temperature.

Analogy would lead us to suppose, that were a sufficient reduction of temperature attainable, every gas and vapour would become a liquid; and these, with all other known liquids, would, in a similar manner, by a still further depression, assume the solid form. This is, however, only the theoretical supposition upon the question, and we are far from being able to prosecute our experiments to such an extent as to verify the position.

The exact freezing point of water has been the subject of careful experiment, from its importance in fixing one extremity of the thermometric scale. It is not doubted that the point of congelation is ceteris paribus invariable; but the mode adopted for applying to that point for the verification or construction of a thermometer, is to make use of the temperature of water in which ice is actually melting, because the temperature of such water is perfectly invariable as long as any portion of solid ice remains. The reason of operating thus indirectly is partly this, that it is found possible, by avoiding agitation, to reduce the temperature of the water even as low as 22° Farenheit, before it assumed the solid state. This point obtained the attention of De Mairan and Fahrenheit, but was most carefully examined by Sir Charles Blagden. He states (a) that the water should previously be freed from atmospheric air; that any small opaque bodies floating in it cause crystallization to take place at very few degrees below 32°; the same effect also follows upon the introduction of a fragment of ice, or by exciting a tremulous motion in the water, but not by stirring it.

(68.) The following observations on this subject we cannot present in a more comprehensive form than that under which they are exhibited in Thomson's Chemistry:

"When salts are dissolved in water, it is well known that its freezing point is in most cases lowered. Thus sea-water does not freeze so readily as pure water. The experiments of Sir Charles Blagden have given us the point at which a considerable number of these solutions congeal. The result of his trials may be seen in the following table: the first column contains the names of the salts; the second, the quantity of salt by weight dissolved in 100 parts of water; and the third, the freezing point of solution. (b.)

"From this table it appears that common salt is by far the most efficacious in lowering the freezing point of water. These solutions may, like pure water, be cooled down considerably below their freezing point without congealing; and in that case the congelation is produced by means of ice, just as in common water, though more slowly.

"When the proportion of the same salt held in solution by water is varied, it follows, from Sir Charles Blagden's experiments, that the freezing point is always proportional to the quantity of the salt. For instance, if the addition of 10 per cent. of salt to water lowers its freezing point 10°, the addition of 20 per cent. will lower it 20 degrees. Hence, knowing from the preceding table the effect produced by a given proportion of a salt, it is easy to calculate what the effect of any other proportion will be. The following table exhibits the freezing points of solutions of different quantities of common salt in 100 parts of water, as ascertained by Blagden's trials, with the same points calculated on the supposition that the effect is as the proportion of salt:

"The strong acids, viz. sulphuric and nitric, which are in reality compounds, containing various proportions of water according to their strength, have been shown by Mr. Cavendish from the experiments of Mr. Macnab, to vary in a remarkable manner in their point of congelation, according to circumstances. The following are the most important points that have been ascertained respecting the freezing of these bodies:

"When these acids diluted with water are exposed to...
Heat. cold, the weakest part freezes, while a stronger portion remains liquid; so that by the action of cold they are separated into two portions differing very much in strength. But when they are very much diluted the whole mixture undergoes congelation; and in that case it appears that the freezing point of water is lowered by mixing it with acid rather in a greater ratio than the increase of the acid. The following table exhibits the freezing point of mixtures of various weights of sulphuric acid, of the density 1.837, temperature 62°, and of nitric acid of the density 1.454, with 100 parts of water:

</table>

The concentrated acids themselves undergo congelation when exposed to a sufficient degree of cold; but each of them has a particular strength at which it congeals most readily. When either stronger or weaker the cold must be increased. The following table, calculated by Mr. Cavendish from Mr. Macnab’s experiments, exhibits the freezing points of nitric acid of various degrees of strength. The strength being indicated by the quantity of marble necessary to saturate 1000 parts of the acid. (d.)

Mr. Keir had previously ascertained that sulphuric acid S. G. 1.78 at 60° freezes most easily, requiring only the temperature of 46°. This agrees nearly with the preceding experiments, as Mr. Cavendish informs us, that sulphuric acid of that S. G. is of the strength 848. From the preceding table we see, that besides this strength of easiest freezing, sulphuric acid has another point of contrary flexure at a superior strength; beyond this, if the strength be increased, the cold necessary to produce congelation begins again to diminish.” (f.)

(69.) The tables exhibiting the point of vapourisation of fluids, may also be resorted to for the purpose of ascertaining the point at which those vapours, upon a reduction of temperature, pass to the liquid state. The freezing points of metals, &c., Table 4, are of course also their temperatures of solidification upon the scale of descending temperature.

With regard to the gases, which have been called permanently elastic fluids, merely with reference to our ordinary temperatures, recent experiments confirm the supposition of their following the general law, and assuming the liquid form upon a sufficient reduction of temperature. The great heat which they give out upon violent condensation, renders it probable that their aeriform state is in a great measure dependent upon caloric. The only one of these fluids, however, that has been liquefied by cold alone, is ammoniacal gas, which, according to Guyton, assumes the liquid form at 54° Fahrenheit.

For the congealing point of some other liquids, see the General Table Appendix, No. 4.

§ 3. Vapourisation.

In this section we shall consider Evaporation and true Vapourisation of fluids at their boiling point.

(70.) By the application of heat, a very considerable number of bodies, both solid and liquid, may be converted into the form of gaseous matter; and as long as that elevation of temperature continues, the form of an elastic fluid is retained. It is clearly proved that in this state they are liquids in combination with caloric, by which change a new order of properties is impressed upon them. Of this action common steam or the vapour of mercury are examples.

But in all such cases a depression of temperature causes the elastic fluid again to assume the liquid or solid form from which it originally set out.

It has been usual to divide elastic fluids into permanent gases and vapours, the former being known only in the aeriform state, except in combination. Ammonia, however, it has long been known, might be reduced to the liquid form by a sufficient depression of temperature, and Mr. Faraday has recently shown, that by disengaging several of the gases from their state of combination, under such pressure that the elastic form could never be assumed, they might be exhibited as liquids.

On the whole there is every reason to conclude from analogy, that every solid in nature might be “melted with fervent heat,” and by a further accession of temperature pass to the state of an elastic fluid. And the same suppositions would lead us to think, that all which we now know in the gaseous and liquid form might by a sufficient cold be reduced to the solid state. By human means it is hardly probable that either of these results should be obtained.

(71.) The essential distinction between gas and vapour may be thus stated:

A gas is not reducible to the liquid state by any at-Gas and tainable pressure alone; is therefore capable of indefinite condensation; and, under such circumstances, the volume is always inversely as the pressure.

A vapour of a given substance can contain only some definite quantity of that substance within a given volume, which quantity varies with the temperature.

Thus, comparing a given space filled with gas, and another saturated with vapour, at a given temperature; if we suppose that space to be diminished, the gas will be compressed, and its elastic force or resistance will be increased; but the vapour will be partly con-
The increase of elastic force by elevation of temperature, is also very different in gases and vapours in a state of saturation with regard to space. For the elastic force of all dry gases at the temperature of melting ice, is to the elastic force at the temperature of boiling water as 1 to 1.375. But the ratio for aqueous vapour in a saturated space (between the same terms) is as 1 to 160. For alcohol, some other ratio, and so on.

(72.) At what temperature bodies pass from the solid to the liquid state has already been an object of inquiry. That they each take their next step, that is, pass from the liquid form to the state of vapour, at some definite temperature also, might be a reasonable supposition, and is in some degree confirmed by experience. But there is this difference in bodies, that some liquids, and even solids, are converted into vapour, more or less at all temperatures; while others undergo no change until their temperature has acquired some given elevation. Of the former sort, water, alcohol, and ether, are examples; we say that they undergo spontaneous evaporation. But sulphuric acid and the fixed oils never begin to assume the form of vapour till they are raised to a certain temperature. These then do not undergo spontaneous evaporation. To this subject we return after a more complete investigation of the laws of vapourisation.

(73.) The evaporation, or vapourisation of liquids, invariably increases with the temperature; and if, as is commonly the case, heat be communicated to liquids from the bottom of the vessel in which they are contained, at some certain point ebullition commences. The boiling of a liquid consists in the rapid formation of vapour at the bottom of the vessel, and the commotion is caused by the ascent and escape of the aerial fluid so produced. When a fluid is boiling, any accession of heat may make it boil faster, that is to say, pass away in vapour more rapidly, but cannot elevate its temperature.

(74.) It was long supposed that the atmospheric pressure alone influenced the boiling point of any given fluid; but with regard to this question we cannot do better than extract the following short paper by M. Gay Lussac.

"We find in the memoirs of the Berlin Academy for 1785, p. 2, or in the Annales de Chémie, x. p. 49, certain experiments of M. Achard, made with a view to ascertain whether the temperature of the boiling point of water is invariable, independent of all other circumstances save the atmospheric pressure. The principal consequences deducible from these experiments are,

"1. That in a metallic vessel a water in a state of ebullition does not preserve a fixed degree of temperature; but that, on the contrary, though the water may not cease to boil, its degree of heat is continually varying, and that this variation is chiefly produced by the action of the air, as well on the sides of the vessel as on the surface of the water; but that in a glass vessel the boiling water maintains a fixed and determinate degree of heat, without the action of the external air upon the sides of the vessel producing any alteration.

"2. That the nature of the vessel has no influence upon the degree of heat which the water assumes in boiling.

"The first of these consequences seems to me inaccu-
vessel in place of the glass one, the noise is less perceptible, the bubbles of vapour smaller but more numerous, the variations of the thermometer less considerable, and the boiling point less high. Of this we may satisfy ourselves in a very simple and speedy manner, by boiling water in a glass flask, and throwing into it some iron filings, the ebullition instantly becomes similar to that in a metallic vessel. Instead of water, if we make use of sulphuric acid, the difference to be seen between its boiling points under circumstances similar to those of the water are very changeable, and frequently amount to several degrees.

"We must observe, and it is a point of importance, that not only does ebullition take place more tardily in glass than in metal, but that a thermometer placed in the liquid, especially if that be sulphuric acid, undergoes very considerable variations, and rises above the true boiling point. The liquid is then under the same circumstances as if it were contained in a vessel in which ebullition could freely take place, and at the lowest possible temperature, under the atmospheric pressure; but that its ebullition was impeded by intercepting its communication with the air. By reestablishing that communication, there will be instantly formed a quantity of vapour proportionate to the excess of the temperature of the water above its true boiling point; the temperature will fall to 100° centigrade, and a sort of explosion will take place. It is only necessary to conceive, in the first case, that the force which prevents the vapour from forming at that temperature, at which it would support the pressure of one atmosphere in a vacuum, is an internal force; owing doubtless to the cohesion of the liquid which the vapour has to overcome, and also to its resistance to any change of state, as in every species of equilibrium.

"The cohesion, or viscosity of the liquid, ought to have a very marked influence upon its boiling point; for it is easy to conceive that the vapour, in order to form within the liquid, has two forces to overcome; first, the pressure to which it is subject, and secondly, the cohesion of the liquid molecules. Besides, it is certain that the vapour of a substance in the liquid or solid state, but at the same temperature, as for instance, water and ice both at zero, has in both cases exactly the same elastic force.

"Upon this last fact we may very well conceive a solid or even a liquid substance, of which the vapour forming at its surface might just counterbalance the pressure of the atmosphere, whilst its interior might reach a temperature more elevated than its true boiling point, provided the substance were fitted within a vessel and heated from beneath, as is the case commonly with liquids. It is obvious that the adhesion of the liquid to the vessel ought here to be compared to its viscosity.

"That which I have termed ‘resistance to change of state,’ is the most difficult to analyse. I shall content myself by remarking, that the power of conducting caloric, and the nature of the surface appear to me to exert an influence upon the position of the boiling point of water. In fact, ceteris paribus, water boils more readily upon a metallic surface than upon one of glass; and more readily in a glass vessel in which is some pounded glass, than in one into which none has been put.

"The disengagement of an elastic fluid dissolved in water is entirely analogous to the ebullition of a liquid. If we take a fermented liquor, beer or sparkling Champagne wine, and wait till the effervescence from the disengagement of carbonic acid has ceased, we may renew this evolution of gas by introducing any powder, a bit of paper, a crust of bread, or even by violently agitating the liquor. The disengagement of carbonic acid takes place chiefly where the liquid is in contact with the glass, and in greatest abundance at those parts of the surface where there are asperities. The bubbles setting out from the surface of the glass are at first very small; but they enlarge in passing through the liquid, because they there establish a solution of the continuity, very favourable to the disengagement of carbonic acid. It seems as if they proceeded more abundantly from the bottom of the glass than from its sides; but this is a deception.

"From the facts that have now been stated, it is easy to explain the phenomenon of a detonation of vapour, (soubreaut.) When from any cause the temperature of a liquid rises above its true boiling point, (viz. that point at which the tension of the vapour of the liquid would be equal to the pressure of one atmosphere in vacuo,) it will shortly happen that this state, in some degree the result of compulsion, will be changed, either by its own excess or by some other cause. An instantaneous puff of vapour takes place, the liquid is dispersed about, and the vessel itself raised up. It is more particularly in the distillation of sulphuric acid in glass vessels that these phenomena are remarked; that distillation cannot be performed without danger of breaking the distillatory apparatus, and we are led to consider it as a difficult and tedious operation. Now, however, setting out from the facts which I have related, we may render the process as easy as that for the distillation of water; it only requires some small fragments of platinum wire to be put into the retort. No more detonations will take place, at least as long as no deposit forms at the bottom of the retort; the acid will flow over without interruption, no particular care need be bestowed upon the process.

"I have employed this method with great advantages for many years in all distillations; and M. Robiquet, to whom I communicated it, found it equally advantageous." (a.)

(75.) Such is the best information upon that subject. Now with regard to water, as its boiling point, in common with that of all fluids, is chiefly influenced by the barometric pressure, we insert the following short table from Dr. Thomson, which is sometimes useful in the comparison of thermometers.

(76.) The experiments of Professor Robison seemed to indicate, that in a vacuum all liquids boil about 124° lower than in the open air when the barometer is at 30 inches.

(77.) "The elasticity of all the elastic fluids into which liquids are converted by heat, increases with the
Heat. When these elastic fluids are exposed to heat, unconnected with the liquids from which they are produced, they undergo precisely the same increase of bulk as air or gas does, when subjected to a similar change of temperature. But when the elastic fluid is in contact with the liquid from which it was produced, the specific gravity of the vapours increase with the elasticity. From the experiments of Mr. Sharpe (b) and Mr. Southern (c) it would appear that the increase of specific gravity is proportional to the elasticity. On the supposition that this is actually the case, the following table gives us the specific gravity of steam at different temperatures, when in contact with the hot water from which it was generated.

Where the specific gravity of air at 60° is reckoned unity. Thomson.

A simple illustration will show the propriety of a division, which we shall follow M. Biot in introducing at this point of our subject. Its object is to show, the necessity of considering the elasticity of pure vapours apart from the same property, when they are mixed with atmospheric air. Fig. 16 represents a common condenser gage, formed of a bent tube, open at one end and closed at the other, containing some mercury. Moisten the interior of the tube with water, and observe the tension; then place the instrument in warm water of known temperature, and again observe the tension; it will be seen that the depression of the mercury in the sealed end is greater than it would have been by an equal increment of temperature, when filled with dry air or gas only. Hence, elastic vapours mixed with air add to its elastic force. Again, if we take a common test tube, and contrive to fill it with some vapour, (permanently so, at the temperature and pressure under which we make the experiment,) and having placed the open end of the test tube on the surface of the mercurial bath; if we gradually sink the tube perpendicularly in the fluid, we observe that the mercury is not depressed, but retains the same level both within and without the tube. This we know would not be the case with air or gas, but is here effected by a portion of the vapour being reduced to the fluid state, so that what remains in the test tube has the same density and elastic force as at first. The experiment may be continued until all the vapour is condensed.

It will tend to simplification then if we first consider,

The elastic force of pure vapours in vacuo.

The earliest scientific publication that entered into this question minutely, was given by Professor Robison, in the Encyclopedia, article Steam, and has been republished in the collection of his philosophical writings by Dr. Brewster. It was known also, that similar researches had been made by Mr. Watt, but they were not made public at the time, and the comparatively recent publication just mentioned, is, we believe, the only place in which any account of them can be found.

(60.) At length our distinguished countryman, Dalton, published a most valuable series of experiments on this subject in 1802. (f) They extend up to the boiling point of water only, but he has attempted to continue the law much higher by calculation. Southern's experiments on the same subject were made under the direction of Mr. Watt in 1803, but not published until some years after. Another series at Paris by M. Biot and Berthollet Jun. (g) And lastly, an interesting paper by Dr. Ure in the Phil. Trans. for 1818. (i) Such are the sources from which the following abstract will proceed. A general tabular view of all their results will be given in the Appendix from Thomson's Chemistry.

Mr. Dalton's process has the merit of great simplicity. He made use of a graduated barometer tube filled with mercury as usual, and carefully deprived of air by boiling. While the tube remains with the open end upwards, and nearly filled with mercury, the remaining space is to be occupied with water, or other fluid to be examined. The tube is then to be reversed, so that the liquid may moisten the interior, and by raising the open end of the tube again, more mercury may be poured in so as to fill the tube entirely. On raising this tube vertically, the mercury will sink, as in the common barometer, but the depression will be greater; for the altitude of the mercurial column will be equal to the altitude of the mercury in a barometer, minus the depression due to the elasticity of the vapour produced within the tube by the liquid. All the liquid in excess which does not pass into vapour, will form a small stratum at the top of the mercurial column. Hence, for that fluid and at that temperature, the elastic force of the vapour is known; and by contriving to surround that portion of the barometer tube which contains the vapour with hot water, the elastic force at other temperatures was determined. By this process may be measured all degrees of elastic force inferior to that produced by the common atmospheric pressure; but for higher temperatures and greater pressures, the barometer tube was bent into the form of a syphon, and the fluid with its vapour being confined in the shorter tube, its elastic force was measured by the length of the column of mercury, which it would support in the longer tube, at the temperature of each experiment.

Such is a very brief notice of the method of Mr. Dalton's experiments, the results may be seen in the table. M. Biot has attempted to deduce from them an Biot's empirical formula, to express the elastic force of the formula

\[ \log F_s = \log 30 + a n + b n^2 + c n^3 \]

where \( F \) is the force, \( n \) the thermometric degrees, and \( a, b, c \), constant coefficients relating to the fluid employed: and that it is not necessary to go beyond the third power of \( n \), from the extreme smallness of the coefficient. The formula with these coefficients inserted as deduced from Dalton's experiments, where \( n \) relates to centigrade degrees, counted from the boiling point; those descending on the scale being called plus, and those ascending minus.

\[ \log F_s = 1.4771213 - 0.00584121972 f - 0.00090801091 f^2 + 0.00000000580 f^3 \]
Upon comparison, this formula agrees extremely well
with Dalton's results, as far as these were determined
by experiment; but at temperatures much above the
boiling heat of water it seems to fail, and as Dr. Ure
states, to err nearly nine inches at the temperature of
266° Fahrenheit.

(61.) We sincerely regret that we cannot give
more space to Mr. Dalton's process, and the same
applies to the notice we are about to take of Dr. Ure's
researches. The method which he employed, as described
in the *Philosophical Transactions*, seems to be a con-
siderable improvement on that of Dalton. His results
will be seen in the table. We quote, however, the
following, regarding it only as a curious coincidence,
but the formula may sometimes serve as a ready ap-
proximation. "The elastic force at 212° = 30 inches,
being divided by 1.23, will give the force for ten degrees
below; this quotient divided by 1.24 will give that of
10° lower, and so on progressively. To obtain the
forces above 212° we have merely to multiply 30 by
the ratio 1.23 for the force at 222°; this product by
1.22 for that at 232°, and thus for each successive in-
terval of 10° above the boiling point. The following is, how-
ever, a more convenient application of the same law for
obtaining directly the elastic force, corresponding to
any temperature moderately distant from 212°: at
much higher temperatures it becomes considerably in
error.

\[ \log F = \log 28.9 - n \log r \]

Then \( \log F = \log 28.9 - 10 \log r \)
the positive sign being used above, the negative below
210."

(82.) The following is another empirical formula by
Mr. Creighton, which, though of singular form, is re-
markably easy of application. \( (k) \)

Let \( D = \degree \) Fahrenheit + 85
\( I = \) corresponding force of vapour in inches of
mercury — 0.09
then \( 6 (\log D - 2.22679) = \log I \)

For example at 212°:
\[ \log 297 = 2.47276 \]
\[ - 2.22679 = 0.24579 \]
\[ 0.24579 \]
\[ \]
\[ 1.4788 = \log 29.91 = 1 \]
\[ + 0.09 \]
\[ \]
\[ \\
\]
\[ \\
\]
\[ \\
\]

Inches 30.00

Mr. Southern's formula may also be briefly noted.

Let \( f \) be the temperature of the experiment in degrees
of Fahrenheit. \( F = \) the elastic force.
Let \( T = t + 51.3 \)
then \( \log E_f = 5.13 \log T - 10.94123. \)

(83.) The experiments of Professor Robison before
alluded to, seem connected with an opinion advanced
by Mr. Dalton in his paper, and which he supposed to
be confirmed by his experiments, viz. that as a general
law "in all fluids, the variation in the elastic force of
their vapour was the same, for the same variation of tem-
perature, reckoning from vapour of any given force."
Heat: and the salt will remain behind. How is it, then, that which is but aqueous vapour in both cases, and at the same temperature, should possess unequal powers of elasticity?"

M. Biot answers, that this inequality must depend upon the actual difference of the liquids on which the vapours rest; exerting a different affinity in the two cases, for in every other condition of the experiment there is no variation. Hence we are led to regard the different strata of which the vapour consists, as the one resting upon the other in succession downwards to the last, which rests immediately upon the liquid. This will necessarily have for its elastic force that with which the liquid tends to emit vapour; whatever cause may operate in giving it that tendency and that faculty. If then the liquid be at first pure water, and it undergoes some change in its constitution, so that its tension becomes weakened, then the strata of vapour which repose immediately upon the surface, or very near that surface, will be more compressed by the elasticity of the superior strata than they are supported by the tension of the liquid. Hence they ought to be precipitated into the liquid, which, by its affinity, will reduce them to the liquid state also; and this process will be extended to the strata next above the former ones, when in their turn they come into contact with the liquid; so that, finally, the elasticity of the rarified vapour becomes precisely equal to the tension of the liquid, that is to say, to the force with which it tends to emit vapour.

(85.) Hence it follows, that in a vessel containing vapour and the substance from which it proceeds, but the parts of the tube being of unequal temperature, the elasticity of the vapour throughout the whole tube will reduce itself to that of the vapour in the coldest portion of the vessel. M. Gay Lussac has made use of this principle to measure the force of vapour at extremely low temperatures; even below the freezing point of water. Thus he found the tension at \(-19.59\)° C. equal to a column of mercury \(1.9718\) millimetres in height. It is certainly a remarkable phenomenon, that the solidification of water should not altogether destroy the elasticity of its vapour.

**Pure Vapours from other Liquids.**

(86.) The elastic force of some other pure vapours, forms a part of Dr. Ure's memoir, and has also been examined by Mr. Dalton. A tabular view of the results of the former may be seen in the Appendix, No. 6.

The vapours are of course exposed to contact with the liquids from which they are formed, and it is seen that the elasticity increases rapidly, compared with the increment of temperature, as in the case of steam.

With regard to ethereal vapour, Dr. Ure remarks this coincidence; that whereas in the case of aqueous vapour setting out from the boiling point, where the tension was equal to 30 inches of mercury, the ratios being \(1.23:1.24:1.25,\) &c. for divisors of 30, by which to obtain the pressures at descending temperatures by steps of ten degrees each; and also where \(1.23:1.22:1.21,\) &c. for multipliers, in order to obtain the pressures at ascending temperatures in intervals of ten degrees. So in the case of ether, where \(104°\) is the boiling point due to a pressure of 30 inches, the same series of ratios will again serve, provided we diminish the corresponding terms in the ratio for ether, by a unit each time in the second decimal place. For example,

(87.) Similarly Dr. Ure states, that for alcohol of S. G. 0.813, the boiling point being \(173°\), but using \(170°\) in calculation for the convenience of a table, the initial ratio each way is \(1.26\); and the common term \(±0.011\) to be applied as before. This accords well with his experiments.

(88.) And that in the vapours of petroleum and turpentine, the elasticity constitutes a regular geometrical progression. "Oil of turpentine is regulated by the constant ratio 1.22, which converts any elastic force into that \(10°\) above or below, multiplying as usual in the former, and dividing in the latter case. For petroleum the ratio is 1.14, it is also constant." (l.)

### Specific Gravity of Pure Vapours.

(89.) Under a given atmospheric pressure different fluids enter into ebullition at different temperatures, as we have already seen; and the specific gravity of the vapours, which they thus form, varies with each individual fluid. The estimation of these densities was a matter of great difficulty, but has been overcome by a most elegant contrivance of M. Gay Lussac. To produce a description of his process, which is founded upon obtaining an accurate measure of the volume of vapour formed from a given weight or volume of the liquid, and at a given pressure and temperature, would lead us into details of too great extent for this place; we must, therefore, only insert the references, and give a table of the results obtained, \((m)\) as cited by Dr. Thomson. **Elastic Force of Gas and Vapour Mixed.**

(90.) The general physical law has already been Mixed gas stated, (38.) that in the case of dry air and gases, the and vapour.
**Evaporation.**

Evaporation (93.) The process of evaporation cannot, in a strict philosophical view of the question, differ from vaporisation; for both depend upon the same physical laws. The former is, in fact, a particular case of the latter; in it atmospheric air is always supposed present, and the operation may comprise one or more fluids.

It has been a matter of discussion, whether the phenomenon of evaporation were produced by a chemical affinity between the molecules of air and the molecules of the liquid evaporated. The experiments of Saus-
HEAT.

vessel over a lamp, or small fire, so as to produce ebullition; and also to hang it to the end of a scale beam in order to ascertain the loss of weight sustained by boiling.

The water is first made to boil, the vessel is then removed and weighed, and then again boiled for a certain number of minutes measured by a stop-watch, then again removed and weighed. The total loss in grains, divided by the number of minutes, gives the loss per minute in grains also. In experiments of this sort extreme rigour would require that the atmosphere should always contain naturally the same quantity of vapour, that the results obtained at different times might be comparable; or, at least, that the humidity should be estimated and taken into the account by calculations. But since the proportion of vapour existing naturally in the air is very small, and, consequently, has but a feeble degree of elastic force, compared with that of boiling water, it follows that it can have only an almost imperceptible influence upon the results obtained at high temperatures, so that at least as a first approximation this point may be neglected.

The stillness of the atmosphere in which the experiment is made, seems a much more important consideration; for the rate of evaporation in a perfectly quiet room was found by Mr. Dalton to be only two-thirds of what it was in the strongest draught he could obtain in a house.

Mr. Dalton's experiments, extending from the boiling point down to 138° Fahrenheit, are given in the following table, to which the corresponding elasticities are affixed:

From this table we perceive that the quantity of evaporation at each temperature is proportional to the elastic force of the vapour which is forming. Such a result might well be expected in the case of air perfectly devoid of vapour at first; but it is reasonable to suppose that the initial vapour in the atmosphere ought to modify the process of evaporation; and such is, in truth, the case; but its influence is not perceptible in experiments like those now related, because the elastic forces of the vapours evolved are very great in comparison with that of the vapour naturally existing in the atmosphere; and the more so, as Dalton undertook these researches at low atmospheric temperatures, when the air must have contained but little moisture.

This circumstance must, however, not be overlooked in calculating the phenomena of evaporation for temperatures below those of the above table. Suppose, for instance, that we wished to apply the same law at the temperature of 60° Fahrenheit, where the tension of vapour, if at its maximum, would be only about \( \sqrt{\frac{f}{T}} \) of that at ebullition; and if, by chance, at the time of the experiment the atmosphere were at the same temperature, and saturated with moisture, the quantity of evaporation would be by no means \( \frac{f^2}{T^2} \) of that corresponding to the temperature of ebullition, as the ratio, according to the elastic force, might indicate; for, in fact, it would be nothing.

(98.) To estimate the influence of the humidity of the atmosphere, Dalton endeavoured to obtain a method for measuring the quantity of vapour existing in it at the time of the experiment. This he performed by pouring into a cylindrical glass some water at different temperatures, in succession, all below that of the atmosphere; by which he learned the exact degree of the thermometer, at which the humidity of the atmosphere began to be deposited as dew upon the exterior of the glass vessel. Having obtained that temperature, he calculated the elastic force of the vapour corresponding to it; and this force being reduced again to that due to the atmospheric temperature at the time, by the common law for gaseous dilatation, gave precisely the elasticity of the aqueous vapour in the air originally.

For example, let the temperature at which dew is deposited be \( t' \), where the original temperature of the atmosphere was \( t \); and let \( \phi' \) be the force of vapour corresponding to temperature \( t' \), as given in the tables, that is to say the force to which the vapour in the air is reduced by refrigeration; then we have but to dilate the quantity \( \phi' \) as a gas, to obtain the true tension \( f' \) of the vapour in the air originally.

\[
f' = \phi' \frac{(1 + t \cdot 0.002083)}{1 + t' \cdot 0.002083}
\]

Where \( t \) is reckoned in degrees of Fahrenheit.

In these calculations it is immaterial whether we consider the experiment as made upon a given volume of air confined in a vessel, or, as with Mr. Dalton, use the cooling of a substance to obtain the deposition of dew in the indefinite mass of the atmosphere. And this is precisely the problem proposed in Art. 95.

(99.) The solution of this problem is, in fact, the determination of an important meteorological question, to which certain instruments, called Hygrometers, have long been applied. Dalton's experiment gives an absolute estimate of the tension of aqueous vapour in the atmosphere at any time; that is to say, determines its hygrometric state. The mode of performing the experiment has been improved by Mr. Daniell; and hygrometers on this construction are now sold by the philosophical instrument-makers in London.

(100.) Having obtained the value of this important correction, we return to Mr. Dalton's investigation of the rate of evaporation. Since the formation of vapour at inferior temperatures must be less rapid, especially when impeded by comparatively large quantities of humidity already in the air, it became necessary to employ a larger surface, that the evaporation might be more perceptible. The cylindrical vessel for the water had now a diameter of six inches, and the experiments were conducted as before.

The law of the results obtained may be thus expressed. Let \( f \) be the maximum tension which vapour could acquire for the temperature of the experiment, (viz. that producing saturation.) Then Mr. Dalton found, that under the same state of the air with regard to its agitation, the quantity of evaporation was constantly proportional to \( f - f' \); that is to say, if the total tension of vapour at 212° be called \( F \), and that at that temper-
Mr. Dalton found that from a vessel six inches in diameter the evaporation in one minute from boiling water, in air dry and calm, was 120 grains. Hence, in a series of experiments made with this same vessel, the area of its surface may be called unity; and then

\[ m = 120 ; \quad F = 30. \]

Hence the evaporation

\[ E = \frac{120}{30} (f - f') = 4 (f - f') \]

But the formula may be made general for all vessels, by making one square inch the unit of surface. Now, as Mr. Dalton's vessel had a diameter of six inches, its area was 28.27431 square inches, from which 120 grains evaporated in one minute at boiling heat. Hence 4.244 grains is the evaporation under these circumstances in one minute for each square inch. Substituting for \( m \) and \( F \) we have

\[ E = \frac{4.244 (f - f')}{30} \]

(101.) This formula is of great general utility in the resolution of several interesting questions of constant occurrence. For instance, if we know the tension of the vapour in the atmosphere \( f' \), and the maximum tension \( f \) due to \( t \), the temperature of the air, we obtain from the formula \( E \) the evaporation in grains per minute.

(102.) And, conversely, if we calculate the force \( f \) and obtain \( E \), the rate of evaporation by experiment, the formula will give \( f' \), that is to say, the tension of aqueous vapour actually contained in the atmosphere surrounding the vessel in which the experiment is made.

Rate of Evaporation of other Liquids.

(103.) Mr. Dalton's researches extended to the evaporation of other liquids also. From the conditions of mutual independence which seem to exist in the mixtures of aeriform matter, if we suppose the vapours of these liquids to be totally free from the admixture of aqueous vapour, and that they have no perceptible affinity for it, the quantity of the latter that may be found in the atmosphere, ought to have no influence upon the evaporation of the other liquids in question; and, consequently, that evaporation in any given time ought to be proportioned to the tension due to them at the temperature of the experiment. This also Mr. Dalton found to be the case. He found, besides, that the absolute quantity of evaporation of each liquid is proportional to the absolute intensity of its elastic force; so that the preceding formula may serve for all liquids, preserving the same numerical coefficients, and only substituting for \( f \) and \( f' \) the calculated elastic forces of the liquid under examination.

For example, the atmosphere being at the temperature 53° Fahrenheit, and almost saturated with moisture, Dalton evaporated alcohol which boiled at 180° Fahrenheit, and found that from a cylindrical vessel of

six inches diameter, the evaporation was 121 grains in twenty-five minutes, or 4.8 grains per minute. This result might be compared with calculation, by using the formula in Art. 100, which applies to such a surface; provided we knew accurately \( f \) the force of alcohol vapour (boiling at 180°) at the temperature 53° of the experiment. By Dr. Ure's table the force of alcohol vapour at 53° is about .95, but then we must remark that his alcohol boiled at 173°, which makes a considerable difference. However, for illustration, we proceed,

\[ E = 4 (f - f') \]

and here \( f' \) vanishes, because we suppose the aqueous vapour in the air to produce no effect; hence

\[ E = 4 \times .95 = 3.8 \text{ grains}, \]

which differs considerably from 4.8 the experimental result. But, in truth, some of our assumptions have been hazardous. The force of alcohol vapour at 53° is little better than a guess, and, consequently, to make any such deduction certain, that the presence of aqueous vapour produces no effect even at 53°, and at higher temperatures it is still more likely to interfere with the operation.

Mr. Dalton calculated the tension at 53° in another manner. Assuming what he conceived he had substantiated by former experiments, (but which has since been questioned,) that as the elastic force of all liquids at the boiling point is the same, so also at any given number of degrees above or below that point, the tensions of the vapours of two fluids are also equal. In the above experiment 180 and 212 are the corresponding temperatures for a pressure of 30 inches; and as 180 − 53 = 127° and 212 − 127° = 85°; if we know the tension of aqueous vapour at 85°, we know that of alcohol vapour at 53°. And this multiplied by 4 ought on the above suppositions to produce 4.8.

(104.) From these laws it clearly follows, that in the case of substances which boil only at very elevated temperatures, such as mercury and sulphuric acid, the elastic forces at all ordinary temperatures ought to be extremely small; and this is found always conformable to experiment. Dalton also made experiments on the evaporation of ice, and found that it continued even many degrees below the freezing point; the tension of ice vapour being at such temperatures exactly that which calculation would assign to water, if it could so exist. This result has been confirmed by M. Gay Lussac, who extended it to below zero of Fahrenheit.

(105.) Mr. Dalton's very beautiful theory of vapour, thus confirmed by experiment, seems to prove that the phenomena of evaporation by no means require the intervention of any dissolving force in the air or gas; and, consequently, it is superfluous to make any such supposition. The true elements of all these phenomena are the tension of the vapours arising from the liquid at the temperature communicated; the tension of the vapour of the same nature existing in the atmosphere; and the mechanical resistance of the air by its inertia opposing the diffusion of the vapours. Knowing these elements from experiment, all results due to given circumstances may be calculated.

(106.) The principles developed in this section will afford explanation for many processes in the arts, and for several curious natural phenomena. It is not, however, in our power to enter so extensively upon such elucidations, as the subject from its interest might appear to demand.
It has long been remarked that the process of distillation is much retarded if the communication between the retort and the vessel in which the refrigeration takes place be through a small aperture; in this case, the current of vapour has to force a passage in opposition to the constant resistance of the body of air within the refrigerant vessel. Again, it has been remarked by M. Gay Lussac, that in the distillation of zinc from a vessel having but a small orifice, the operation does not proceed without the fused metal be actually in ebullition; but that the distillation goes on even at much lower temperatures, from a mixture of oxide of zinc and charcoal. Thus gaseous oxide of charcoal is formed, which by its expansive force carries away with it the vapours of the zinc as rapidly as they are formed, thus making room for further vapourisation, and the process is accelerated.

In those evaporations which are conducted on the large scale in several sorts of manufacture, it is found, as might be expected, that the larger the surface exposed, and the more free the communication with external air, the more rapidly is the operation performed. And as it is obvious that the pressure of a mass of vapour incumbent on the surface of a liquid must impede the process of evaporation, it is frequently advisable to allow a current of air to pass over the surface of the liquid, for the purpose of removing the vapour as fast as it is formed.

Again, we have formerly remarked (28) that thermometers of alcohol or water, if well made, so as to be quite free from atmospheric air within, might be employed for the measure of temperatures considerably above the boiling points of those respective fluids. In the dilatation of these liquids by heat, they emit freely from their surfaces, that is to say, from the extremity of their columns as much vapour as the vacant part of the tube can contain; and as this vapour can rise from the surface freely, without any effort, because it expands into a vacuum, or else into vapour already existing, we perceive that there is no reason for the formation of vapour from the interior of the liquid also. For, supposing the temperature uniform throughout the instrument, such vapour formed within the liquid could only possess an elastic force equal to that of the vapour within the void space of the stem; and besides this equal, and therefore counterbalancing force, it would have to overcome the weight of the incumbent column of liquid; this being impossible, the formation of vapour constituting ebullition does not take place in the interior. But if air were mingled with the liquid, the case becomes altogether changed; for the elasticity of that air, increased by heat, would be added to the elastic force of the vapour formed within the liquid. Thus ebullition might commence whenever the sum of these two interior forces exceeded the elastic force of the vapour within the stem, plus the weight of the column of fluid incumbent upon the nascent bubble of vapour and air; or, in short, whenever the elasticity of the bubble of air surpassed the weight of the column of liquid incumbent upon it.

A very beautiful practical application of the dependence of the boiling point of fluids upon the atmospheric pressure, has been made by the late Archdeacon Wollaston. He constructed a thermometer having but a small range of temperature, and that extending some degrees from the boiling point of water downwards, but with these degrees so large as to be capable of accurate subdivision. It is obvious, that from the diminution of atmospheric pressure in ascending a mountain, the temperature at which water boils is also diminished. Hence, it is evident, that by boiling water over a small lamp, at the bottom and top of a mountain, and carefully estimating the temperatures, the relative heights may be determined. (q.)

References from (65) to (106) inclusive.

§ 4. Incandescence.

(107.) The effects of caloric hitherto described, are those dependent upon an increase of distance between the integrant molecules of bodies. Incandescence, or, as it is sometimes termed, Ignition, seems to be utterly independent of such a mode of action. Solids are capable of it, so that they do not pass to the state of vapour, nor enter into combustion before they arrive at the temperature proper for luminous emanation. Liquids too are supposed to pass under the same law, but must be confined to prevent their assuming the state of vapour. No experiments have, however, as yet exhibited the gases in a luminous state from artificial heat, though the flash seen in the dark upon the discharge of an air-gun is a fact that ought to be well considered, before we pronounce such an extension of the law impossible. The term ignition we conceive objectionable, because it is commonly appropriated to the commencement of combustion.

Incandescence seems to be produced at one invariable temperature in the same substance, at least in the absence of other light, or in light of given intensity; it is independent of the presence of air, for it has been made to take place within a mass of melted glass; it is permanent, so long as the exciting degree of heat continues, and after having disappeared, is again renewale by a repetition of the process by which it may have been originally developed.

Absolute incandescence is preceded by an emission of red rays of light; and the temperature at which this phenomenon takes place, is supposed to be the same for all substances. Mr. Wedgwood having gilded some lines upon a piece of porcelain, luted it to the end of a tube, which was placed within a heated crucible. The substances were extremely dissimilar in their nature, but no difference could be perceived in the time at which the gold and the earthenware both became luminous. Newton estimated the temperature of a red heat just visible in the dark to be at 635° of Fahrenheit; a full red heat 752°; and absolute incandescence visible in day light to be beyond 1000°. Irvine esti
Heat.

Mr. Wedgwood placed the point of red heat visible in the dark at — 1° of his pyrometer, or 947° Fahrenheit; and he placed incandescence visible in daylight at 1077° Fahrenheit. The progress of heating first elicits the red, then yellow, and finally absolutely full white light.

Mr. Wedgwood fully proved that the same temperature which renders solids luminous, has not the same effect upon air. He passed a current of air through an earthenware tube in a state of incandescence, the air was thus conducted into a globular vessel, from which it again escaped through an opening at the top. In the side of this vessel was a glass, through which whatever passed within could be observed. The air was not luminous, and yet it was of sufficient temperature, for it rendered a gold wire incandescent, which was suspended in its current. (b.)

The incandescence produced by percussion and attrition, seem to us to fall only within the general law of a certain effect being produced by a certain increment of temperature, no matter how it may have been developed.

DIVISION II.

Chemical Effects of Heat.

The extent to which this subject will here be pursued is by no means proportionate to its importance. This Division might indeed without impropriety have been altogether omitted, but its title is retained for the purpose of clearly pointing out that which to us appears the connecting link between Physical and Chemical Science, as far as Heat is concerned.

As soon as Heat, applied to any substance, has ceased to affect its physical state only, and has commenced a true chemical action, we hold that the subject no longer falls under the legitimate consideration of this article. We have strictly confined our researches into the effects of Heat, to those which act upon the integrant molecules of all bodies; and we refer to the department of chemical science, all those effects which take place upon the constituent molecules. This latter explanation may at first sight appear inappropriate, with reference to simple substances, which possess integrant molecules only in our sense of the word. But, in truth, the instant chemical action commences, the presence of an integrant molecule of some other simple or compound substance is implied: and thus the molecule in our supposed case, though an integrant and simple one at first, becomes a portion of a constituent one, in union with others which it may have met with.

Under this view of the subject, the Chemical Effect of Heat is to produce a change in the affinities of the atoms or molecules of matter. By the influence of such a change, either in quantity or intensity, compositions and decompositions are effected: the elements of simple bodies are made to unite; or those of compound ones are compelled to separate themselves.

Substances which at one temperature may remain in contact without entering into combination, will by a change of temperature enter into intimate and permanent chemical union. Thus, at ordinary temperatures, a lump of bismuth and a lump of lead show no tendency to unite; but let both be heated in a ladle, and combination commences with the fusion of the one, even below the temperature required for the fusion of the other. In other cases, where a true chemical combination is supposed already to exist; yet the physical effects of an increase of temperature upon the elements may be so dissimilar as to produce a force overpowering that of the affinities of the bodies; and a separation is effected by removing the constituent molecules beyond the sphere of their natural chemical attraction. Of this sort of effect, the decomposition of chalk, and the separation of mercury from some of its alloys, by the application of Heat, are instances. But in the case of an alloy of gold with silver, as the constituent molecules of neither element are capable of volatilization by any Heat we can apply, no decomposition is effected.

Let Combustion be defined as it may, Inflammation differs from it in this particular, that it is combustion taking place under the form of flame. In a piece of wood that is burning, we see both inflammation and combustion; but in a piece of charcoal we observe combustion without inflammation. These are, however, chemical phenomena, and must be studied as such in a future article; wherein Heat, though admitted an important agent, is, nevertheless, only an agent in common with Light and Electricity.
CHAPTER II.

ON THE SOURCES OF HEAT AND COLD.

§ 1. The Sun.

(109.) The sun is the most obvious and unvarying source from which heat is communicated to our earth. Its action is modified in a thousand ways, but its operations and effects are ever present. To the Astronomer its light is the source from which heat is communicated to our earth. To the Physiologist relating to the nature and substance of that luminary, and confine ourselves to a brief statement of those operations which are immediately connected with our subject. How far the heat and light of the sun are separable, or the contrary; whether they be of different natures, or only modifications of the same property or substance, we do not as yet pause to inquire, but we describe the effects of the solar beam in its ordinary state.

When transparent bodies are exposed to the light of the sun, it is well known that the heating effect is greatly inferior to that which is produced upon opaque substances. Those bodies which, like coloured glasses, intercept some part of the sun's light only, have, roughly speaking, a similar partial effect upon the passage of its calorific rays; and the less the quantity of heat transmitted, the greater is the quantity absorbed by the coloured medium. Opaque bodies, which all equally and totally resist the passage of light, are not equally affected in temperature by its incidence upon them. That modification of their nature which produces in us the sensation of colour, develops in them also a corresponding difference in the absorbing power, or capability of imbibing caloric from the appulse of light. This was made the subject of experiment by Hooke, Franklin, and more recently by Sir H. Davy. Dr. Franklin placed some square pieces of cloth of different colours upon a surface of snow, and noted those for the best absorbers of caloric which sunk in most deeply by melting the snow.

Sir H. Davy exposed to the sun, one side of six copper plates, which had been painted of different colours. To the opposite side of each plate, a bit of cerate adhered, which melted at a temperature of 70° Fahrenheit. The wax melted on the coloured plates in the following order. First black, then blue, green, red, yellow, and lastly on the white. (a.) It is obvious, that this order is, as far as our sight is concerned, the reverse of the illuminating power of the reflected rays. The black copper absorbed most heat, as is proved by the experiment; and judging by our vision, it absorbed all the light. To what extent do these properties coincide?

(110.) We shall have to examine hereafter the widely different effects of coloured substances in the absorption of caloric, when radiating from a body artificially heated; but for the present content ourselves with stating, that this law seems very nearly if not quite true with the solar beam; that its calorific effect produced by direct impact varies inversely as the quantity of illuminating power reflected from surfaces differing in colour.

On this subject the following simple experiments may be cited in illustration. Cavallo found that a thermometer with a blackened bulb stood higher than one with its bulb not blackened; whether exposed to the sun's rays, the light of day, or the light of a lamp. (b.) M. Pictet also found that two thermometers, one blackened, the other not, manifested the same temperature in the dark. (c.)

(111.) Different substances acquire different increments of temperature by exposure to the sun's rays, and these depend on many adventitious circumstances. It is said that in these climates few bodies are able to manifest more than 120° Fahrenheit. M. Saussure constructed a small box, lined with cork, and charred internally, so as to be a good absorber and a bad conductor of heat. The box, enclosing a thermometer, was covered with a disc of glass. By exposure of this apparatus for a few minutes to the direct rays of the sun, the thermometer stood at 291° Fahrenheit; the temperature of the external air being 75°. (d.) With an arrangement somewhat similar, Professor Robison frequently obtained an elevation of 290° Fahrenheit, and once of even 237°. Before a bright fire the thermometer rose to 215°. (e.)

(112.) Such are the effects of a sunbeam in its ordinary state, but by the application of those processes by which its light is concentrated, an analogous effect is produced upon its calorific properties. A convex lens of diaphanous matter, or a concave metallic speculum, will by this method of condensation set fire to combustible bodies, or fuse the most refractory substances. Indeed the heat produced by such means is almost as intense as by the powers of the Voltaic pile, or by the energy of the gas blowpipe. Count Rumford proved by experiment, that this great increase of power is not the effect of any change in property from the altered direction of the rays, by thus concentrating them into a focus, but was due solely to the increased intensity of action, arising from the accumulation of numbers, thus brought to bear upon the same point. (f.)

The dissimilar calorific effects of the different parts...
§ 2. Electricity.

(113.) The instantaneous restoration of electrical equilibrium which takes place in a common discharge, has been long known as a source of caloric; and some of the most intense degrees of heat that have ever been witnessed sprung from the action of the Voltaic pile. For the agency of common electricity in the development of heat, we have but to refer our readers to the article Electroactivity, ch. vi. art. 179. Those details which are entered into there with propriety, would here be absolutely out of place.

There is, however, a very curious experiment of M. Pictet, which proves that Electricity, in addition to its immediate calorific effect by discharge, exerts a singular influence upon the communication of caloric. This able experimentalist exhausted a glass globe of 1300.199 cubic inches capacity, till the manometer within stood at 1.75 lines. In the middle of the globe was a thermometer suspended from a glass stand. The calorific effects of two lighted candles were concentrated upon the thermometer bulb, by means of two concave reflectors. The globe and the candles were all placed upon the same insulated stool. An electrical machine, standing 23 feet from the globe, had its conductor connected with a brass ring at the mouth of the globe, so that an electrical atmosphere could be kept up within the globe, and even extending some distance round it, as M. Pictet inferred from the candles burning dimly. The experiment commenced with the thermometer at 49°.8. Electricity being communicated, the thermometer rose to 70°.2 in 793 seconds. The experiment being repeated without the electricity, it required 1050 seconds to produce the same rise in the thermometer. It would seem then, that the electrified state increased the rate of the communication of caloric; though it appeared from other experiments, that the maximum temperature producible by each method was the same.

The candles were then insulated, by being placed on discs of varnished glass. In the electrified vacuum the thermometer rose from 52°.2 to 74°.7 in 1050 seconds, but in the unelectrified vacuum in 965 seconds. The maximum temperature that could be obtained in the electrified vacuum was 77°, but in the unelectrified only 86°. Hence it appears, that when the globe and candles are in electrical communication, electricity accelerates the transmission of caloric; but that when they were on separate insulators, the contrary effect of retardation was produced. (a.)

(114.) Another fact worthy of notice is mentioned by Thomson, that when metals are heated to incandescence by electric energies, they continue to evolve light longer than if heated by common fire; other circumstances remaining the same. (b.)

§ 3. Mechanical Action.

(115.) There are nominally three modes of mechanical action by which heat is developed,—percussion, condensation, and friction. The two former, perhaps, are identical, and may be considered only as differences of phrase, arising from the varied nature of the bodies submitted to experiment. Thus, percussion seems to apply but ill to the molecules of a gaseous fluid, and yet possibly the heat evolved during the condensation of that form of matter, may be justly referred to the mutual percussion of its particles. Again, condensation may not appear the most appropriate term to apply to the hammering of a metal, a process by which heat is evolved; and yet condensation is the invariable accompaniment of this action, and may possibly be essential to its production.

Friction has by some been supposed to produce its effects upon the principle of its inducing a state of momentary condensation, but of this hereafter. We are now only desirous of showing that these three modes of action are sufficiently nearly allied to each other to be permitted to fall under the same section of our article.

(116.) If a piece of iron be struck with a hammer, Percussion. the metal acquires a sensible elevation of temperature, and by repeated blows it may be made red hot. Again, in the common process of striking a light with flint and steel, the heat is evolved by percussion; and to such an extent, as to determine a chemical combination between the minute fragments of metal separated, and the oxygen of the air. These fragments are not luminous in vacuo, from the absence of the air which is essential to combustion.

The elevation of temperature produced in metals by percussion is said to be attended by condensation, that is, their density is increased. The best set of experiments on this subject has been made by Biot, Berthollet, and Pictet. The following is Professor Thomson's abstract of their memoir:

"The experiments were made upon pieces of gold, silver, and copper, of the same size and shape; and care was taken that all the parts of the apparatus had acquired the same temperature before the experiments began. Copper evolved most heat, silver was next in order, and gold evolved the least. The first blow evolved the most heat, and it diminished gradually, and after the third blow was hardly perceptible. The heat acquired was estimated by throwing the piece of metal struck into a quantity of water, and ascertaining the change of temperature which the water underwent. The following table exhibits the increase of temperature experienced by two pieces of copper from three successive blows:

<table>
<thead>
<tr>
<th>Blow</th>
<th>1st piece</th>
<th>2nd do.</th>
<th>3rd do.</th>
</tr>
</thead>
<tbody>
<tr>
<td>1st piece</td>
<td>1°.90</td>
<td>2°.46</td>
<td>1°.90</td>
</tr>
<tr>
<td>2nd do.</td>
<td>7°.30</td>
<td>3°.69</td>
<td>1°.46</td>
</tr>
<tr>
<td>3rd do.</td>
<td>1°.90</td>
<td>1°.46</td>
<td></td>
</tr>
</tbody>
</table>

"The whole quantity of heat evolved by each of these pieces of copper is nearly the same; that from the first piece being 26°.64, and that from the second 25°.95."

The following table exhibits the heat evolved from two pieces of silver treated in the same way:
HEAT.

The change in specific gravity which the metals underwent, was found to be proportional to the heat thus evolved, as appears from the following table, deduced from their experiments. The specific gravities were taken at temperature 40°.5.

Specific gravity of gold............ 19.2357
Ditto ditto annealed............. 19.2420
Ditto ditto struck............. 19.2457
Ditto silver.................... 10.4667
Ditto ditto annealed............. 10.4465
Ditto ditto struck............. 10.4638
Ditto copper..................... 8.8529
Ditto ditto struck............. 8.8898
Ditto ditto struck a 2nd time........ 8.9081

From these experiments it is obvious, that the heat evolved when metals are struck is owing to condensation. Hence, when they cannot be condensed they cease to evolve heat. These philosophers observed during their experiments, that heat or cold is propagated much more rapidly from one piece of metal to another when they are struck, than when they are simply placed in contact." (a.)

In the rolling of metallic plates, and in the drawing of wires, considerable heat is evolved; and it is worthy of remark, that after the evolution of caloric from any metal by mechanical pressure or percussion, the metal is rendered more brittle, and will not afford any more heat by a repetition of the process, until after it has been again heated in the fire. In this particular the effect of friction seems to differ, the source of heat there appears inexhaustible.

No effects have been observed from the percussion of liquids, neither can they be very subject to its influence, from the mobility of their particles. The same reasoning applies to the gases; and, as we have before remarked, the percussion they undergo when in confinement falls under the title of condensation.

(117.) Instances have already been given in which the condensation of a solid is accompanied by an elevation of its temperature; but as aeriform fluids are the most capable of undergoing that mechanical operation, so they are (in proportion to their quantity of matter) capable of exerting the most marked caloric effects.

It had been observed by others, and was confirmed by a trial before the French Institute, that a slight flash of light accompanied the discharge of an air-gun in the dark. By a rapid stroke of the piston for compressing air in the ball of that engine, a piece of prepared amadou was ignited; and if a lens be fixed in the side of the copper ball, a flash of light may be seen at each stroke of the piston. By an application of these observed facts, the condensing tinder-box was constructed. It consists of a brass tube about six inches long, closed at one end and open at the other. Into this tube there is fitted a piston, which by means of a little silk or leather well greased is made to fit the tube accurately. At the end of this piston is a small hook, made to receive a fragment of tinder. The Boletus Ignarius, a species of fungus, well beaten, steeped in a solution of nitre, and then dried, answers best. It is sold by the name of Amadou. By one rapid and violent stroke of the piston, the tinder may generally be ignited. (b.)

(118.) Desmarières has shown that atmospheric air, or oxygen gas, are the only fluids with which condensation produces this effect. If it be therefore argued, that the oxygen is in both cases essential to the combustion, it may be answered that the amadou being impregnated with nitre, renders that objection nugatory; for upon trial with amadou thus prepared the same result was obtained. Another circumstance requiring explanation, is, that if the effect depended solely upon the combustion, or combination with oxygen being determined by the condensation, phosphorus or ether ought to be kindled, which is not the case. (c.)

(119.) M. Biot, by condensation, effected the combination of oxygen and hydrogen gases, having compressed them violently by the piston of an air-gun. The heat evolved added so greatly to the expansive force of the gases, that in two out of three experiments the barrel was burst by the explosion. (d.)

Although, during the combination of gases with liquids, and with each other, great heat is evolved, and of this much is probably due to condensation, yet chemical action is so manifestly combined to produce these effects, that we reserve such instances for a future examination.

(120.) The explanations given by different authors of the development of heat by percussion and condensation, will, of course, greatly depend upon their peculiar views with regard to the nature and origin of heat. Those who do not believe in the materiality of caloric, and advocate the hypothesis of vibrations, will refer the caloric effects to the violent concussion of the particles of the bodies; and as in this article we only seek to give a clear abstract of the researches and reasonsings of the most eminent experimentalists, we select the following opinion on the contrary theory from Professor Thomson's Chemistry:

"It is not difficult to see why condensation should occasion the evolution of caloric, and rarefaction the contrary. When the particles of a body are forced nearer to each other, the repulsive power of the caloric combined with them is increased, and, consequently, a part of it will be apt to fly off. Now, after a bar of iron has been heated by the hammer, it is much harder and more brittle than before. It must then have become denser, and consequently must have parted with caloric. It is an additional confirmation of this, that the same bar cannot be heated a second time by percussion, until it has been exposed for some time to a red heat. It is too brittle, and flies to pieces under the hammer.

"It deserves attention too, that condensation diminishes the specific heat of bodies. After one of the clay pieces used in Wedgwood's pyrometer has been heated to 120°, it is reduced to one-half of its former bulk, though it has lost only two grains of its weight, and its specific heat is at the same time diminished one-third. But we can hardly conceive the specific heat of a body to be diminished, without an evolution of heat taking place at the same time. These observations are sufficient to explain why heat is evolved by percussion. It,
RAREFACTION

(121.) As increased temperature is ever the consequence of the condensation of air, so it follows in reason, and is proved by experiment, that during its rarefaction heat is absorbed, that is to say, the sensation of cold is produced. In experiments of this sort, as the mass of air operated upon, (whatever be its volume,) bears so small a proportion to the mass of the vessels in which it is confined, and the thermometer by which it is to be measured, and that the evolved heat is communicated to these bodies with rapidity, it is not surprising that the elevation produced upon a common thermometer is not great.

Dr. Cullen remarked that a thermometer remaining in the receiver of an air-pump during the process of exhaustion sank two or three degrees. Darwin says, that a fall of from five to seven degrees took place in a thermometer placed in the current of air effecting its escape from the reservoir of an air-gun, in which it had suffered condensation. It would seem, however, that these experiments are of some uncertainty, or at least require great nicety of performance to insure unvarying results; for some observations made by MM. Welter and Gay Lussac in examining the heat evolved by gases, as their volume varied under different states of pressure, are thus briefly described. "It is known that when air or any other elastic fluid is diluted by augmenting the space in which it is confined, cold is produced. The air, however, which escapes from a vessel, issuing from an orifice, under any pressure, does not change its temperature, although it dilates in issuing from the vessel."

It would seem to result from this, that heat is produced by the shock of the issuing current of air, and that heat is so much the more considerable, as the difference of pressure producing the blast is greater; so that the heat thus produced exactly compensates the cold arising from dilatation.

This fact explains the heat which is produced when air rushes into a vacuum, or into a space occupied by air in a state of attenuation. It will also explain why the blast from the pressure of the column of water at Chemnitz produces cold and freezes water; while the blast from the reservoir of the fire engine at Chaillot, where there is a constant pressure of 2.6 atmospheres, does not produce any change in the thermometer. (c.)

A more full description of the Chemnitz furnace in the mines of Hungary, or the furnace of Hiero, as it is sometimes called, may be seen in the Philosophical Transactions. (k.) A body of air is confined in a large vessel under the pressure of a column of water 260 feet in height.

The effect of sudden rarefaction is most elegantly exhibited by one of Breguet's metallic thermometers, fig. 10. If one of these be placed in the glass receiver of a condensing engine, and the whole apparatus be suffered to acquire a uniform temperature after a considerable condensation, and then the air be suffered to escape, a depression of many degrees will be indicated by the thermometer. This effect will be greater in proportion to the rapidity of the escape of the compressed air. In an experiment of this sort made by Dr. Ure, a delicate common thermometer suffered a depression of 7° only, while Breguet's sank 50° Fahrenheit. This experiment was not, however, made with a condenser, but by rapidly exhausting the receiver of an air-pump. Upon the readmission of air, Breguet's thermometer marked increased temperature 50°, and the other 7°, as at first.

(122.) For the most interesting experiments on the friction of heated bodies, we are indebted to Count Rumford, and we know not that we can present a better abstract of his results than in the words of Professor Thomson, especially as we fully subscribe to the caution implied in his theoretical reasoning on this subject.

"Fires are often kindled by rubbing pieces of dry wood smartly against one another. It is well known that heavily loaded carts sometimes take fire by the friction between the axletrees and the wheel. Now, in what manner is the heat evolved or accumulated by friction? Not by increasing the density of the bodies rubbed against each other, as happens in cases of percussion; for heat is produced by rubbing soft bodies against each other; the density of which therefore cannot be increased by that means, as any one may convince himself by rubbing his hand smartly against a heavy loaded cart. It is true, indeed, that heat is not produced by the friction of liquids; but then they are too yielding to be subjected to strong friction. It is not owing to the specific heat of the rubbed bodies decreasing; for Count Rumford found that there was no sensible decrease; nor, if there were a decrease, would it be sufficient to account for the vast quantity of heat which is sometimes produced by friction.

"Count Rumford took a cannon cast solid and rough as it came from the foundry; he caused its extremity to be cut off, and formed in that part a solid cylinder 7½ inches in diameter, and 9½ inches long. It remained joined to the rest of the metal by a small cylindrical neck. In this cylinder a hole was bored 3.7 inches in diameter, and 7.2 inches in length. Into this hole was put a blunt steel borer, which, by means of horses, was made to rub against its bottom; at the same time a small hole was made in the cylinder perpendicular to the bore, and ending in the solid part a little beyond the end of the bore. This was for introducing a thermometer to measure the heat of the cylinder. The cylinder was wrap round with flannel to keep in the heat. The borer pressed against the bottom of the hole with a force equal to about 10,000 pounds avoirdupoise; and the cylinder was turned round at the rate of thirty-two times in a minute. At the beginning of the experiment the temperature of the cylinder was 60°; at the end of thirty minutes, when it had made 960 revolutions, its temperature was 130°. The quantity of metallic dust, or scales, produced by this friction, amounted to 837 grains. Now if we were to suppose that all the heat was evolved from these scales, as they amounted to just 1/14 part of the cylinder, they must have given out 945° to raise the cylinder 1 degree, and consequently 66560° to raise it 70°, or to 130°, which seems incredible." Nicholson's Journal, ii. 106.

"Neither is the heat evolved during friction owing to the combination of oxygen with the bodies themselves, or any part of them. By means of a piece of clockwork, M. Pictet made small cups (fixed on the axis of one of the wheels) to move round with considerable rapidity, and he made various substances rub against the outsides of these cups, while the bulb of a very delicate thermometer placed within them marked the heat produced. The whole machine was of a size sufficiently small to be introduced into the receiver of
From some experiments upon the heat evolved during the friction of different kinds of wood upon each other, given in Nicholson’s Journal, it would appear that the increase of temperature is not in any ratio direct or inverse of their hardness. (h.)

Mr. Wedgwood found, that by pressing a piece of window-glass against a revolving wheel of grit, the glass became red hot at the point of friction, and gave off sparks capable of inflaming gunpowder, these then must have been particles of glass heated to redness at least. (i.)

“The heat then which appears, in consequence of friction, is neither produced by an increase of the density nor by an alteration in the specific heat of the substances exposed to friction, nor is it owing to the decomposition of the oxygen gas in the atmosphere. Whence then is it derived? This question cannot at present be answered; but this is no sufficient reason for concluding, with Count Rumford, that there is no such substance as caloric at all, but that it is merely a peculiar kind of motion. Were it possible to prove that the accumulation of heat by friction is incompatible with its being a substance, in that case Count Rumford’s conclusion would be a fair one; but surely this has not been done. We are certainly not yet sufficiently acquainted with the laws of the motion of heat, to be able to affirm with certainty that friction cannot cause it to accumulate in the bodies rubbed. This we know at least to be the case with electricity. Nobody has hitherto been able to demonstrate in what manner it is accumulated by friction; and yet this alone has not been thought a sufficient reason to deny its material existence. (k.)

One would be apt to suspect the agency of electricity in the following experiment by M. Pictet. Into one of the brass cups, formerly described, a small quantity of cotton was put to prevent the bulb of the thermometer from being broken. As the cup turned round, two or three fibres of the cotton rubbed against the bulb, and without any other friction the thermometer rose five or six degrees. A greater quantity of cotton being made to rub against the bulb, the thermometer rose 15°.” (f.)

Sir H. Davy recently contrived to melt ice by friction within an atmosphere which was not suffered to rise above the temperature of 39°Fahrenheit.

References from (115) to (122) inclusive:

§ 4. Change of Temperature, by change of Physical-condition.

(123.) Changes in the physical state of bodies are intimately connected with alterations in their inherent quantities of caloric. But in some cases the sensible temperature is altered, while in others it is not so. In the preceding chapter we have noticed many changea
produced in substances by the operation of heat, wherein caloric appears to act as a part or cause; but
here we would speak of those phenomena, which arising from other known laws of nature seem to manifest change of temperature as an effect.

Of the changes of physical state, produced by mechanical action, and of the concomitant effects with regard to caloric, we have spoken in the preceding section, and it only remains that we should here advert to a similar series of operations not so produced, but seeming to depend upon the same general laws. Those inducing elevation of temperature, i.e., the evolution of caloric, form the successive stages of transition from the gaseous to the liquid, and from the liquid to the solid state. And those during which caloric is absorbed, or the sensation of cold produced, are the successive converse operations of liquefaction and vapourisation.

The due management of such changes is, practically speaking, a source of heat; for matter in all its forms may be considered as a reservoir of caloric, and by availings ourselves of a knowledge of its habits, we may compel such changes of state, as shall promote elevation or depression of temperature at our pleasure. To enter fully in this question we ought to be acquainted with the doctrines of latent heat, but as these cannot be studied, except in a series of experiments wherein the physical change is frequently produced artificially, by the addition or abstraction of caloric; and, at other times, by its own spontaneous action may be considered a source of heat or cold, we must leave this most important question for the more ample details of a separate chapter. For the present, therefore, we only adduce some striking general illustrations of this species of action, not considering whether the changes of temperature produced be dependent upon latent heat or not.

The ordinary freezing point of water is 32° Fahrenheit; but Sir Charles Blagden managed to cool it down to 91°, and Mr. Dalton to 5° Fahrenheit, before solidification took place. But if in this state of things the water be agitated, or a morceau of ice be added, either of which will determine the instant solidification, a thermometer inserted instantly rises to 32°. Heat then was evolved by the act of crystallization.

Precisely analogous instances are afforded by preparing a hot saturated solution of Glauber's salts, which is to contain the bulb of a thermometer, and must be corked closely while still hot; it is well to avoid agitation here also. When the vessel has become cold, admit the atmospheric air by piercing the cork. Crystallization instantly takes place, and the thermometer indicates considerable elevation of temperature, so great indeed as to be sensible to the hand.

It is, in fact, no means improbable, that the effects produced during ordinary solidification and regular crystallization, ought to be considered as due to the same order of causes; that is to say, in solidification there is always more or less of tendency to the development of regular crystalline structure. At all events analogy would lead us to conclude, that the caloric evolved during crystallization may be attributed to solidification; and whether the formation of a perfectly or imperfectly crystalline structure, can influence the phenomenon, other than as it influences the resulting volume of the body, we know not.

We have seen then, heat produced by a liquid becoming solid; and in the subsequent section, wherein the presence of chemical affinity is avowedly present, we shall see a similar effect from the analogous operation of an asemen fluid passing into the liquid state.

In the converse process, during which a liquid passes to the state of vapour, or a solid to the state of liquid, as much caloric is essential to the operation, it is rapidly absorbed from the surrounding bodies, and, of course, reduction of temperature is produced. The cold excited by evaporation was observed by Cold by Wilcke and Maier, and still more accurately investigated by Cullen. He dipped the bulb of a thermometer in alcohol, and remarked that the mercury fell during the evaporation of the spirit, and returned to its original elevation after that process had ceased. Other liquids were found to produce the same effect, and this in the order of their volatility; thus, the greatest cold which he obtained was from ether. He found also, that the diminution of temperature was rendered greater by increasing the rate of evaporation. By directing a current of air upon the thermometer bulb, when moistened with water, the mercury fell 5° Fahrenheit; by using alcohol 12°, and by employing sulphuric ether it fell more than 30°.

By wrapping a piece of linen round the bulb of a thermometer, and exposing it to a brisk current of air, after it has been dipped in ether, a fall of 45° may be produced below the ordinary temperature of a room. Alcohol, similarly applied, will sink it from 50° to 31°, and water to 38°.

On this principle is a neat experiment of Dr. Cullen. Let about half an ounce of ether be put into a wide-mouthed bottle or small jar, and let a test tube of thin glass, containing eight or ten drops of water, be suspended, so that the part of the tube with the water may be just dipped into the ether. If this apparatus be placed under the receiver of an air-pump, and the air be rapidly exhausted, the ether will evaporate so rapidly as to boil, and in this process will rob the water of so much caloric, as to convert it into a mass of ice. Dr. Higgins states, that in a frosty day he produced a cold of 40° below the freezing point of water by this method. (c.) By the same process, Dr. Lescarre effected the freezing of mercury. He subsequently found that he could produce a still greater degree of cold by a similar application of a more volatile compound, the sulphur of carbon. This indeed forms the readiest method with which we are acquainted, for exhibiting a small quantity of mercury in the frozen state. It requires only to surround an elongated thermometer bulb of very thin glass with cotton wool. This bulb is to pass into the receiver of an air-pump; for which purpose a receiver, open at top, and fitted with a perforated brass plate, is extremely convenient. The cotton is then moistened with sulphuret of carbon, and the exhaustion of the receiver conducted as rapidly as possible. The freezing of the mercury is readily observed by its great and instantaneous contraction at the instant of congelation.

We are indebted to Professor Leslie for some ingenious experiments founded upon these principles. (d.) When the evaporation of a fluid is accelerated by placing it in vacuo, the vapour which is formed from it, acts by its elastic force in retarding the progress of the evaporation, and a continuance of the process of exhaustion, is necessary to remove this. Mr. Leslie obviated this difficulty by introducing some substance having a tendency to absorb the vapour.
Thus, he placed upon the plate of the air-pump a flat dish of sulphuric acid, or muriate of lime, and suspended over it the water to be frozen, in a small capsule. By either of these substances, the aqueous vapour was absorbed as rapidly as produced, and the vacuum maintained. Hence the evaporation proceeds uninterruptedly, and a degree of cold sufficient to the freezing of the water is speedily produced. In this elegant experiment a fluid is frozen by the abstraction of heat, necessary to its own evaporation.

Other and more singular substances were obtained for producing the same effects, by absorption of the aqueous vapour; such are the calcined powder of basalt, and even dried oatmeal, with many absorbent earthy bodies. Air-pumps were constructed for performing these experiments on a large scale, and exported for the purpose of obtaining the luxury of ice in India. Mr. Leslie also coated the bulb of a mercurial thermometer with ice, and suspended it over sulphuric acid, within the vacuum of an air-pump, and thus he readily effected the congelation of mercury.

(130.) We shall conclude these illustrations with the description of a most elegant little instrument invented by Dr. Wollaston, and called the Cryophorus. Fig. 17 represents a glass vessel eight or ten inches in length, consisting of two bulbs communicating by a tube. A small quantity of water is enclosed within the instrument, about as much as will fill one-third of one of the balls; and while in the maker's hands the fluid is made to boil, and the other end being instantly sealed hermetically, a vacuum is produced on cooling. For experiment, the water is all brought into one ball, and the other ball is placed in a freezing mixture, by this process the vapour in the latter ball is constantly undergoing condensation, while a fresh quantity is demanded from the opposite ball, and with such rapidity of evaporation, as to produce the freezing of the water in the ball from which it arises. It is very curious to see congelation taking place at such a distance from the point to which the cold is primarily applied.

§ 5. Variations of Temperature produced during simultaneous Physical and Chemical change.

(130.) In this department of our subject, as in many philosophical inquiries, a doubt must sometimes arise about the application of cause and effect. For we frequently learn from observation the circumstances under which some phenomenon is invariably developed; but we are not always certain that we understand the specific action of each individual agent. Artificial changes of temperature are adverted to in another part of this article, (ch. i. Div. ii.) as the means whereby certain chemical effects are produced; and, in such a case, we venture to consider heat the cause, be the source of that heat what it may. But in the section now before us, we wish to confine ourselves to those changes of temperature which may be considered as directly or indirectly the effect of chemical action.

Thus the reasons become apparent why we have assumed so comprehensive a title for this section; and all that now remains, is that we should give a selection of the most striking experimental confirmations of our position, with the most useful practical applications resulting therefrom. For the sake of simplicity we may divide the matter before us into two classes of experiments: those which produce elevation, and those which produce depression of temperature.

Let a moderate quantity of water be poured upon a mass of fresh quick lime, and a very considerable heat is evolved, far exceeding that of boiling water. For to a certain extent the two substances have the power of combining, in which process the water undergoes a physical change, and becomes a part of a dry solid body. Here vigorous chemical action is present, but the effect from the physical change alone would be the same in kind, though we know not whether it would in degree.

(131.) Let ammoniacal and muriatic acid gases be mixed together; instead of a gaseous mixture remaining, chemical combination takes place, with a great physical change also; for the new compound passes at once to the solid state, and much caloric is evolved.

(132.) A more easy mode of performing the experiment is to make use of the vapour of alcohol or ether. For this purpose, let a few drops of ether be placed in the bottom of a small glass jar, and let a coil of platinum wire, or even a piece of watch spring be tied to the end of a thin rod of wood or the stem of a tobacco-pipe. Make the metal red hot in the flame of a spirit lamp, and in that state plunge it into the atmosphere of vapour, over the surface of the ether in the jar. The metal will continue in an intense glow of heat, as long as there is any vapour to be consumed by the oxygen of the air.

(133.) A neat variation of this experiment is made by filling a wide mouthed phial with oxygen, a little ether is then to be poured in, and the experiment conducted as before; but here the wire frequently arrives at such a degree of heat, from the rapidity of the
combination, as to produce the union of the gaseous elements on a large scale with detonation.

(136.) Sometimes the platinum wire is coiled round the wick of a spirit lamp, so as to leave a few coals free above the cotton. The lamp is lighted for the purpose of heating the wire, and then blown out; the wire, however, continues its operation, and will glow as long as any spirit remains to produce vapour, and be consumed.

In the more delicate of these experiments, platinum and palladium were the only metals found to succeed. For this preeminence they were indebted to their low degree of specific heat, and the imperfectness of their conducting power. (a.)

In these cases we remark, in the first place, chemical combination, and then a great physical change, viz. condensation from the gaseous to the liquid state, as water is part of the result.

The preceding section was confined to those appreciable physical changes which were obviously independent of chemical action. Under this head there may of course be included both simple and compound substances; but the change which the latter may undergo must be confined to their integrant molecules, and must not extend to their constituent ones. Within the limits of our definition we seem to be able to refer to great calorifice effects, we fully believe, for we think it the examples already cited in sec. 4 with confidence. That chemical action alone, unaccompanied by physical effect, (if it ever so exist,) may produce great calorific effects, we fully believe, for we think it clearly proved, that heat is a frequent result of the mutual action of substances possessed of strong chemical affinities. The following are instances of this kind, wherein physical action is either inappreciable, or is by no means adequate to account for the calorific effects developed.

(138.) Let a few copper or lead filings be mixed with a little sulphur, and placed in the closed end of a glass tube; then hold the part containing the mixture over the flame of a lamp. At a certain elevation of temperature, combination will take place, and this with the appearance of vivid combustion; light and heat being copiously evolved, though the tube be removed from the flame of the lamp. The presence of oxygen is quite unnecessary to this experiment. Heat also is evolved in forming an alloy of potassium, with either arsenic or tellurium.

(139.) Again, M. Berzelius discovered in 1811, that several antimoniates with metallic base, when they are heated nearly to redness, exhibit a sudden and vivid glow of heat. He ascertained also that oxygen was not necessary to the effect, and that no change of weight was produced in these salts by the operation. Dr. Wollaston pointed out a similar phenomenon in gadolinite, and Berzelius in the oxides of chromium, tantalum, and rhodium, with many other bodies. The only appreciable change produced in all these cases, is that the substances so acted upon are rendered insoluble in those acid or alkaline menstrua to which they had been before subject.

(140.) It might at first sight appear a reasonable supposition, that whenever the chemical and physical effects harmonize together, that is, whenever by the chemical action heat is evolved, and at the same time a great condensation of volume is effected, the total calorific result would be increased. And this is true in many cases, but is directly opposed to the indisputable evidence of others. Of these modes of action we adduce the following examples.

(141.) Let one volume of oxygen gas and two volumes of hydrogen gas be united by detonation, from the effects of an electric spark, so as to form water. Here is very violent chemical action, and the passage of the whole volume of mixed gases from their original state to that of a liquid; and the heat produced is very great.

(142.) Again, if we add a lump of amalgam of bismuth to a lump of amalgam of lead, though both are originally solid, or nearly so, yet by a little trituration the whole becomes liquid, and considerable cold is produced; an effect according with the physical action, but, as far as we can tell, independent of, or even possibly opposed to, the effect of the chemical action. See also ref. (e.) (p.)

(143.) The converse case is that in which the chemical action is attended by some considerable physical and chemical action, from which latter a marked elevation or depression of temperature might be expected, and yet the change of temperature takes place in a direction immediately opposite to that anticipated by the application of a general physical law. Thus the following instances go to prove, that chemical action, accompanied with great expansion of volume, do not produce cold.

(144.) If a vessel, containing the protoxide of chlorine (euchlorine) be exposed to the sun's rays, or to artificial heat, the gas is decomposed with explosion, the volume of the mixed gases is increased in the ratio of 3 to 2, and yet light and heat are evaporated.

(145.) A similar effect is produced in heating oxide of rhodium, obtained from the soda muriate. Water is first given out, and subsequently a further decomposition takes place, by the escape of one portion of the oxygen, leaving a metallic suboxide. But during this passage of oxygen from the solid to the gaseous state, the remaining oxide is seen in a state of ignition.

(146.) The chloride of azote (azotane) is an oily looking fluid, and yet by its decomposition the gaseous elements acquire a volume 600 times as great as in the fluid state, yet light and heat are evaporated by the explosion. The extreme violence of the action, and the danger of the experiment, present however some difficulties in the way of a minute examination of the circumstances.

(147.) The nitrates and chlorates in deflagration with metallic bodies, or with sulphur, phosphorus, charcoal, &c., undergo a great enlargement of volume, and yet produce light and intense heat. The firing of gunpowder is a familiar, but striking example. It consists of nitre, sulphur, and charcoal. The detonation may be performed in vacuo, the product being for the most part gaseous, the volume in this state is many hundred times greater than in the original solid form, yet light and heat are copiously evolved.

(148.) By dissolving some pounded marble in sulphuric acid, the heat evolved is very considerable, although the evolution of carbonic acid gas must tend to produce a depression of temperature. But if caustic lime be employed, this counteracting cause is cut off, and the heat evolved becomes very considerable indeed.
HEAT.

(149.) To cite but one case more, the following experiments of M. Gay Lussac afford an example of the opposite kind of action. A mixture of volume in a liquid produced cold instead of heat.

Water and a saturated solution of nitrate of ammonia, both at temperature 61°, were mixed together in the proportions of 3376 to 4405. The original specific gravities were 1 and 1.932. After mixture the calculated mean specific gravity was 1.51. But by experiment, the specific gravity at temperature 61° was 1.159, therefore there had been a condensation, and yet the thermometer again sank 3°.9.

Again, water was added to some of the mixture formed during the last experiment; the proportions were 3364 to 3928. The density of the fluid was found to exceed the calculated mean specific gravity, and yet the thermometer again sank 3°.4. Similar results were obtained with other saline solutions.

(150.) The heat evolved during many chemical combinations may be conveniently estimated by the ice calorimeter, an instrument invented by Lavoisier, which we shall find of important service hereafter. The following is M. Biot's description of it. (b.)

Lavoisier's calorimeter "It consists of two similar metallic vessels, A B C D, A'B'C'D', the one contained within the other, and kept separate by small triangles of metal, which might with advantage be of wood or glass. The interval between these two vessels is filled with ice, broken into small fragments, and packed so as to form a complete envelope. In order to introduce this, the cover A B is removed, and afterwards replaced. It is obvious, that by taking care to constantly renew this ice, according as it melts by the heat of the atmosphere supposed above 0°, the interior vessel, A'B'C'D', and the space which it encloses will be kept constantly at 0°. But in order to this renewal, the water formed by the gradual melting must be removed; this is the purpose of a stop-cock, placed at the lower part, of the interval between the two vessels.

Again, within the interior vessel, another still smaller is suspended, A''B''C''D'', formed simply of iron net, and designed to hold the body that is to be cooled. The interval between this third vessel and A'B'C'D' is also filled with pounded ice in very small fragments, which also is introduced by removing the lid A'B'; and the water, which this latter produces in melting, flows out by a stop-cock R' into a vessel which receives it, that it may be accurately weighed. These things being premised, let us admit for a moment that the external air has no access to the interior of the calorimeter. Then, after a greater or less time, the interior will have arrived at the temperature of the exterior shell, that is to say at 0°, and will remain at that temperature without variation, as long as the exterior case of ice remains unmelting; but by introducing into the vessel A'B''C''D'' any body of a temperature raised above 0°, this body will be gradually cooled, and in the process of cooling will melt the surrounding ice, thus producing a certain quantity of water, which will flow out by the inferior stop-cock R'. If this water be collected and weighed, it will evidently be the measure of the quantity of heat disengaged by the body in cooling down to 0°.

In order to the success of this experiment some precautions are necessary. In the first place we must be careful not to make use of ice which is below zero; for the heat at first given out by the enclosed body will be employed in raising the ice to that temperature before it can melt, and thus a fallacious result is obtained. This evil is avoided by making use of actually melting, or nearly so, and by operating in an atmosphere raised one or two degrees above zero, rather than in one below that point. For then we may be sure that the temperature of the ice employed is truly 0°, as it is required to be; for it will remain fixed at that point as long as any portion remains unsettle. There is in this another advantage. We can never altogether avoid the introduction of the external air within the calorimeter, and if it were at a much higher temperature than the ice within, it would melt some appreciable quantity, by which the results would be vitiated. If, on the other hand, the air were below 0°, it must tend to lower the temperature of the ice, and thus prevent it from melting. In consequence of the slight density of air, two or three degrees of temperature in excess have but little influence, by which consideration the opportunities of experimenting are increased. But we may obtain still greater exactness if we work always at temperatures rather above zero, and provide a second calorimeter, in all respects similar to the first, and similarly charged, with this difference only, that no heated body is placed within. The quantity of ice melted in this latter will measure the effect produced by the action of the air. To render these two calorimeters strictly comparable, after having charged them, they are left to stand some time, an hour for example. The water from both is removed, and the heated body being introduced within one of them, the observations commence upon both. When the process of cooling is terminated, which may be known by the slowness of any further liquefaction, the water produced by each calorimeter is weighed, and the one being subtracted from the other, the difference will express that which is due to the sole action of the heated body introduced into the one; and for still further certainty the experiment may be repeated, alternating the calorimeters.

Another difficulty presents itself. After the close of the experiment, and the removal of the body from within, each fragment of ice remaining in the apparatus will retain upon its surface a film of water. Now this stratum of water, though very thin upon each fragment, must, from the total quantity of ice contained in the calorimeter, amount to something considerable. This is true; but if the experiment be made with the precaution before mentioned, that is to say, at some few degrees above the melting point of ice, a small film of water exactly equal, would at first adhere to the surface of each fragment of ice, at the introduction of the heated body. This film, which would be the first to flow away, would exactly compensate for that which must remain at the close of the experiment."

Mr. Wedgwood found another source of inaccuracy in the use of this instrument, namely, that after some time the water percolating through the ice again froze in the interstices at the lower part of the vessel, and thus prevented the free escape of the water which had retained its fluid state.

(151.) To measure the heat evolved in a case of chemical combination by this instrument, both the substances must be separately cooled down to 0°. We here speak of the centesimal scale, for convenience. The combination must then be made in the calorimeter, and the mixture left there to cool down to 0°. The quantity of ice melted measures the quantity of heat disengaged.
Heat.

In an experiment of this sort, MM. Lavoisier and Laplace mixed 1.5 pounds of water at 0°C with 2 pounds of sulphuric acid of specific gravity 1.8705 at 0°C. The heat thus evolved melted 3.1406 pounds of ice. If we divide this product by 3.5 pounds, we obtain 0.8973 pound, the quantity of ice melted by one pound of the mixture.

On the contrary, some substances in combining absorb caloric instead of evolving it. These must be raised to some common temperature, so high that even after their combination they shall remain above 0°C. The mixture is then made within the calorimeter, and the quantity of ice is measured which the mixture will melt in cooling down to 0°C. The mixed mass must then be again heated to 0°C, and placed within the calorimeter, noting the quantity of ice melted as before. Now it is obvious, that the difference between the ice melted in the two cases, arises from the cold produced in the process of combination. Hence, the ice melted in the latter case, minus the ice melted in the former, gives the quantity of ice which is due to the difference of effect in the two cases, and this may be divided by the total quantity of the substances, to obtain a result analogous to the former one.

To absolute measures thus obtained, we shall have to return shortly.

(152.) The physical changes then, which some or other of them are the frequent concomitants of chemical action, are solidification, condensation, liquefaction, evaporation, and combustion. Of all these, instances have been adduced, for the purpose of proving the uncertainty of any general law arising out of a physical change, when that change is combined with chemical action. But after these illustrations we come to a practical view of the subject, with reference to the specific object of this section. We have to describe to return shortly.

(153.) For elevation of temperature, that which is best known to us, and is of the readiest application, is combustion. It may be necessary here to state, that for the sake of avoiding those difficulties and conflicting opinions which arise out of the attempts to define combustion, we here use it only in its ordinary and familiar application, to provide a strict definition for that term, and to enter upon the question of what varieties of chemical action are truly expressed thereby.

(154.) Different substances enter into combustion at different temperatures; but as our present object is to consider the burning of bodies as a source of heat, for practical application, we ought to know something of their relative powers for that purpose. On this head, however, the information afforded by numerous experiments, and those performed by very distinguished philosophers, is by no means so satisfactory as we could desire. Dr. Crawford attempted to estimate the heat evolved during the combustion of given weights of certain substances, by surrounding them with water, and estimating its increase of temperature. (c.)

(155.) Lavoisier and Laplace attempted the same thing by measuring the quantity of ice melted by various substances during their combustion. These experiments were made with the calorimeter already described. To effect this purpose, it was necessary that the air within the cold enclosure should be changed, being partly absorbed or altered by the combustion. By conducting the process in an atmosphere not much above zero, the introduction of a fresh quantity of such air will bring no sensible accession of heat, and, consequently, will not vitiate the results. This renewal of air should only be made when absolutely necessary, in order that the air confined within may have ample time to part with all the increase of temperature which the combustion has communicated to it. The introduction of fresh air is easily made by a pair of common bellows, of which the pipe only passes into the chamber of the calorimeter, the valve remaining without. We might even, for greater accuracy, not force the air immediately into the calorimeter, but previously pass it into a confined vessel, surrounded with ice, so as to reduce its temperature actually to 0°C. Another tube may be employed for the casual emission of the air from within. The following experiments were made by MM. Lavoisier and Laplace with every precaution. The quantities of ice melted are expressed in decimals of the French pound.

Deflagration of 1 of saltpetre with 1 of sulphur 32.00
1 of nitre with 0.9125 charcoal 12.00

(156.) In the same manner it is obvious that experiments may be conducted for ascertaining the heat communicated to air by the respiration of animals. (d.)

(157.) Count Rumford, in a similar series of respiration searches, employed for a calorimeter a metallic vessel calorimeter filled with water of a given temperature. This vessel was made of thin sheet copper, 8 inches long, 4 inches broad, and 4 1/2 deep, fig. 19. The interior contained a worm tube of the same material, which made three horizontal revolutions, and was designed for the reception of the gaseous products, by which the water was to be heated. This circulating tube was in the form of a flat pipe, half an inch in depth and 1 1/4 inches at the mouth, and 1 inch at the other orifice. The mouth consisted of a circular tube, 1 inch in diameter, and 1 inch in depth. By this (which also extended upwards into the worm tube, so as to be a quarter of an inch above its bore) the products entered. The other extremity of the tube issues vertically near the edge of the vessel, opposite to the one where the products enter. A thermometer, having a cylindrical reservoir in length equal to the depth of the calorimeter, shows at all times the mean temperature of all the contained water. And, lastly, the whole apparatus is supported by four slight pillars of dry wood.

Now it is evident that if we burn bodies under the mouth of the circulating tube the gaseous products which result, and even the air heated by their contact, will rise into the circulating channel of the apparatus; and there, giving up the excess of their temperature above that of the surrounding water, will elevate it some degrees. In order that this operation be exact, it is essential that the combustions thus produced should be complete; this may be known by the burning body being entirely consumed, with a clear flame, without
smoke or smell. Thus, if tapers are employed they
must be weighed before and after the operation, taking
great care to arrange the flame and wick in such a
manner that there shall be no smoke. Wood may be
reduced to small billets of five or six lines in thickness,
which may be lighted under the mouth of the tube,
holding them in the hand, or with forceps; thus they
will burn with the greatest ease. In regard to the
combustion of spirits, such as alcohol and ether, it is
necessary, that the operation should be complete, to
employ certain precautions of which hereafter.

In order to estimate all the heat disengaged, we
must know the temperature at which the products issue
after they have traversed the whole tube. To ascertain
this, Rumford joined the issuing tube of the calorimeter
to the mouth of a second instrument of the same kind;
and he found that by limiting the operations in the first
calorimeter to slight changes of temperature, such as
the method described requires, the water contained in
the second calorimeter obtained no increase of tempe-
rance. Thence he concluded, that within these limits
the second calorimeter was useless, and he ceased to
employ it.

It is necessary, however, to take an account of the
quantities of calorick absorbed by the tube and sides of
the calorimeter. This may either be done by direct
experiments, ascertain ing how much a given mass of
water is heated or cooled by being introduced into the
apparatus; or else by calculation from the weight, and
the specific heat of the sheet copper employed for
constructing the vessel. Rumford having once obtained
a correction for his calorimeter, which made the water
and the vessel together equal to so much water,
constantely calculated upon that number in all his results.

But there is another source of error to be obviated,
which is that produced by progressive heating or cooling
of the apparatus, from radiation and contact in the
surrounding atmosphere. This correction Count Rum-
ford made by a method, at once accurate and ingenious.
He first brought the temperature of his apparatus to
some degrees, 5 or 6 for example, below that of the
surrounding air, the temperature of which we may call
\( t \); he then began to introduce the product on which
he wished to experiment. This, in passing through the
tube, gave out its heat, which was again shared with
the water enclosing it. As long as that water has not
attained the temperature \( t \) of the surrounding air, it
receives from the surrounding bodies more calorick than
it again transmits to them, and is, in fact, partly heated
by them. But after it has passed that temperature, the
contrary takes place; it then emits more heat than it
receives in a given time, and thus tends to heat the
surrounding bodies. If then we suppose the operation
so conducted, that as much time may be passed in one
of these states as in the other, there will be a compen-
sation in the exchanges, and the quantity of calorick
retained by the calorimeter will be exactly the same as
if it had neither received nor emitted extraneous heat.
Thus Rumford operated, and the success of his experi-
ments is doubtless due, in a great measure, to this
ingenious precaution. (c.)

(158.) The following is an example of the method
employed for the estimation of the heat disengaged by
combustion.
The mass \( m \) of the calorimeter, filled with liquid,
being in Count Rumford's experiments always = 2781
grammes of water, a wax taper carefully weighed was
placed under the mouth of the tube, and lighted. The
temperature of the air was 16.1111\( ^\circ \), that of the water
13.3333\( ^\circ \). The experiment was continued until this
temperature was brought to 18.8889; the taper was
then extinguished, and being weighed was found to
have lost 1.63 gramme. This, therefore, was the weight
of the wax consumed.

Now let \( c' \) be the quantity of calorick which one
gramme of wax gives out or produces by burning in air,
at the temperature of 16.1111; a number \( m' \), therefore,
of grammes will disengage on the same notation \( m'c' \)
of heat. This quantity introduced into the mass of water
\( m \) of the calorimeter, will raise its temperature \( t' — t \)
degrees, always calling the temperatures of the calor-
imeter at the beginning and the end of the experiment
\( t \) and \( t' \). Then if we always represent by \( c \), the quantity
of calorick capable of raising the temperature of one
gramme of water \( ^\circ \), the calorimeter will have absorbed
\( mc \) \( (t' — t) \).

Hence we ought to have

\[
m'c' = m c (t' — t)
\]

whence \( c' = \frac{m c (t' — t)}{m'} \)

a formula which will serve in all similar experiments.

By applying this formula to the example just cited
\( m' = 1.63; t' — t = 5.5555; m = 2781, \) whence \( c' =
9478.51 \cdot \text{c.} \cdot 10^\circ \). That is to say, the quantity of calorick
evolved by the combustion of one gramme of white
wax under the circumstances mentioned, would heat
one gramme of water 9478.51\( \circ \) on the centigrade scale;
or, which is the same thing, and is more applicable, it
would raise 9478.51 grammes of water one degree
upon that scale; or, lastly, it would just boil 94.7581
grammes of water taken originally at \( 0^\circ \); and if we
substitute for \( c \) its absolute value \( \gamma \), we shall find that
it would fuse 126.3749 grammes of ice at \( 0^\circ \). The
mean of three similar experiments gave 126.242. MM.
Lavoisier and Laplace obtained 110 by the ice calori-
meter.

(159.) The combustion of ether and alcohol pre-
sented great difficulties, the tendency of these liquids to
vapourisation placing always a great obstacle in the
way of complete combustion. Nevertheless, Rumford
did succeed in this by only presenting at each instant a
very small quantity of the liquid to be burnt, and keep-
ing it quite cold, almost up to the very point where its
inflammation commenced. For this purpose he con-
structed a very small lamp of thin sheet copper, in the
form of a snuff-box, in diameter \( \frac{1}{8} \text{ inch} \), and in depth
three-quarters of an inch, fig. 20. The upper part has
a small aperture \( A \), through which the liquid is intro-
duced, and which is closed with a ground metal stopper.
From the bottom of this vessel there passes a tube of
\( \frac{1}{8} \text{ line} \) in diameter, which first proceeds for a short
distance horizontally, and then rises vertically to form
the beak of the lamp. This tube is extremely thin
throughout, except at the beak, which is just thick
enough for a stopper to be made to fit it accurately, so
as to extinguish the lamp suddenly when we wish to
conclude the experiment. This accuracy of fitting is
necessary, in order that the liquid may not continue to
evaporate. Before the experiment a wick is introduced
into the tube, which for greater exactness may be made
of asbestos, in order that no part may be consumed.
After the lamp is filled, the openings \( A \) and \( B \) are
closed with their stoppers; the vessel is weighed, and,
what is the essential point, the whole is immersed in a
} line in diameter, which first proceeds for a short
distance horizontally, and then rises vertically to form
the beak of the lamp. This tube is extremely thin
throughout, except at the beak, which is just thick
enough for a stopper to be made to fit it accurately, so
as to extinguish the lamp suddenly when we wish to
conclude the experiment. This accuracy of fitting is
necessary, in order that the liquid may not continue to
evaporate. Before the experiment a wick is introduced
into the tube, which for greater exactness may be made
of asbestos, in order that no part may be consumed.
After the lamp is filled, the openings \( A \) and \( B \) are
closed with their stoppers; the vessel is weighed, and,
what is the essential point, the whole is immersed in a
Heat. mixture of ice and water, so as to be entirely covered, all but just the extremity of the beak. This done, the spout is uncovered and lighted, and after the combustion has continued a certain time the lamp is extinguished by covering up the spout as before. But in order that the flame may not grow weak during combustion, which would render the process much more slow and imperfect, it is necessary, towards the beginning, to admit a little air to the interior by removing the stopper A, so that the liquid may not be confined by the action of the atmosphere pressing upon the orifice of the lamp. This requires that the stopper A should fit into a small tube, elevated a little above the cooling mixture. By the help of these precautions, Rumford satisfied himself that he obtained complete combustion, by this very delicate indication, that no smell was perceptible. The process completed, and the lamp closed, it is removed, well wiped, and again weighed. Thus we know the loss it has sustained, that is to say the mass of liquid consumed, and the rest of the calculation proceeds as in the former example.

In the following table are collected the values of \( c' \) for a few substances, such as they result from the experiments of Count Rumford and MM. Lavoisier and Laplace. They are expressed, according to our formula, in degrees of the centigrade scale, adopting for the unit the value of \( c \) for water.

If we divide the numbers in this table by 100, we obtain the number of grammes of water at 0º which 1 gramme of each substance will boil by its combustion; and if we divide by 75, we obtain the number of grammes of ice at 0º which that combustion will melt.

(160.) Mr. Dalton's researches were principally directed towards the gaseous bodies. A bladder, which would hold 30000 grains of water, was filled with the gas, and fitted with a tube and stop-cock. A tin vessel, holding the same quantity of water, was provided, and its capacity for heat estimated, and then as much water added for a correction as might make the specific heat of the vessel and water together exactly equivalent to that of 30000 grains of water. The gas was suffered to issue from the bladder, and burned with its flame applied to the bottom of the vessel. The heat evolved was measured by a thermometer placed in the water. In this process some little heat would be lost by radiation, and by the currents of heated air passing the tin vessel. (f)

(161.) This subject occupied the attention of Sir H. Davy also, during the course of his admirable researches on flame. A copper vessel was provided, holding olive oil previously raised to the temperature of 212º Fahrenheit, for the purpose of avoiding the possible interference of aqueous vapour condensing upon the vessel. A thermometer was placed in the oil, and the flame of the burning gas issuing from a platinum jet, connected with the gas-holder, was suffered to play upon the bottom of the copper cup containing the oil. Thus the elevation of the temperature, and the quantities of each gas consumed in a given time were known; and from the latter the quantity of oxygen gas consumed could be obtained by calculation. Upon these two data Sir Humphry calculated the relative heating power of the series of gases which he examined.

All the gases issued as nearly as possible under the same pressure, and equal intervals of time were employed for each experiment.

The following table exhibits the results:
mixtures, Freezing Heat.

Appendix from Dr. Ure, No. IX. For Count Rumford's voisier, Crawfurd, Dalton, and Rumford, is given in the producing rapid combustion, is obtained. On these fuel, or some certain convenience of its disposition for mention his own very elaborate papers. (e.)

It is not, however, to these slight variations in the calorific effects of combustible bodies that we look for ordinary practical applications; but to the varied construction of furnaces, by which economy of fuel, or some certain convenience of its disposition for producing rapid combustion, is obtained. On these points see Furnace, in the Article on the applications of Science to the Arts. For another very powerful source of applied heat, see the Article Blowpipe in the Miscellaneous Division of this Work.

(162.) A general tabular view of the results of La-voisier, Crawford, Dalton, and Rumford, is given in the Appendix from Dr. Ure, No. IX. For Count Rumford's results, referring to different woods, we can only again mention his own very elaborate papers. (e.)

(163.) It is not, however, composed of snow or ice mixed with solid salts, and by these very great reductions of temperature are obtained.

"In conducting the process of artificial refrigeration, a number of circumstances require to be attended to, in some measure varied according to the kind of freezing mixture that is to be used. In obtaining cold from the solution of salts in water, or in acids, it is necessary that the salts should be fresh crystallized, neither efflorescent nor humid, and reduced to fine powder; the material ought to be quickly and thoroughly mixed; the vessel should be just large enough to contain the mixture; and the vessel in which the substance to be subjected to refrigeration is contained, ought to be of glass, and thin. In employing mixtures of snow with acids or salts, the snow should be loose, dry, and, if possible, newly fallen; the quantities of materials should be mixed at once in due proportion, and as quickly as possible. If muriate of lime be employed it should be dry and in fine powder. Lowitz and Walker both direct that it should be in that state in which it is crystallized with the largest quantity of water of crystallization, by putting its solution to cool, when of the density of 1.5 or 1.53. In cooling the materials, where this is requisite, they ought to be put into separate glass or tin vessels, placed in a freezing mixture of the requisite power; but care must be taken not to cool them beyond that point at which they act upon each other; or, in other words, near to that at which the liquid resulting from their mutual action congeals. Lastly, the due proportion of the ingredients should be

It is remarked, however, by Sir Humphry, that these ratios can only be considered as approximations to the truth; as there are unavoidable sources of inaccuracy in the experiments. For instance, charcoal was deposited upon the bottom of the vessel, both from coal gas and from the olefiant gas, and sulphur from the sulphuretted hydrogen. (g.)

When salts are dissolved in acids more or less diluted, still more intense degrees of cold are produced, owing to the solution proceeding more rapidly. Sulphate of soda added to nitrous acid, diluted with one part of water, produces a fall of temperature from 51 to — 1, and so of many others.

It has long been known that ice or snow added to acids dissolves quickly, and during its solution produces considerable cold. This was remarked by Boyle, and by persevering in such methods, mercury was first frozen by Braun at St. Petersburg. (k.) According to Lowitz, when the acids are undiluted the muriatic is most effectual. (l.) The most powerful of these mixtures are, however, composed of snow or ice mixed with solid salts, and by these very great reductions of temperature are obtained.

As water though saturated with one salt, will dissolve a portion of a second, and even of a third, it is possible, by adding two or more salts to water, to obtain a greater cold than from the solution of one. By this method Mr. Walker produced degrees of cold which before had not been obtained without the assistance of ice. (i.)
observed; for any considerable excess of either, merely communicates caloric to the mixture during refrigeration and so far diminishes the effect."

The phenomenon of freezing mixtures was explained by Irvine, (m) on the general principle of the absorption of caloric which attends the rapid liquefaction of the materials, arising out of their chemical action; and is ultimately to be referred to the enlargement of capacity consequent on that change of form; the cold produced being greater as the capacity is more enlarged.

"Thus we may in some measure predict what substances are best fitted, by their mutual action, to produce cold; what degree of cold may be expected from their mixture in any given case; what will be the maximum of refrigeration; and what will be the best proportions of the materials to obtain that maximum.

"It is obvious that those substances will produce the greatest cold, which by mutual action produce the most rapid solution; which, during that solution, suffer the greatest augmentation of capacity; and which form a solution that at low temperatures remains liquid. There is, perhaps, no individual mixture in which all these circumstances are present to the greatest extent; yet the knowledge of them enables us to point out the respective powers of the different mixtures which are employed.

"Thus, in the solution of a salt in water, there is merely the gradual transition of the solid to the fluid form; hence, the cold produced is not considerable. When two salts are mingled together, these, by their reciprocal action, both accelerate the solution of each other, and enable a given quantity of water to dissolve a greater quantity; as more solid matter, therefore, passes to the fluid state, and passes more quickly, a greater portion of caloric is absorbed, and a greater degree of cold is produced. The attraction of acids to water, or, to state it more correctly, to the solid matter of water, is strong, and their mutual action is energetic; ice too is a substance which, in its transition to fluidity, suffers a very considerable augmentation of capacity; hence it may be concluded, what experiment proves to be just, that from the action of acids on snow or ice, a great degree of cold will arise. Lastly, in the mixture of two solid substances, which by mutual action pass to fluidity, the enlargement of capacity must be greater, and a greater diminution of capacity produced. It is so, in fact; at the same time there is a limit placed to it, from two solids acting with greater slowness than a solid and fluid do; the transition to fluidity is therefore more gradual, and the caloric not so rapidly absorbed. Hence the cold which is produced in these cases is not equal, as Blagden observed, to the cold arising from the solution of the salt in water, added to the cold that would also arise from the sudden liquefaction of the ice. This is the reason why mixtures of acids with snow or ice are often equal to the mixtures with solid salts; because, although in the latter case more matter passes to the fluid form, in the former a given quantity is liquefied more rapidly. And those salts which produce the greatest cold are those which exert the strongest attraction to water, and act on it most rapidly, as potash and muriate of lime.

"There is another principle to be attended to, which in these mixtures modifies the quantity of caloric absorbed from the liquefaction. Although the indirect consequence of the chemical action between the substances mixed is absorption of the caloric, in conse-quence of the liquefaction it occasions, yet its direct tendency is to evolve caloric by the increase of density which it occasions, independent of change of form. Hence two effects arise from the mutual action of the ingredients of freezing mixtures; evolution of caloric, as the result of the combination, and absorption of caloric, as the result of the liquefaction to which the combination gives rise; and the ultimate effect is compounded of these, so that the actual change of temperature is only the excess of one over the other.

"It may even happen, that the one shall exactly counterbalance the other; of this is an example in the solution of sulphate of soda in alcohol, which produces neither heat nor cold; or, it may happen, that the heat from condensation shall exceed the cold from liquefaction, as in the solution of potash in water."

The general principle now stated is exemplified in the action of acids on ice, and, as applied to this case, is clearly stated by Laplace: "If the mixture of an acid, with a given quantity of water, produce heat; in mixing that acid with the same quantity of ice, it will produce heat or cold, according as the heat which results from its mixture with water is more or less considerable than that which is necessary to melt the ice." (n.)

On this principle many of the facts connected with the operation of freezing mixtures are explained. Thus we perceive why concentrated sulphuric acid poured on snow or ice produces at first heat instead of cold; the action is so energetic, that the caloric evolved from the combination is superior to what is absorbed by the liquefaction. But when the acid is combined with a portion of water, its affinity being thus weakened, its action is less energetic, and less augmentation of temperature attends their union. Hence, in the progress of the experiment in which the concentrated acid is poured on snow, although heat is at first produced it is soon succeeded by cold; or if the acid has been previously diluted with a portion of water, it will, when added to the snow, immediately produce cold. Even nitric acid, as Cavendish observed, produces at first a degree of heat when added to snow; but when diluted with one-fourth of water, it immediately occasions cold. The requisite dilution is, therefore, less in nitric than it is in sulphuric acid, and it is still less in muriatic; and we perceive the reason of this,—these acids evolving less caloric when they combine with water than sulphuric acid does, and therefore counteracting less the cold from the liquefaction. And, lastly, if the dilution of the acid be carried too far, its attraction may be so much weakened, that its action on the snow will be feeble, the liquefaction will be slowly performed, and no great cold will be occasioned.

In the other kind of freezing mixtures, there can be no doubt that the same circumstance operates. The heat from combination always counteracts the cold from liquefaction; it is only the excess that prevails, and in no case is the whole reduction of temperature that would arise from the liquefaction of the quantity of matter employed, obtained. This explains the fact, that crystallized salts produce more cold than the same salts deprived of their water of crystallization; as by its presence the mutual action of the salt and the substance mixed with it is rendered less energetic, and therefore less heat is evolved from the combination; and, probably, water, in becoming liquid, suffers a greater enlargement of capacity than a salt does; which will
HEAT.

increase the refrigerating power of the crystallized salts.

From these observations it follows, that the greatest cold will be from the mutual action of substances which pass most quickly into the fluid state, and which in that transition have their capacities most enlarged. But as this rapid action is the result of an energetic affinity, this may counteract, by the evolution of caloric to which it gives rise, the cold that would be produced. In all cases, therefore, there will be a certain state of concentration of the materials, and a certain proportion of them, from which the greatest cold will be obtained.

It may be remarked too, that we do not obtain the reduction of temperature to the lowest point in the thermometrical scale from those mixtures which, during their mutual action, absorb most caloric. If we take two freezing mixtures at 32°; the one, for example, muriate of lime and snow, the other diluted sulphuric acid and snow, the former will produce more cold than the latter, it will sink the thermometer to — 40° or — 50°, while the other will sink it to not more than — 25°. But we may reach a lower point in the scale of temperature by successive applications of diluted sulphuric acid and snow, than we can do by muriate of lime and snow; for, past a certain temperature, the latter mixture does not liquify, but, on the contrary, were it liquid would become solid, while the former remains liquid at lower temperatures than this. If we cool, previous to mixture, muriate of lime and snow to — 73°, no advantage is gained; for they cannot produce a temperature lower than this, as their combination cannot exist liquid below that point; and even by approaching closely to it before mixture, we diminish their mutual action by adding to the cohesion of each. But by previously cooling diluted sulphuric acid and snow, an important advantage is gained; the same limit is not placed to their mutual action, and the lower the temperature is reduced, it is obvious that the lower will the temperature be that results from their mutual action, down to the point at which the liquid formed by the action of the acid on the snow congeals.

The cold, therefore, from a freezing mixture, can never exceed that point at which the liquid resulting from that mixture congeals or crystallizes, and must indeed always be a degree or two above it. A saturated solution of sea-salt in water congeals at a few degrees below 0 of Fahrenheit; and hence the cold resulting from that salt mixed with ice is never lower than this. This gives us the reason why sulphate of soda scarcely produces any cold when mixed with ice, as it lowers the freezing point of water only a few degrees, while potash or muriate of lime produce intense colds, as they lower that point to a much greater extent. It also, in some measure, determines the proportions in which the substances should be mixed; those being best, in which the action shall be most rapid, without being too energetic to evolve heat from the combination; and in which the resulting solution is of that strength that is least liable to congeal or crystallize. A little sea-salt added to water depresses its freezing point only a few degrees; and, therefore, to add a small portion of it to snow, cannot produce much cold; while, when added until the water is saturated, that is in the proportion of 1 of salt to 24 of snow, the freezing point is lowered to — 6°; and, therefore, by adding in it that proportion to snow, nearly that temperature is attained. (h.)

For the tables of freezing mixtures, see Appendix, Nos. X., XI., XII.

References from (130) to (165) inclusive

(166.) In this chapter we propose to consider certain properties of heat, which if they do not depend upon any such actual state of existence, are at least capable of description and explanation with great convenience, on the supposition that heat is a fluid, the particles of which are endowed with a prodigious idio-repulsive force, and move in right lines with unmeasured velocity in appropriate media, wherein no resistance is opposed to them. It is obvious that the most simple case to be considered is the motion of heat in free space; and the circumstances under which we obtain the nearest approximation to these conditions for the purposes of experiment, are those of a heated body placed either in a vacuum, or in some aeriform medium. Boundless space is in this case not attainable, but the enclosing substances, such as the walls of a room, &c., may be at such a distance as produce no appreciable effect upon the cooling of the heated body. The case of the heated substance in contact with either a solid or a liquid, is more particularly considered in Chapter IV., because there we say the heat is chiefly conducted by a motion from particle to particle in succession, though this may not be the case altogether. The free motion of heat above described, is called its Radiation.

(167.) The reflection of heat is readily explained by the well known reflection of light; for it is found that the rays of heat which impinge upon various substances are reflected back again under certain laws.

(168.) The refraction of heat is a term of precisely the same import as when applied to the rays of light.

(169.) The polarization of heat is also precisely analogous to its corresponding term in optical science.

(170.) The absorption of heat implies that power which substances possess of retaining the heating rays which impinge upon them, and thereby acquiring an elevation of temperature.

Some other terms connected with this branch of our subject have been made use of by M. Fourier, and even admitted as elements in his formula. We have made little use of them in these pages, because there is a need of some experiments for the establishment of their importance, and indeed without which they are useless in a treatise like the present, professedly founded upon experiment alone. Still we admit that when such researches shall be undertaken, we are disposed to think that the properties themselves will not be found unimportant.

By penetrability, M. Fourier understands the power of entering in or issuing out through a surface; this he considers to vary with the nature or state of the substance. Permeability he applies to the power of traversing the interior of a body. Of the symbol expressing this property, he says he has used it as constant, in the absence of experiments to prove the contrary, though it seems to change more than even capacity. "Penetrability of surface depends," says he, "upon two different qualities: the one has reference to the ambient medium, and expresses the facility of communication by contact. The other consists of the property of admitting or emitting radiant heat. As to specific permeability, it is peculiar to each substance, and is independent of the state of the surface."

(171.) We have already said that we consider the heating or cooling of the body in comparatively free space, as the simplest case to enter upon; and after mature consideration, upon the best mode of undertaking this task, we find it impossible to do better than to present to our readers that portion of a memoir by MM. Dulong and Petit which relates to our present inquiry. This admirable paper, which obtained for its authors the prize from the French Institute, comprises all that we feel a confidence in upon this subject. In saying this, we by no means wish to undervalue the able researches of our distinguished countryman, Professor Leslie, nor those of M. Biot, to whom every branch of science is under the deepest obligation; but the extension of the Newtonian law has it seems deceived the former, and though M. Biot has avoided that danger, of which he was fully aware, and has made some excellent experiments on this very point, yet we feel that to do justice to this subject, our extract from MM. Dulong and Petit will be of such length as to preclude all other matter; but with this assurance to our readers, that we have nothing of equal value to communicate in its place.

On the Laws of Cooling.

(172.) The first views relative to the laws of the communication of heat, are to be found in the Opuscula of Newton. (a.) This great Philosopher admits, à priori, that a heated body exposed to a constant cooling cause, such as the uniform action of a current of air, ought to lose at each instant a quantity of heat proportional to the excess of its temperature above that of the ambient air; and that, consequently, its losses of heat in equal and successive intervals of time, ought to form a decreasing geometrical progression. Kraft, and after him, Richmann, (b,) endeavoured to verify this law by direct experiments on the cooling of liquid masses. These experiments, afterwards repeated by different philosophers, prove that for differences of temperature not exceeding 40 or 50 degrees, the law of geometrical progression represents pretty exactly the rate of cooling of bodies.

In a dissertation, little known, on several points of the theory of heat, published in 1740, and, of course, several years before Kraft and Richmann published their researches, Martine (c) had already pointed out
Fourier, on the laws of the distribution of heat, the Chap. III. reason is, that all the results of his analysis are deduced from the law of Newton, admitted as a truth founded on observation, while the sole object of our experiments is to discover the law that ought to be substituted for it. But the very remarkable consequence to which this profound mathematician has been led, will preserve all their precision in the circumstances, and within the limits in which the Newtonian law is true, and to extend them to other cases, it will be sufficient to modify them conformably to the new laws which we shall establish.

On Cooling in general.

When a body cools in a vacuum, its heat is entirely dissipated by radiation. When it is placed in air, or in any other fluid, its cooling becomes more rapid; the heat carried off by the fluid being in that case added to that which is dissipated by radiation. It is natural, therefore, to distinguish these two effects; and as they are subject in all probability to different laws, they ought to be studied separately. We shall examine then successively the laws of cooling in a vacuum and in elastic fluids.

But as the plan which we have followed in each of these researches is founded on the same principles, it will be proper to explain these principles in the first place.

The most simple case of cooling, will be that of a body of so small a size that we may suppose at every instant all its points at the same temperature. But to arrive at the object which we proposed, the discovery of the elementary law of cooling, it would have been an useless complication to the question, and would have rendered it almost incapable of solution to have observed, in the first place, the rate of cooling in solid bodies; because in that case the phenomenon includes an additional element, namely, the interior distribution of the heat, which is a function of the conductivity. Obliged by the nature of the problem to have recourse to liquids, the mercurial thermometer itself appeared to us the body best adapted for these experiments. But as it is necessary to be able in observations at high temperatures to give to the body on which the experiment is made such a size that the cooling shall not be too rapid for following its rate with accuracy, it was necessary, in the first place, to examine what influence the greater or smaller mass of liquid, contained in the bulb of the thermometer, had upon the law of cooling. It was not less important to examine whether that law depends on the nature of the liquid, or on the nature or form of the vessel in which it is contained. These first comparisons were the object of a series of experiments which we shall state, after having explained the uniform mode of calculation which we always employed, in order to render our results more easily comparable.

Suppose we observe at given intervals of time, every minute for example, the excess of temperature of a body above the surrounding medium, and that for the times 0, 1', 2', 3', &c. . . . . t' the excesses are A, B, C, . . . . T.

If the law of geometrical progression held good, we should have B = A m, C = A m², m being a fraction which would be different for different substances. This
law never holds exactly, especially when the temperatures A, B, C, are high. But it is clear, that we may always represent a certain number of the terms by an expression of the form $A m^{s} + \beta t^{2}$, by determining properly the coefficients $m$, $\alpha$, $\beta$, and by means of that formula, we may calculate very nearly the value of the time $t$, corresponding to any excess of temperature $T$, provided that this excess be comprehended in the portion of the series which has served for interpolation.

This same expression gives us the means of determining the rapidity of cooling corresponding to each excess of temperature; that is to say, the number of degrees which the temperature of a body would sink in a minute, supposing the rate of cooling uniform during that minute, we have, in fact, for that velocity,

$$\frac{dT}{dt} = (\log m) \cdot T \cdot (a + 2 \beta t)$$

This quantity must always exceed the real loss of temperature during the time, since the rapidity of cooling diminishes during its whole duration, how short soever it may be. It was not, as may easily be conceived, to correct the small difference of which we have just spoken that we employed this process. But it is obvious, that when a series is divided into several parts, represented each by empirical formulae, which correspond, as exactly as possible, with the numbers observed, the velocity of cooling deduced from these formulae for the different excesses of temperature, are always free from the uncertainties and inaccuracies which the crude results of the observations present.

Let us return now to the first comparison, of which we spoke a little ago, and for this, let us examine how the velocity of cooling has varied in the three series, the calculated results of which are contained in the following table:

<table>
<thead>
<tr>
<th>Excess of temperature above the air</th>

The first column contains the excess of the temperature of the thermometers above that of the surrounding air. The second exhibits the corresponding velocities of cooling of the thermometer A, the diameter of whose bulb was about two centimetres. These velocities were calculated from the observations by the method explained above. The third and fourth columns exhibit the velocities of the cooling of the thermometers B and C, calculated in the same way for the excess of temperature indicated in the first column. The diameter of the bulb of the thermometer B was about four centimetres; that of the thermometer C about seven.

A simple inspection of this table shows us at once the inaccuracy of the law of Richmann; for we see that the velocities of cooling increase according to a more rapid progression than the excesses of temperature. Now if we take the ratios of the corresponding numbers in the second and third columns, we shall find that they have varied as follows, beginning with the terms which correspond with the greatest excess of temperature:

These numbers, which differ very little from each other, and which are alternately greater and less, form us that the rate of cooling follows the same law in the two thermometers A and B. If we compare in the same way the numbers contained in the second and fourth columns, we obtain for their ratios,

3.78... 3.81... 3.80... 3.80... 3.77.

The near approximation to equality in these numbers shows us that the law of cooling is likewise the same for the thermometers A and C; for the differences in the preceding numbers must be ascribed to unavoidable errors in the experiments, and they are owing to inaccuracies merely of one hundredth of a degree in the velocities. We are entitled to conclude, from what precedes, that the law of cooling observed in a mercurial thermometer is independent of the size of its bulb; and, consequently, that it is the elementary law of cooling of which we are in search, or in some measure, the law of cooling of a point.

We have not examined how the velocity of cooling varies with the extent of surface, in consequence of the little precision of measurement of which the surface of a ball of glass, blown at the extremity of a tube, is susceptible; and because that research was foreign to the object which we had in view. However, it will be seen from the approximate measures which we have in view of the diameters of the bulbs, that the velocities of cooling are nearly inversely as the diameters, as would be the case with a solid sphere of indefinitely small size.

Let us now proceed to the examination of the influence which the nature of the liquid in the vessel may have upon the law of cooling. There the difficulty of constructing thermometers with liquids different from mercury (a difficulty depending upon the uncertainty which still exists respecting the laws of dilatation of these bodies) determined us to observe the cooling of these liquids enclosed in the same glass mattress, in the centre of which was placed a very sensible mercurial thermometer. We even ascertained that the position of the thermometer is indifferent, and that at any given instant the temperature of all the points of the mass is sensibly the same. This evidently depends upon the interior conductivity, which in liquids is the result of the currents being nearly perfect, at least for masses of the size of those which we employed.

The first of the following tables contains the velocities of the cooling of mercury and water compared; the second exhibits a similar comparison between mercury and absolute alcohol; and the third between mercury and concentrated sulphuric acid.
The ratios inserted in the last columns of these tables show us that the law of cooling is the same for the four liquids compared; for the small irregularities in these ratios proceed evidently from uncertainty in the observations, and, besides, to make them disappear, it would be sufficient to alter the values of the velocities observed, by quantities which scarcely amount to the hundredth of a degree.

Now if liquids so different in their nature, their density, and their fluidity, exhibit laws of cooling absolutely similar, is it not natural to draw the same conclusion to which we were already led by a comparison of the cooling of unequal masses? That, within the limits of our observations the cooling of a liquid mass is subject to the same law as a body of indefinitely small dimension. It remains now to examine the influence of the nature and shape of the vessel.

We, in the first place, compared the cooling of two spheres, the one of glass, the other of tin plate, both filled with water. (The diameter of the tin plate sphere was a little greater than that of the glass sphere.)

Here the ratios in the fourth column vary always the same way, and show us that the law of cooling is more rapid in the tin plate sphere than in the glass sphere. Mr. Leslie obtained the same result, which he has generalized by admitting that this law changes with the nature of the body, and that it is most rapid in those bodies which radiate least. This proposition is true in the portion of the scale to which Mr. Leslie's experiments were confined; but, by a very remarkable casuality, the contrary effect takes place at high temperatures, so that when we compare the laws of cooling of two bodies with different surfaces, that of the two laws which is most rapid at the lower part of the scale becomes the least rapid at high temperatures. Thus, in the series given above, the ratios inserted in the last column diminish in proportion as we consider greater excesses of temperature; but they would again augment if we were to extend the series further; and, as is the case with all quantities which change their sign, these ratios remain nearly the same during a considerable extent of the thermometric scale. This is one of the most important points of the theory of cooling. If we do not deceive ourselves respecting the accuracy of our observations, a very simple explanation will be found in the subsequent part of this memoir of this remarkable fact, which can only be observed by making experiments, as we have done, on the cooling of bodies raised to a high temperature.

It is because they did not follow this plan that Messrs. Dalton and Leslie have obtained such inaccurate results respecting this question. The first led away, without doubt, by the notion that the law of Richmann is verified in his thermometric scale, and not having compared the cooling of different surfaces for a sufficiently large interval, has been led to suppose that the law of cooling is the same in all bodies. And Mr. Leslie, who had remarked that the law changes with the nature of the surface, not having included in his experiments temperatures sufficiently high, concluded that the difference which he observed always increases as we advance in the thermometric scale. This has led him to consequences very far from the truth, respecting which we shall have occasion to make observations in the sequel. We shall merely remark, in expressing our surprise, that Mr. Leslie, whom the influence of the nature of the body on the law of cooling did not escape, and who had concluded in consequence that the law of Richmann must be inaccurate, has nevertheless made use of this in most of his experiments. We terminate these preliminary researches by examining the cooling of water in three vessels of tin plate of the same size.

The first spherical; the second cylindrical, having a height equal to twice the diameter of its base; and the third likewise cylindrical, but having a height equal to half its diameter.
The law of cooling remains the same for the three vessels of different shapes, as appears by the ratios of flatsurface, which is rendered horizontal by means of an introduction, and which constituted the basis of the researches which we are now going to explain.

**Apparatus destined for Experiments on Cooling.**

The bodies whose cooling we observed were (conformable to the principles just explained,) thermometers of such a size, that the diminution of their temperature could be observed with precision.

We constructed two of them; the bulb of one of which had a diameter of about six centimetres, that of the other, of two. The first, containing about 3 lbs of mercury, served for observations at a high temperature. The smaller one was employed for low temperature, in order to shorten the duration of the experiments. It was easy to deduce from the results given by the last, those which would have been given by the large one, if the series of its cooling had been prolonged. For that purpose, it was sufficient to commence the observations with the small thermometer at a higher temperature than that at which the large one had terminated. By determining, then, the ratio of the velocity of the cooling of this last to that of the small thermometer for a common excess of temperature, we obtained the number by which it was necessary to multiply all the results given by the small thermometer to obtain the corresponding velocities of the other.

These two instruments, constructed with all the care possible, did not differ from common thermometers except in this particular, that the tube on which the degrees were marked was separated from the bulb by an intermediate tube, the calibre of which was very small. We shall see immediately the motive of this construction.

The experiments on cooling in a vacuum, with which we had to commence, required that the thermometer could be transported into a pretty large space, in which a vacuum could be made very rapidly. It was necessary, also, that the surface which surrounded the thermometer on every side should be maintained at a known temperature; and as it was requisite that the same apparatus should serve for observing the cooling in air and in gases, it was requisite that the gases should be introduced into it in a convenient and prompt manner. All these conditions were satisfied by the following construction. The enclosure in which the cooling takes place is formed of a large, thin, copper balloon **M'M'M'** (fig. 21,) whose diameter is about three decimetres. The neck of this balloon is ground at its upper part, so as to be terminated by a perfectly flat surface, which is rendered horizontal by means of a level. This balloon is plunged almost completely into a large wooden cylindrical trough full of water, in which position it is kept by the strong cross beams. It is evident that the sides of this balloon, being very thin and very good conductors, must assist constantly the temperature of the surrounding water, and being covered with a lamp black they cannot reflect any sensible quantity of the heat sent to them from the thermometer. Besides this effect, if it were to take place, would increase almost as much as the loss of heat of the body, so that the error produced would affect equally all the results. It was easy to raise the temperature of the surrounding medium, by passing vapour into the water through the tube **S'U'V,** plunging to the bottom of the liquid. The orifice of the balloon is shut by a thick plate of glass **A B,** ground with the greatest care upon the edge of the balloon itself. The surfaces in contact have besides, in consequence of the thickness of the neck, a sufficient extent, so that the interposition of a small quantity of hog's-lard renders the contact very close, and prevents all external communication.

This plate is perforated at its centre by a circular opening, into which a cork is fitted, which contains the tube of the thermometer; and the intermediate tube, **C O,** is of such a length that the bulb is precisely in the centre of the balloon. By giving this intermediate tube a very small diameter, the quantity of mercury without the bulb is diminished, and the swelling which takes place at the commencement of the scale enables us to fix the tube more firmly in the cork. Thus the thermometer is fixed in the plate, and this disposition is shown particularly in fig. 22, where the bulb of the instrument is placed above the furnace which serves to heat it. The screens, **A A',** are leaves of tin plate separated from each other, which serve to screen the plate **A B** from the action of the heat.

Let us now return to fig. 21. The stem of the thermometer, which is without the balloon, as is evident from the figure, is covered by a hollow tube, **S T;** the ground bottom of which is applied to the upper surface of the glass plate. This kind of vessel is terminated above by a stop-cock, to which is cemented the end of the very flexible leaden tube, **D E F.** The other extremity of this tube is fixed to the plate of an air-pump, **H K.** The canal, which in this machine makes the communication between the centre of the plate and the barometer, is connected with another tube with a stop-cock, to which is cemented a tube filled with muriate of lime. It is through this tube that the gas passes by way of the bent tube, **m n p r.** The glass air-holder being movable up and down, enables us to make the elasticity of the gas introduced the same as that of the atmosphere.

We shall now describe our mode of proceeding in each experiment.

The water in the trough being brought to the requisite temperature, and the thermometer fixed in the glass plate being heated to nearly the boiling point of mercury, it was transported rapidly into the balloon. The glass **S T,** already cemented to the leaden tube, was then drawn over the stem, while the surfaces in contact were carefully luted, an assistant rapidly exhausted the balloon by means of an air-pump. The communication between the balloon and the glass tube was rendered very free by the openings **a** and **b,** made in the plate near the central opening.

If the cooling was to be observed in vacuo, the process was stopped when the machine ceased to dilate the air, and we measured immediately the tension of
HEAT.

277

Heat. what remained in the balloon. The stop-cock was then shut, and the observations commenced. When the experiment was to be conducted in air, that of the balloon was at first dilated, in order to facilitate the contact of surfaces, and then the proper quantity was allowed to enter. When the cooling was to be observed in a gas, the balloon was first emptied of air, gas was then allowed to enter, and a vacuum was again made; after which the requisite quantity of gas was introduced. By this contrivance it was mixed with only an inappreciable quantity of air.

We shall terminate this description by saying, that the dimensions of the thermometer had been calculated so that the observation of the cooling could begin at about 300°. The experiments in air and in the gases require rather a long preparation, and cannot be commenced with safety till the equilibrium is restored through the whole extent of fluid. The series of observations belonging to them commence at about 250°.

The experiment for cooling in vacuo, or in gases, being thus prepared, it remained merely to observe the rate of cooling by means of a watch with a second's hand at instant of time. But these temperatures require two corrections, which we shall point out. In the first place, it is obvious, from the nature of our apparatus, that after a short time the stem of the thermometer was cooled down to the temperature of the surrounding air. Every temperature observed, therefore, was too low by a number of degrees equal to that to which the mercury in the stem would dilate, when heated from the temperature of the surrounding atmosphere to that of the bulb. This correction was easily calculated, and was applied to all the temperatures observed. The object of the second correction was to reduce the indications of the mercurial thermometer to that of the air thermometer; for this we employed the table given in art. 57.

Having thus obtained a series of consecutive temperatures of the thermometer, it only remained to apply to that series the mode of calculation which we have explained above. We divide it then into two parts, which were represented each by expressions of the form \( m t + n t^2 \) in which \( t \) denotes the time; and these formulas served to calculate the velocity of cooling for the different excesses of temperature; but these velocities required a diminution easily determined in each case. That it may be conceived in what this consists, we must remark, that the cooling of the bulb of the thermometer, arising from the loss of heat which takes place at the surface, is always a little augmented by the entrance of cold mercury from the stem of the thermometer. But the volume of mercury being known, and likewise its temperature, it was easy to estimate exactly the amount of this correction, which, though very small, ought not to have been neglected.

Such is the mode which we always followed in conducting all our experiments. We satisfied ourselves with determining the velocity of cooling for excesses of temperature differing from each other by 20 degrees. And that we might not make this memoir too tedious, we have withheld all the intermediate calculations which led to our determinations.

We shall now enter upon a detail of our experiments; stating them in the order in which they were made.

Our preliminary researches having made us acquainted with the influence of the nature of the surface upon the law of cooling, it was necessary to study that law under the different states of the surface of our thermometer. Chap. III.

But it was necessary, likewise, that these surfaces should not experience any alteration from the highest temperatures to which they should be exposed. The only two which appeared to us to answer this condition, are surfaces of glass and silver. Accordingly most of our experiments were made, first preserving to the thermometer its natural surface, and then covering it with a very thin leaf of silver. These two surfaces possess, as is known, very different radiating powers, glass being one of the bodies which radiate most, and silver of those which radiate least. The law to which we have arrived, by comparing the cooling of these two surfaces, are of such simplicity, that there can be no doubt of their being applicable to all other bodies.

On Cooling in a Vacuum.

The observations on the cooling in vacuo, calculated as before explained, are all affected by an error, very small indeed, but which it is easy to correct. This error arises from the small quantity of air remaining in the balloon, and which, in the greater number of experiments, amounted only to two millimetres. This correction cannot be applied immediately to the series of temperatures furnished by observation; but it can be easily applied to the velocities of cooling obtained by calculation. It is merely necessary to diminish them by a quantity corresponding to the heat carried off by the air remaining in the balloon.

To determine the amount of this correction in each case, we observed the cooling of our thermometer in air of different degrees of density; and we calculated for the different excesses of temperature, the velocities of cooling corresponding to each density. By subtracting from these velocities those which take place in vacuo, we obtain exactly the quantities of heat caused by the air in its different states of rarefaction. We shall have nearly accurate values of these same quantities, by subtracting the velocities already very near each other, which are given by the observations of cooling in the balloon, when it contains only a very small quantity of gas.

Having thus determined for each excess of temperature, and for different densities, the quantities of heat carried off by the air, we observed that they followed a simple law, by means of which we determined, with sufficient precision, the corrections which calculated velocities ought to undergo.

The numbers, therefore, which we shall give in the subsequent part of this Chapter, may be considered as differing exceedingly little from those which would be obtained by making the experiments in an absolute vacuum. Let us now proceed to the examination of the different series calculated and corrected, and let us begin with that in which the balloon was surrounded by melting ice. The thermometer preserved its natural vitreous surface.

The first column contains the excesses of temperature of the thermometer above the sides of the balloon, that is to say, the temperatures themselves, since the balloon was at $0^\circ$. The second column contains the corresponding velocities of cooling, calculated and corrected by the methods already pointed out. These velocities, as we have already frequently observed, are the number of degrees that the thermometer would sink in a minute, supposing the cooling uniform during the whole minute. The first series shows clearly the inaccuracy of the law of Richmann; for, according to that law, the velocity of cooling at $200^\circ$ should be double that at $100$; whereas we find it more than triple. When we compare, in like manner, the loss of heat at $240^\circ$ and at $80^\circ$, we find the first about six times greater than the last, while, according to the law of Richmann, it ought to be merely triple.

Nothing would be easier than by a formula composed of two or three terms to represent the results contained in the preceding table, and to obtain in this way an empirical relation between the temperature of bodies and the corresponding velocities of cooling. But formula of this kind, though without doubt they are useful when we wish to interpolate, are almost always inaccurate beyond the limits within which the observations have been made, and never contribute to make us acquainted with the laws of the phenomena which we study.

We have thought it necessary, therefore, before endeavouring to find any law, to vary our observations as much as the nature of the subject would admit; and we have been guided in this by a remark relative to the theory of radiation, which we think has not hitherto been made by any philosopher.

</table>

This table, which requires no explanation, confirms, as is evident, the principle which we have established; but the results which it contains lead us to a very simple approximation, which discovers the law of cooling in vacuo. If we compare the corresponding numbers of the second and third columns, that is to say, the velocities of the cooling for the same excess of temperature, the surrounding medium being successively at $0^\circ$ and at $20^\circ$, we find that the ratios of these velocities were as follows:

$1.16$ : $1.15$ : $1.16$ : $1.15$ : $1.16$ : $1.15$ : $1.16$ : $1.18$ : $1.15$.

These numbers, which differ very little from each other without showing any regularity in their variations, only require to be made equal by changes in the observed velocities, which would scarcely amount to one per cent.

Let us now compare the velocities observed when the surrounding medium was at $20^\circ$ and $40^\circ$. We shall find for the ratio of these velocities, $1.16$ : $1.15$ : $1.16$ : $1.15$ : $1.16$ : $1.15$ : $1.16$ : $1.17$ : $1.15$ : $1.18$ : $1.17$ : $1.15$ : $1.16$.

These three last comparisons lead us to the same conclusion as the first, and inform us, besides, that the constant ratio between two consecutive series, has remained always the same when the surrounding medium was heated from $0^\circ$ to $20^\circ$, from $20^\circ$ to $40^\circ$, from $40^\circ$ to $60^\circ$, and from $60^\circ$ to $80^\circ$. The preceding experiments then prove the following law.

The velocity of cooling of a thermometer in vacuo, if the temperature of the substance surrounding the same remains constant...
HEAT.

Excess of temperature, or values of \( t \) | Values of \( V \) observed | Values of \( V \) calculated
---|---|---
240° | 10.69° | 10.68°
220 | 8.81° | 8.89°
200 | 7.40° | 7.34°
180 | 6.10° | 6.03°
160 | 4.89° | 4.87°
140 | 3.88° | 3.89°
120 | 3.02° | 3.05°
100 | 2.30° | 2.33°
80 | 1.74° | 1.72°

Let us now take the series obtained when the surrounding medium was at 20°, the preceding coefficient of \((a^2 - 1)\) must then be multiplied by \( a^{20} = 1.165\), we have then \( V = 2.374 \ (a^2 - 1)\)

Excess of temperature, or values of \( t \) | Values of \( V \) observed | Values of \( V \) calculated
---|---|---
240° | 12.40° | 12.46°
220 | 10.41 | 10.36
200 | 8.58 | 8.56
180 | 7.04 | 7.01
160 | 5.67 | 5.68
140 | 4.57 | 4.54
120 | 3.56 | 3.56
100 | 2.74 | 2.72
80 | 1.99 | 2.00
60 | 1.40 | 1.38
40 | 0.86 | 0.85
20 | 0.39 | 0.39

Let us proceed to the series obtained when the surrounding medium was at 40°, the preceding coefficient of \((a^2 - 1)\) must still be multiplied by \( a^{40} = 1.165\). Hence \( V = 2.766 \ (a^2 - 1)\)

Excess of temperature, or values of \( t \) | Values of \( V \) observed | Values of \( V \) calculated
---|---|---
240° | 14.35° | 14.44°
220 | 11.98 | 12.08
200 | 10.01 | 9.97
180 | 8.20 | 8.17
160 | 6.61 | 6.68
140 | 5.32 | 5.29
120 | 4.15 | 4.14
100 | 3.16 | 3.17
80 | 2.30 | 2.33
60 | 1.62 | 1.61

For the series in which the surrounding medium is 60°, we shall have \( V \ 3.222 \ (a^2 - 1)\)

Excess of temperature, or values of \( t \) | Values of \( V \) observed | Values of \( V \) calculated
---|---|---
200° | 11.64° | 11.61°
180 | 9.55 | 9.52
160 | 7.68 | 7.71
140 | 6.14 | 6.16
120 | 4.84 | 4.82
100 | 3.68 | 3.69
80 | 2.73 | 2.71
60 | 1.88 | 1.87

Lastly, when the surrounding medium is 80°, we have \( V = 3.754 \ (a^2 - 1)\)

Excess of temperature, or values of \( t \) | Values of \( V \) observed | Values of \( V \) calculated
---|---|---
200° | 13.45° | 13.52°
180 | 11.05 | 11.09
160 | 8.95 | 8.98
140 | 7.19 | 7.18
120 | 5.64 | 5.61

It only remains, in order to verify the accuracy of this law, to compare it with the different series contained in the table inserted above. Let us begin with that in which the surrounding medium was at 0°. We find in this case that it is necessary to make \( m = 2.037\); we have then for this case,

\[
V = 2.037 \ (a^2 - 1)
\]
in which \( a = 1.0077\).
HEAT.

The remarkable agreement of the results of calculation and observations leaves us no doubt of the accuracy of the law at which we have arrived. Without stopping at the consequences which may be deduced from it, and to which we shall return immediately, let us examine the series of the velocity of cooling when the bulb of the thermometer is covered with silver. These series having been calculated, we immediately perceived, on comparing them with the analogous series when the thermometer was naked, that the velocities of cooling in these last for the same temperature of the surrounding medium, and the same excess of temperature of body, were proportional to the corresponding velocities of cooling when the bulb was silvered. The formula found above, then, will apply also in the case of silver, preserving to a the same value, and by making the proper diminution in m.

Our first observation on the cooling of the silvered thermometer was made, θ being equal to 20°. We found that it was necessary to suppose m = 0.357, and consequently ma^θ = 0.416. Hence

\[ V = 0.416 (a^\theta - 1) \]

A series so extensive as the preceding is sufficient to prove that the formula which applies to the cooling of the glass bulb in vacuo, extends likewise to the case of the silver bulb, preserving to a the same value. However, that we might not neglect any of the means of verification in our power, we altered the temperature of the surrounding medium, and raised it to 80°. The preceding coefficient of \((a^\theta - 1)\) must be multiplied by \(a^50\), which gives \( V = 0.556 (a^\theta - 1) \).

The simplicity and generality of the law which we have just established, the precision with which it is confirmed by observation, through an extent of nearly 300°, clearly that it will represent rigidly the rate of cooling in vacuo at all temperatures and for all bodies.

Let us now return to the calculation which led us to the discovery of this law. The total radiation of the surrounding medium is represented in it by \( F (\theta) \), and we find for its value \( m \cdot a^\theta \) + a constant quantity.

But the point of commencement from which the absolute temperatures \( \theta \) are reckoned, being arbitrary, we may choose it in such a way that the quantity shall be null; which will reduce the expression to \( m \cdot a^\theta \). We may conclude then, that if it were possible to observe the absolute cooling of a body in a vacuum, that is to say, the loss of heat by the body, without any restoration on the part of the surrounding bodies, this cooling would follow a law in which the velocities would increase in a geometrical progression, while the temperatures increase in an arithmetical progression; and further, that the ratio of this geometrical progression would be the same for all bodies, whatever the state of their surface may be.

From this simple law is deduced as a consequence, that of the real cooling of bodies in vacuo; a law which we have already announced above. In fact, to pass from the first case to this, it is only necessary to take into the account the quantity of heat sent back every instant by the surrounding medium. This quantity will be constant, if the temperature of the surrounding medium does not vary. Hence it follows, that the real velocity of cooling of a body in vacuo, ought for excesses of temperature in an arithmetical progression, to increase in a geometrical progression, diminished by a constant quantity. This number itself must vary according to a geometrical progression, when the temperature of the surrounding medium, (of which it represents the absolute radiation,) varies according to an arithmetical progression.

These different results are already expressed in the equation obtained above, making \( m a^\theta = M \). We have

\[ V = M (a^\theta - 1) \]

\( M \) is the number which we must take from the different terms of the geometrical progression expressed by \( M \cdot a^\theta \), and we see, besides, that this number \( M \) is connected with \( \theta \) by the relation announced above.

Since the value of \( a \) is independent of the nature of the surface, it follows that the law of cooling in vacuo is the same for all bodies; so that the radiating power of different substances preserves the same ratio at all temperatures. We have found this ratio equal to 5.7 on comparing glass with silver. This result is little less than that of Mr. Leslie; owing, no doubt, to the surface of our silvered thermometer being tarnished, while that of Mr. Leslie's was polished. We see, likewise, according to the hypothesis which has given us the law of absolute radiation, that we must make \( \theta = \infty \) to render the velocity null; which fixes the absolute zero at infinity. This opinion, rejected by a great many philosophers, because it leads to the notion that the quantity of heat in bodies is infinite, supposing their capacity constant, becomes, nevertheless, very probable, now that we know that the specific heats diminish as the temperatures sink. In fact, the law of this diminution may be such, that the integral of the
quantities of heat, taken to a temperature infinitely low, may, notwithstanding, have a finite value.

The law of cooling such as we have represented it, and such as it may be represented in vacuo, applies solely to the velocities of cooling, estimated by the diminutions of temperature indicated by an air thermometer. We may see by the correspondence of all the thermometrical scales, that if we make use of any other thermometer, the relations between the temperatures and velocities of cooling would lose that character of simplicity and generality which we have found them to possess, and which is the usual attribute of the laws of nature. If the capacities of bodies for heat were constant when we determine them by the same thermometer, the preceding law would still give the expression of the quantities of heat lost, in some function of the corresponding temperatures; but as we have proved that the specific heat of bodies is not constant in any thermometrical scale, we see that in order to arrive at these real losses of heat we must admit an additional element; namely, the variation of the capacity of the bodies subjected to observation. In considering the question under this point of view it would be necessary to know, in the first place, the law of the capacities for a certain body, and then to determine by direct observations, the quantities of heat lost by the same body at certain fixed points of temperature indicated by the air thermometer. Then, by multiplying the velocities of cooling deduced from the preceding law by the corresponding capacities, we should obtain the absolute losses of heat. It is not in the interval of the first two or three hundred degrees of the Centigrade scale that we can hope to verify the accuracy of these conclusions. The variation of the capacities not beginning to become very sensible till we pass that term, it would be necessary to observe at temperatures of 500 or 600°. It is easy to see the difficulty of such observations. However, we have succeeded in constructing an apparatus fit for the purpose; and we have already made a great many observations relative to this subject. But as our results do not yet present all the regularity which we expect to be able to give them, we have determined to delay their publication, and so much the more willingly, that the question which it is their object to answer, does not come within the limits of the prize proposed by the Academy. The method which Mr. Leslie employed for measuring the radiating powers of different surfaces, is very good for making us acquainted with the radiating heat lost by a body at all temperatures. It is well known that his method consists in estimating the radiation of a body by the heat communicated to an air or mercurial thermometer placed at a certain distance from the hot body; and to render the effects more sensible, this thermometer is placed at the focus of the reflector.

It was by means of this apparatus that Laroche obtained the result which we have mentioned above. Among the series of observations made by this method, there is one which extends, indeed, to very high temperatures; but it cannot be of any utility, because the temperatures were determined by a process founded on the supposition that the capacities were constant. The numbers which represent the losses by heat are, besides, affected by another error, proceeding from the heat of the focal thermometer being too great, because the inaccuracy of the Newtonian law had already become very sensible. But to show that our law agrees with the observations made by this process when they are freed from the causes of error of which we have just spoken, we shall apply them to the series given in the same memoir, which do not go beyond the limits in which the variation of capacity produces no sensible effect. These series belong to the radiation of an iron crucible filled with mercury; here the temperature of the body not having exceeded 200°, we may suppose the specific heat constant. We may likewise neglect the correction which the mercurial thermometer would require to bring it to the air thermometer; because this correction is very small, and because it is probable that it is more than compensated from the stem of the thermometer employed by Laroche not being completely plunged into mercury. Instead of taking each of the series which is given by this philosopher, we have taken in some measure the mean of them, assisted by a formula by which M. Biot has represented these observations, a formula inserted in p. 634, of the IVth Volume of his Traité de Physique. The numbers which we give as the result of observation are then deduced from the formula of M. Biot. To represent them by means of our law, we must make V, which here represents the radiation, equal to

\[ t \text{ being the excess of the temperature of the crucible, and } A \text{ a constant quantity, which we have found precisely equal to 1.0077.} \]

This last series furnishes its agreement with our law a new proof that the number a depends neither upon the mass nor upon the state of the surface of the body, since we find it here to have the same value as in our experiments on cooling vitreous and silvered surfaces in vacuo.

From the expression for the velocity of cooling in vacuo we can easily deduce the relation which connects the temperatures and the times. If we denote the time by \( t \), we have

\[ V = \frac{d}{dx} = M (a' - 1) \]

M being a constant coefficient, which depends solely on the temperature of the surrounding medium: from this we have

\[ ds = \frac{1}{M \cdot \log a} \left( \log \frac{a'}{a} \right) + \text{a constant quantity.} \]

The arbitrary constant quantity and the number M will be determined in each particular case, when we have observed the values of \( t \) corresponding to two known values of the time \( x \).

If we supposed \( t \) so small that considering the smallness of the logarithm of \( a \), we might confine ourselves to the terms of the first power in the development of \( a' \), we should fall again into the Newtonian law.
On Cooling in the Air and in Gases.

Heat.

The laws of cooling in vacuo being known, nothing is more simple than to separate from the total cooling of a body surrounded with air, or with any other gas, that portion of the effect which is due to the contact of this fluid. For this, it is obviously sufficient to subtract from the real velocities of cooling those velocities which would take place if the body, ceteris paribus, were placed in vacuo. This subtraction may be easily accomplished now we have a formula which represents this velocity with great precision, and for all possible cases. We can then determine the energy of cooling due to the sole contact of fluids, and such as it would be observed directly if the body could be deprived of the faculty of radiating. This part of our labour required a very considerable number of experiments, because the laws which we wished to discover were to be studied with respect to different gases, and for each of them at different temperatures, and under different pressures. Each experiment was made and calculated as we have explained above. We shall, therefore, satisfy ourselves with stating the mean results of these experiments.

In the first, we observed the cooling of the largest of our balloons containing air under a pressure of 0.72 metre and the temperature of 20\°.

First Case.—The thermometer in its natural state.

We see, by comparing the last columns of the two preceding tables, that the corresponding numbers deviate so little, that the deviation may with propriety be ascribed to error in the experiments. Air then, other things being the same, takes away the same quantity of heat from vitreous and metallic substances. The two following tables contain all the elements of a similar comparison made with hydrogen gas. The small thermometer in these experiments being substituted for the large one. The experiments were made at the temperature of 20\°, the gas being subjected to a pressure of 0.74 metre.

This comparison gives for hydrogen a result similar to that for air. The equality being thus verified for surfaces differing so much from each other as glass and silver, and for gases of such different qualities as air and hydrogen, it is natural to generalize the result, and to deduce from it the following law.

The loss of heat owing to the contact of a gas, other things being equal, is independent of the state of the surface of the body which cools. This remarkable law of the communication of heat has been already admitted by Mr. Leslie. But this skilful philosopher has only given it as a probable consequence of two indirect experiments, which consist in proving that the state of the surface has only a very feeble effect on the time of cooling in those circumstances in which radiation can contribute but slightly to the loss of heat. This, for example, is what happens when a hot body is exposed to a violent wind, or when it is plunged into a liquid. But these experiments, however ingenious, can never completely supply the place of direct observations. And in the present case, would it not have been possible, for example, to suppose that a property observed in air while violently in motion could only be applied in a limited sense to air in a state of rest? This doubt would appear still better founded, or would be changed into certainty, if we admitted, with Mr. Leslie, that air in a state of rest deprives bodies of heat by two different ways; namely, by a conducting property, such as exists in solids, and by the renewal of the fluid from ascending currents. Our process, by enabling us in the first place to show the existence of the same law in different gases, dissipates all the doubts which the experiments of Mr. Leslie still allowed to remain. This is one of the cases in which the advantages of the uniform method which we have adopted can be best seen.
Heat.

The principle which we have just established being fully verified, we may confine ourselves in the remainder of our experiment to observe the cooling of the thermometer with the bulb naked in air and in the different gases. Henceforth we shall give only in our tables the effect produced solely by the contact of the gas. They have been always calculated, as we have said before, by subtracting from the total velocities of cooling those which would take in the same circumstances if the thermometer were cooling in vacuo. We shall now enter into the examination of the different circumstances which may modify the action of the elastic fluids in the production of the phenomenon which occupies our attention. We shall study the influence of each of these causes, first in air, then in hydrogen, carbonic acid, and olefiant gases. We made choice of the first two, in consequence of the great difference of their physical properties. Air and olefiant gas, on the contrary, offer the curious comparison of two gases of almost the same specific gravity, but of very different composition.

The example of the influence of the temperature of the surrounding medium has upon the rate of cooling in vacuo, naturally led us in the first place to examine, if the temperature of the gases does not produce analogous effects upon the quantity of heat which they carry off. It is needless to say that such experiments had not yet been attempted, the philosophers who have turned their attention to this subject having always supposed that the velocities of cooling depend only on the excess of temperature. Without stopping to detail our first attempts, we shall state immediately those tables in which the law shows itself manifestly. In the experiments in question, the temperature of the gases was varied by heating sufficiently the water of the balloon; but the gas was at the same time allowed to dilate itself, so that it always preserved the same elasticity. The following table contains the results of such a set of experiments made upon air:

<table>
<thead>
<tr>
<th>Excess of the thermometer above the surrounding air</th>

The mere inspection of this table is sufficient to show us that the velocities of cooling have remained the same in each of the four series for the same excess of temperature. This simple law was of too great importance not to endeavour to verify it with other gases. The following table exhibits a similar comparison for hydrogen gas heated successively to 20°, 40°, 60°, and 80°. The elasticity in each experiment was 0.72 metre.

<table>

This table leads to the same consequences as the preceding. To show that it extends to all the gases whatever be their nature or density, we shall add here a similar set of experiments on carbonic acid, under a pressure of 0.72 metre, and on dilated air under a pressure of 0.36 metre.
From all these comparisons we may deduce the following law:

The velocity of cooling of a body, owing to the sole contact of a gas, depends (for the same excess of temperature) on the density and temperature of the fluid; but this dependence is such that the velocity of cooling remains the same, if the density and the temperature of the gas change in such a way that the elasticity remains constant.

Hence in experiments on cooling by the gases we need only attend to their elasticity. It is, therefore, the influence of this last element that we must endeavour to appreciate.

With this view we have determined for each gas, at different elasticities, the velocities of cooling for the same excesses of temperature. Of each of these series of experiments we shall merely give what is necessary to demonstrate the law which we have obtained. Let us begin with air.

The following table exhibits the corresponding velocities of cooling, owing to the sole contact of air under the following pressures: 0.72 m., 0.36 m., 0.18 m., 0.09 m., 0.045 m., that is to say under pressures decreasing as the numbers 1, 1/2, 1/4, 1/8.

If we take the ratio of the corresponding numbers in the second and third columns, we find their values commencing with the uppermost as follows:

1.37, 1.35, 1.37, 1.34, 1.37, 1.34, 1.37, 1.36.

We have likewise for the ratios of the numbers in the third and fourth columns

1.36, 1.35, 1.37, 1.34, 1.37, 1.34, 1.37, 1.35.

The ratios between the fourth and fifth columns are

1.34, 1.37, 1.36, 1.36, 1.37, 1.36, 1.37, 1.35.

And, lastly, the ratios between the fifth and sixth columns are

1.38, 1.38, 1.35, 1.37, 1.36, 1.37, 1.35, 1.37.

The small irregularities which these corresponding
Heat.

The ratios present in the numbers which represent them, being less than the uncertainty of the observations, we have a right to draw from them the following conclusions:

1. The law, according to which the velocity of cooling by the contact of air varies with the excess of temperature, continues the same, whatever the elasticity of the air.

2. The elasticity of the air, varying in a geometrical progression, its cooling power changes likewise in such a manner that when the ratio of the first geometrical progression is 2, that of the second is 1.366, the mean of all the numbers given above. It will be easily seen that the law just announced was not recognised till we had made many experiments. But when once verified for air, it was natural to try it on the other gases. We shall now give a tabular view of the observations relative to each of these.

Let us begin with hydrogen.

<table>

</tbody>
</table>

The ratios between the numbers in the second and third columns are 1.29...1.30...1.31...1.29...1.31.

The ratios between the numbers of the third and fourth columns are 1.31...1.30...1.31...1.32...1.29.

The ratios between the numbers of the fourth and fifth columns are 1.31...1.29...1.30...1.31...1.32.

The ratios between the fifth and sixth columns are 1.29...1.31...1.29...1.32...1.30...1.29.

The very near approach to equality in these numbers furnishes us with a result analogous to that which refers to air.

Hence, 1. The law, according to which the velocity of cooling due to the sole contact of hydrogen varies with the excesses of temperature, is the same, whatever be the elasticity of the gas.

2. The cooling power of hydrogen decreases in a geometrical progression, whose ratio is 1.301, when its elasticity diminishes in a geometrical progression, whose ratio is 2.

We obtained the same results for carbonic acid and olefiant gas. This may be easily verified in the two following tables, arranged for each of these gases as the tables given above for air and hydrogen.
Heat.

Mean of all these ratios.

For carbonic acid ........ = 1.431
For olefiant gas .......... = 1.415

From all that precedes, we may draw the following consequences:

1. The losses of heat due to the contact of a gas increase with the excess of temperature, according to a law which remains the same whatever be the elasticity of a gas.

2. The cooling powers of the same gas vary in geometrical progression, while the elasticities also vary in geometrical progression: and if we suppose the ratio of this second progression to be 2, the ratio of the first progression will be 1.366 for air; 1.301 for hydrogen; 1.341 for carbonic acid; and 1.415 for olefiant gas.

This result may be enunciated in a manner still more simple, to which we are led by the following calculation.

If we call $P$ the cooling power under the pressure $p$; this power will become $P(1.366)$ under a pressure $2p$; $P(1.366)^2$ under a pressure $4p$; and under a pressure $p\cdot 2^n$, it will be $P(1.366)^n$, making $p\cdot 2^n = p'$ and $P(1.366)^n = P'$, we shall obviously obtain by eliminating $n$,

$$\frac{\log P'}{\log 1.366} - \frac{\log P}{\log 1.366} = \frac{\log p'}{\log 2} - \frac{\log p}{\log 2}$$

Hence,

$$\frac{P'}{P} = \left(\frac{p'}{p}\right)^{0.45}$$

We shall find in the same way for hydrogen

$$\frac{P'}{P} = \left(\frac{p'}{p}\right)^{0.38}$$

</table>

On dividing the numbers in the third column by those in the second, we find for the ratios between the losses from hydrogen and those from air

3.49 . 3.42 . 3.45 . 3.48 . 3.51 . 3.43.

Now, as it would be sufficient to render these ratios equal to alter the velocities which have served to determine them by quantities within the limits of the uncertainty to which all such experiments are exposed, we may conclude that the law is the same for hydrogen and for air.

We shall come to a similar conclusion for the two other gases, if we take the ratios of the velocities of cooling which they produce to the corresponding velocities produced by air. The numbers for carbonic acid are

0.958 . 0.962 . 0.965 . 0.972 . 0.977 . 0.955.

For carbonic acid the exponent will be 0.517, and for olefiant gas 0.501.

From this we conclude that the cooling power of a gas is, everything else being equal, proportional to a certain power of its elasticity, but that the exponent of this power varies from one gas to another. It is 0.38 for hydrogen; 0.45 for air; 0.517 for carbonic acid; and 0.501 for olefiant gas. These last three numbers differing little from 0.5, we may say that in the gases to which they belong, the cooling power is nearly as the square root of the elasticity.

If we compare the law which we have thus announced with the approximations of Leslie and Dalton, we shall be able to judge of the errors into which they have been led by the inaccurate suppositions which serve as the basis of all their calculations, and by the little precision attainable by the methods which they have followed. The first by photometrical experiment calculated by the law of Newton, finds the cooling power of air proportional to the fifth root of its density; and Mr. Dalton finds it proportional to the cube root, supposing, as he always does, the law of cooling the same for all bodies and in all the gases.

Now, that we know the influence that the temperature, and the density of the gas in which it takes place have upon cooling, it remains to discover, how for a given state of fluid the velocities of cooling depend upon the excesses of the temperature? We have already observed, that the law which expresses this dependence remains the same for the same gas when its elasticity changes. Let us now see what happens when we pass from one gas to another, and for this purpose let us resume, from the preceding tables, the velocities of cooling due to the sole contact of air, of hydrogen, carbonic acid, and olefiant gases, these four fluids being under a pressure of 0.72 metre.

| Those for olefiant gas are | 1.35 . 1.36 . 1.30 . 1.33 . 1.32 . 1.37 . 1.32.

The law of cooling produced by the sole contact of a gas is then independent on the nature and density of the gas, and the comparison of the series given above, with an analogous series of cooling in vacuo, shows clearly that the law of which we are in search differs from that of radiation. After a great many trials, of which it would be superfluous to give an account, we have found that the velocities of cooling due to the sole contact of a gas vary with the excesses of temperature of the body, according to a law analogous to that which connects the cooling power of a fluid with its elasticity; that is to say, that the quantities of heat which a gas carries off from a body increase in a geometrical progression, while the excesses of
Heat.

Taking the cooling power of air at unity, and supposing the pressure = 0.76 m., we have for the cooling power of hydrogen 3.45, and for that of carbonic acid 0.965. These numbers will change with the elasticity belonging to the three gases. This Messrs. Leslie and Dalton did not perceive; but it is easily deduced from our formula. However, their determinations differ but little from those which we have calculated for the pressure of 0.76 m. We should deduce, likewise, ratios very little different from these from the experiments made more recently by Sir Humphrey Davy.

The simplicity of the general law which we have just made known, made us eagerly desire to be able to verify it at temperatures more elevated than those which we had attempted in our experiments. We succeeded by a very simple process, the idea of which was first suggested by Mr. Leslie. When our thermometer with the naked bulb cooled in the open air, the total velocity of this cooling is the sum of the velocities due separately to the contact of air and to radiation. Denoting these by \( v \) and \( v' \), the total velocity is \( v + v' \). If the thermometer be covered with silver, the velocity \( v \) due to the air remains the same for the same temperature, and \( v' \) is reduced to \( \frac{v'}{5.707} \), since the constant ratio of the radiating powers of glass and silver is 5.707. The total cooling of the silvered thermometer is then \( v + \frac{v'}{5.707} \). Hence it is easy to conclude, that in order to know at all temperatures the losses of heat produced by the contact of air, it is sufficient to determine the total velocities of cooling of our thermometer, first when the bulb is naked, and again when it is covered with silver. These velocities being represented by \( a \) and \( b \) we shall have,

\[
a = v + v' \quad b = v + \frac{v'}{5.707}
\]

Hence,

\[
v = \frac{5.707 \times b - a}{4.707}
\]

Let us apply this formula to the results contained in the following table:

The second and third columns contain the total velocities of cooling of a thermometer with a naked and a silvered bulb, for the excesses of temperature contained in the first column. The last column contains the corresponding values of \( v \), that is to say, the losses of heat which the contact of air alone produces in both thermometers. But the law which these losses
Heat. of heat follow, is expressed by the following equation:

\[ v = m t^{1.233} \]

in which \( m \) must be determined in each particular case. For the one which we are considering \( m = 0.00857 \). By giving successively to \( t \) all the values for every \( 20^\circ \), from \( 80^\circ \) to \( 260^\circ \), we shall have the corresponding values of \( v \), which will differ but little from those deduced experimentally; to make this comparison more easy, we have united in the following table the observed and calculated values of \( v \).

Thus, the law of the losses of heat by air is confirmed when we extend our observations to greater excesses of temperature. The results already stated will, likewise, furnish us with the means of verifying the law of cooling in vacuo. It is sufficient for that, to subtract from the total velocities of cooling those which are due to the sole contact of air, that is to say, the successive velocities \( v \). The remainder will evidently be the velocities of cooling, owing to radiation, or, which comes to the same thing, those which would have taken place in vacuo.

We give here the numbers thus determined for the thermometer with its bulb naked, we join to them the velocities deduced from the law of cooling in vacuo. The velocity in this case is expressed by

\[ m(a' - 1) \]

\( t \) representing the excess of temperature of the body, \( m \) a constant coefficient, which must be determined in each case, and which is here equal to 2.61 ; \( a' \) denoting the exponent 1.0077 common to all bodies.

We see from the example which we have just given, that it is possible by intermediate observations on cooling in air to estimate separately the loss of heat due to contact and to radiation, and that for this it is necessary to observe the cooling of the same body under two different conditions of surface. But the mode of calculation depends, on the one hand, on the supposition that the quantity of heat carried off by the air is independent of the nature of the surface of the body, and, on the other, on this principle, that bodies of a different nature preserve at all temperatures the same ratio between their radiating power. These two propositions are rigorously true, but can only be proved by direct experiments, such as those which we have stated above; and though Mr. Leslie has adopted them in the use which he has made of the principle which we have just explained, his results have not all the accuracy that could be desired, because he has always calculated the velocities of cooling according to the Newtonian law.
in what manner the law of total cooling changes for the same body with the nature and density of the gases.

The total velocity of cooling is expressed by

\[ m(a^t - 1) + n t^b \]

If we consider another gas, or the same gas, at a different density, the velocity of cooling will be for the same body

\[ m(a^t - 1) + n t^b \]

for the coefficient \( n \) is the only part of the expression which changes in this case.

On comparing these two expressions, we find that their ratio becomes equal to unity, whether we make \( t = 0 \) or \( t = x \). Hence the total velocities of cooling in different gases approach equality at very high temperatures, and very low, while in any intermediate part of the scale these velocities may be very different. This result is sufficient to show the inaccuracy of the processes which Mr. Dalton and Mr. Leslie employed, to compare the losses of heat due to different gases; for those processes are founded on the supposition, that the total velocities of cooling in the different gases preserve the same ratio at all temperatures. But from a very singular circumstance, upon which it is needless to insist, the particular temperature at which they operated renders the error very small, and they were far from ascribing it to their mode of calculation. Accordingly their determinations, as we have said before, are near the truth, provided they be restricted to the circumstances under which they have been made.

The necessity of estimating separately the influence of each of the causes which modify the progress of the cooling of a body, not having allowed us to bring together the different laws at which we have arrived, we conceive that a summary recapitulation will be so much more useful, because we shall have it in our power to reestablish the natural order, which the description of experiments and the discussion of the results have often obliged us to interrupt.

Distinguishing, as we have done, the losses of heat due separately to the contact of fluids and to radiation, we soon perceive that each of these two effects is subject to particular laws. These laws ought to express the relations which exist between the temperature of the body and the velocity of its cooling for all possible circumstances. We must recollect, that by velocity of cooling we mean always the number of degrees which the temperature of the body would sink during an infinitely small and constant interval of time.

**First Law.**—If we could observe the cooling of a body placed in a vacuum surrounded by an enclosure totally destitute of heat, or deprived of the faculty of radiating, the velocities of cooling would decrease in a geometrical progression, while the temperatures diminished in an arithmetical progression.

**Second Law.**—The temperature of the vacuum in which the body is placed remaining constant, the velocities of cooling for excesses of temperature in arithmetical progression decrease as the terms of a geometrical progression diminished by a constant number. The ratio of this geometrical progression is the same for all bodies, and is equal to 1.0077.

**Third Law.**—The velocity of cooling in vacuo for the same excess of temperature increases in a geometrical progression, while the temperature of the vacuum increases in an arithmetical progression. The ratio of this progression is likewise 1.0077 for all bodies.

**Fourth Law.**—The velocity of cooling due to the sola...
Fifth Law.—The velocity of cooling due solely to the contact of a fluid, varies in a geometrical progression, while the excess of temperature itself varies in a geometrical progression. If the ratio of this second progression be 2, that of the first is 2.35, whatever be the nature of the gas and its elastic force. This law may be likewise enunciated by saying, that the quantity of heat carried off by a gas is in all cases proportional to the excess of the temperature of the body raised to the power 1.233.

Sixth Law.—The cooling power of a fluid diminishes in a geometrical progression when its tension itself diminishes in a geometrical progression. If the ratio of this second progression is 2, the ratio of the first is 1.366 for air; 1.301 for hydrogen; 1.431 for carbonic acid; and 1.415 for olefiant gas.

This law may likewise be presented in the following manner:—The cooling power of a gas is, all other things being equal, proportional to some certain power of the pressure. The exponent of this power, which depends on the nature of the gas, is 0.45 for air; 0.315 for hydrogen; 0.517 for carbonic acid; and 0.501 for olefiant gas.

Seventh Law.—The cooling power of a gas varies with its temperature in such a manner, that if the gas can dilate, and if it preserves always the same elastic force, the cooling power will be as much diminished by the rarefaction of the gas, as it is increased by its augmentation of temperature, so that, ultimately, it depends only on its tension.

We see from these propositions that the total law of cooling, which would be compounded of all the preceding laws, must be very complicated; we shall not, therefore, attempt to translate it into ordinary language. We have given it in the course of the memoir under a mathematical form, which permits us to examine all its consequences. We shall satisfy ourselves with remarking, that it is doubtless to the very complicated nature of this law that we must ascribe the little success of the attempts hitherto made to discover it. It is obvious that we can only arrive at it by studying apart each of the causes which contribute to the total effect.

Radiation.

(173.) Hitherto we have considered the property well known and generally understood by the term of Radiation in the light of a gradual loss sustained by the heated substance, analogous to the slow dissipation of electricity from an excited body. We now proceed a step further in the inquiry, and attempt to give a summary of the researches of those who have traced the progress of these rays, be they real, or be they only imaginary, and adopted as a mode of speaking for the purpose of convenient illustration.

Mariotte. In pursuing this question Lambert more particularly attempted to separate the effect of the light from that of the heat; with this view he intercepted the light of a clear fire with a large lens, and found that it produced scarcely any appreciable heat to his hand placed in the focus; but by two concave mirrors he reflected the heat of burning charcoal, so as to set fire to combustible bodies at a distance of more than 30 feet.

He Scheele also directed his inquiries to this point. He Scheele first made use of the term Radiant heat, and showed that it did not communicate warmth to the air through which it was made to pass. He proved also that its passage through a space filled with air was not changed in direction by a current in that air, and that its intensity was not diminished by violent agitation taking place in the air. By the interposition of a pane of glass between the fire and his hand, the heat was intercepted, though the light was transmitted and might afterwards be concentrated to a focus by a lens. He states that a glass mirror reflects the light of a fire but not the heat, but that a polished metallic surface reflects both the light and the heat. The metallic reflector therefore may be exposed to the fire, and held in the hand with safety; but by blackening its surface the reflecting power was destroyed, and in four minutes it became too hot to hold. (d.)

MM. Saussure and Pictet repeated the preceding experiments with a very convenient apparatus represented and Pictet in fig. 23. Two concave mirrors of polished tin, each a foot in diameter, were placed at a distance of 12 feet apart; the focal length of the mirrors was 44 inches each. In the focus of one was the bulb of a thermometer, and in the focus of the other they placed a ball of iron 2 inches in diameter, which was first heated red, and then suffered to cool until it ceased to be visible in the dark. Another thermometer was placed at the same distance from the heated ball as the former one, but without the focus of the reflecting mirror. Upon the introduction of the heated ball to its place the thermometer instantly rose, and in six minutes indicated an increase of temperature of 10°.5 Reaumur, while that not in the focus advanced only 2°.5, setting out from the same point. Here the two thermometers, being at equal distances, may be supposed to have been equally affected by the direct rays from the hot ball; the one without the focus received the direct rays, and also was on the spot for the reception of other calorific rays, had such been reflected from its mirror on the same principle as those of light; and as so marked an effect was produced upon this thermometer, it is fair to ascribe the difference to the reflective power of the mirror, and to infer that the motion of radiant heat is analogous to that of light, proceeding in right lines, and following the same law in its reflection.

In a repetition of this experiment by M. Pictet, with a lighted candle in place of the heated ball, the focal thermometer rose from 4°.6 to 14° Reaumur.

M. Pictet particularly endeavoured to prove that these effects were not due to the action of light, which might possibly be supposed to exist, though in a state too feeble to excite the ordinary sensation of vision. He therefore interposed a plate of glass between the radiant body and the thermometer. In this case, rays of light would be supposed to have a free passage; and if (as it proved) the calorific rays were intercepted by the glass screen, their separate existence and distinct
H E A T.

nature must be admitted. The candle was placed in one focus; and when it had raised the thermometer in the opposite focus from 2° to 12°, the glass screen was interposed, and in nine minutes the thermometer fell to 5°, and again rose on the removal of the glass. He was disposed to attribute the degree of heating effect which still remained, after the interposition of the screen, partly to its not in reality intercepting all the calorific rays, and partly to its own acquired increase of temperature, by which it in turn became a source of radiant heat to the second mirror.

(174.) Again, a small glass flask, containing more than two ounces, was filled with boiling water, and placed in one focus; the mirrors being 10 1/2 feet from each other; while a small Fahrenheit's thermometer occupied the other focus. In two minutes the rise was from 47° to 50 1/4°, and upon the removal of the mattrass the mercury again fell. It seems clear from these experiments, that calorific rays exist independently of luminous rays; that they proceed in right lines from heated bodies; and that they are capable of reflection from polished metallic surfaces.

It was long known that blackened substances received or absorbed more heat when exposed to the rays of the sun, than others did which had not been so prepared; and Scheele's experiment, with the blackened reflector, had proved that in this respect the calorific rays from a common fire followed the same law with those proceeding from the sun. This also Pictet proved by a slight variation upon the last experiment. The bulb of the thermometer which when clean rose from 47° to 50° was blackened, and then in the same time it rose from 51 1/2° to 55°.

(175.) A concave mirror of glass was substituted in place of the metallic reflector, but by this scarcely any effect could be produced upon the thermometer in one focus, with the heated iron ball in the other. This also proved the inferiority of glass as a reflector of heat. M. Pictet could not ascertain satisfactorily whether the calorific rays were capable of refraction or not. He also attempted to measure the velocity with which they moved; for this purpose he placed the reflectors at a distance of 69 feet from each other, having in the one focus a heated ball, and in the other a delicate air thermometer. A cloth screen was interposed between the reflectors. Upon the removal of this screen the rise of the thermometer was instantaneous. Within this distance then it seemed, that no perceptible interval elapsed between the passage of the calorific rays from one part of the apparatus to the other.

Herschell. 176.) In the chronological order of research we now arrive at a name with the rare distinction of standing successively for two generations preeminent in the annals of science. In the year 1800, Dr. Herschell published a much more minute dissection of the solar beam than had before been attempted. In his astronomical observations he had been struck by the different sensations of heat experienced in the use of screens of coloured glass. Rochon had found that an air thermometer exposed to the action of the coloured rays of the prismatic spectrum, rose from the violet to the red extremity; and he considered the ratio of heating power between the clear red and deepest violet to be about that of 8 to 1; and that in the intermediate stages the decrease of heat was rapid in proceeding towards the violet extremity. (f.)

Dr. Herschell mounted a piece of pasteboard upon a movable frame, so that one or more of the coloured pencils in the prismatic spectrum could be brought upon the bulb of a mercurial thermometer, and thus the relative heating powers might be compared. The progressive increase of effect in moving from the violet to the red extremity seemed to follow these proportions. In ten minutes the thermometer rose in the red ray 7° Fahrenheit; in the green 3° 5'; and in the violet ray 2°.

But in the prosecution of these experiments Dr. Herschell found the heating power extended beyond the extreme limit of the visible red rays, and that it was even quite without the visible spectrum that the maximum heating position existed. From this result it seemed to follow, that the refrangibility of the calorific rays was greater than that of the luminous solar rays; and that, therefore, when the sunbeam was concentrated by a convex lens the most perfect focus of light would not strictly coincide with that of heat. This was submitted to an experiment which seemed to prove, that the distance of the focus of heat from the lens exceeded that of the light by not less than one quarter of an inch. (g.)

(177.) These experiments were repeated by Sir Henry Englefield, who obtained similar results, which are shown in the following table:

<table>

</table>

Here it appeared, that beyond the full red light, and where only a faint blush of red was perceptible, the greatest heat existed; and that even half an inch beyond the edge of the red ray, where there was no illuminating power, the heat was still greater than in the red ray. (h.) Mr. Leslie's experiments on this point indicated the same, or even a greater, increase of calorific effect, in traversing the spectrum from the blue to the red extremity; but he did not find an excess of heating power beyond the red rays.

This subject we shall have to resume hereafter; but to return to our point. It appears clear, that as the calorific rays are separated from the calorific or visible rays by transmission through a prism, both the former and the latter are bent from their course, or suffer refraction. And as the calorific rays are dispersed over a space greater than that of the luminous rays, and greater even than that occasioned by the visible rays of light, it follows that a beam of radiant caloric must consist of rays differing in refrangibility, and also that the range of its refrangibility is even more extensive than that of the coloured rays.

Dr. Herschell further endeavoured to ascertain whether the radiant calorific issuing from a heated body were also refrangible. A lens was placed at a small distance from a burning candle; a pasteboard screen being interposed with a hole in it, so that only a pencil of direct rays proceeded from the candle to the lens, and being there refracted upon the bulb of a thermometer, a rise of 21° was obtained in the course of three minutes. Similar experiments upon the rays from a common fire, from a mass of red hot iron, and from a mass of iron not heated to redness, and also
from the invisible calorific part of the solar spectrum, proved all to be capable of refraction.

It followed, however, from Herschell's experiments, that the calorific rays which accompany the solar light, and those which issue from heated bodies, though similar in most points have distinct habits; for the former pass through transparent media with much greater ease than the latter. On exposing two thermometers of equal sensibility,—the one covered with glass or some other transparent substance, while the other remained uncovered,—first to the solar rays, and afterwards to those from a candle, he found that a greater proportion of the calorific rays were intercepted in the latter case than in the former. An experiment of the same kind was performed without the interference of the presence of light; by comparing the invisible calorific rays of the spectrum with those of iron heated, but not to redness, and the same general result was obtained. It is easy to state a simple and analogous fact, showing that the solar rays do, but that the rays of common artificial heat do not, easily pass through transparent media; thus a vessel of water does not acquire so much heat on exposure to the sun, as it does by exposure to an equal degree of radiant culinary heat. Subsequent researches will show, that the power of calorific rays to pass through transparent media is greatly dependent upon the temperature at which they issue. (g.)

Dr. Maycock employed a flask of hot water as the source of radiation, and here of course no light could be suspected; but by a simple yet ingenious variation of coloured glass screens, he fully proved that some of this invisible heat did pass through a plate of glass and affect a thermometer placed in the focus of a reflecting mirror. (l.)

(178.) Before we proceed to the more elaborate researches of Leslie, Delaroche, and Berard, we may here introduce a very elegant experiment of Pictet's, which is familiarly termed the radiation of cold; a phrase again arising out of the mere comparative scale of our own feelings and notions. The Florentine Academicians may be said to have first instituted such an inquiry. "We were desirous (say they) of trying whether a concave speculum, exposed to a mass of ice weighing 500 pounds, would reflect any sensible degree of cold on a very delicate thermometer of 400 degrees placed in the focus. The result was that the thermometer instantly sunk; but a doubt remained whether the thermometer was acted on more by the direct cold of the ice, or by that reflected from the speculum. This doubt was removed by covering the speculum; and certain it is (whatevser might be the cause) that the spirit instantly began to rise again; yet still we will not presume positively to affirm, that this rise might not have been owing to some other cause than the taking off the reflection from the speculum, all the precautions not having been taken which might be considered necessary to secure absolute assent to the experiment."

This very same question was proposed by M. Bertrand to M. Pictet, and the experiment was carefully repeated by these two in conjunction. M. Pictet placed in the focus of a metallic reflector a flask filled with snow, while an air thermometer occupied the focus of another mirror at a distance of 10½ feet. The thermometer instantly fell several degrees, and again rose upon the removal of the flask. By the addition of nitrous acid to the snow, a more intense cold was produced, and the thermometer fell five or six degrees more. p. 82.

Professor Leslie showed, that this radiant cold observes in its relations to different bodies the same laws as radiant heat. Thus, it differs in intensity according to the nature of the surface from which it is radiated. It varies also by changes made in the absorbent power of the surface of the thermometer, and follows the usual laws when changes are made in the surface of the reflecting mirrors. In all respects this radiant cold comported itself precisely like radiant heat in the mode of its affections by other bodies. To the explanation of these phenomena we shall return hereafter.

(179.) The facts which we are now about to select from Mr. Leslie's Inquiry into the Nature of Heat, will by no means be of sufficient extent to give an idea of the estimation in which we hold the work. Independently of the very curious and important information which it disclosed, we conceive that it did much towards exciting other experimentalists, and thus to it we are indirectly indebted for some of the elaborate and beautiful researches of the French philosophers.

The differential thermometer has been already noticed (30); the reflectors were much such as former chemists had employed, viz. of polished sheet tin. Mr. Leslie had them both parabolic and elliptical. For experiments upon radiant heat he introduced another piece of apparatus of great convenience and simplicity. Fig. 24 represents a square tin canister, the lid of Fig. 24, which removes, and is perforated for the insertion of a thermometer stem. This canister is filled with hot water; and it will be obvious to every one, that the four sides which can be alternately turned towards the reflector, may with great convenience be coated with different substances, for the purpose of examining their respective powers of radiation.

When in this manner three of the surfaces were lamp-black, writing-paper, and crown-glass cemented to the tin, the effects produced upon the thermometer were in the ratio of the numbers 100, 98, and 90 respectively, these being the number of degrees which the differential thermometer rose in each case. These, therefore, are all tolerable radiators of heat; but when the fourth side of the canister, which remained in its original state of polished metal, was turned towards the reflector, the thermometer fell immediately 12 degrees. The same took place when a surface of tin-foil was spread over the canister; polished metals, therefore, are bad radiators of caloric.

(180.) The following experiment refers to the concise operation of the absorbing power of surfaces: power.

"Cover the focal ball with a small bit of tin-foil, and make this to fit close all around, smoothing down the creases, but carefully avoiding to leave any scratches. Replace the differential thermometer, fill the canister again with boiling water, and present its blackened surface. The effect will now be reduced from 100 to about 20 degrees. Bring the clear side of the canister into the same position, and the effect will not exceed 2½ degrees." Leslie, p. 20.

(181.) A repetition of Pictet's experiments is thus described: "In place of the tin reflector substitute a concave mirror, remove the cup of tin-foil from the focal ball, dispose the whole apparatus properly, and,
having presented the canister's blackened side, refill it with boiling water. The coloured liquor will rise through a small but visible space. Rub off the silvering from the back of the mirror, and the effect will remain unaltered. Roughen the surface of the back by grinding it with sand or emery, the same effect will still be perceived; a decisive proof, that the reflection of heat is produced entirely at the anterior surface of the mirror. Over that surface spread a body of China ink, which will form an even and glossy coat; replace the mirror, and the effect now becomes altogether insensible. Cover the face of the mirror with a sheet of tin-foil, by pasting and carefully adapting it to the curvature, and smooth away as much as possible all wrinkles, a very great change will instantly be perceived in the degree of the performance. The effect of this reflector will ten times exceed that produced by the naked mirror.

"Hence it appears, that independent of the polish and figure, the nature itself of the substance of which a surface consists, has a most predominant influence in determining the measure of the reflection of heat; indeed the former requisites are comparatively of much inferior consequence. The very different effects of metallic and vitreous surfaces, in the reflection of heat, cannot fail to strike the most indolent observer.

"It may be desirable to exhibit the several results of the foregoing experiments in a collective view. Suppose that the bright side of the canister fronts a concave mirror, and that the focal ball properly placed is coated with tin-foil; an effect very minute indeed, but under favourable circumstances still perceptible, will be produced. Call this 1. Cover the face of the mirror with tin-foil, and the liquor of the differential thermometer will mount to 10. Remove the cap from the focal ball, and the action will be increased to 50. Now present the blackened side of the canister, and the extreme effect will be produced equal to 400. All these experiments succeed equally with cold, which exhibits the same diversified effects, and after the same proportions, though necessarily more limited." p. 28.

(184.) We have one slight subject of complaint against Mr. Leslie's work; that it has neither index nor table of contents; hence it is sometimes difficult to refer to experiments which it would be convenient to examine in connection with each other. The table of comparative radiating powers, as given in his experiments, will be found in the Appendix, No. XIII. Also a table of the comparative powers of substances made use of as reflectors, No. XIV. By applying coats of certain substances to one surface of the tin cube, it appeared that where these could be extremely thin, there was a marked difference in the effects produced; such was the case with some varnishes. Thus, where the effect of one coat of jelly applied to one surface of the tin was 38°, the effect of four such layers applied to another surface, was augmented to 54°. This increase continued till the thickness of the jelly was 3/4 of an inch, and then remained unchanged by further additions. With regard to metals, it seemed that a plate of the finest leaf that could be applied, rendered the radiating power as great as a thicker plate of the same metal; but it was supposed that differences might have been found within certain limits, as in the jelly, had it been possible to increase the tenuity of the metals sufficiently. (i.)

(185.) Count Rumford's memoir affords a striking instance of a circumstance by no means uncommon in the annals of science; that there is a certain point at which the generally diffused knowledge relating to any subject arrives; and that then, as there may remain but a few slight steps to reach some important development, these steps are readily passed over by more than one individual at the same instant. Such was the case here, the Treatise of Professor Leslie, and the Memoir of Count Rumford, both appeared in the same year; and as they present two series of independent but highly accordant results, they may fairly be considered as strongly corroborative of each other. (k.)

(186.) The original Memoir of M. De la Roche, we regret to state we have not been able to examine, and roche. therefore can only offer the following condensed outline of its contents, extracted from Thomson's Annals. (p.)

"I propose in this memoir to state several propositions which appear to me capable of throwing some light on the theory of radiant heat; and which I think I have established by decisive experiments. These experiments, indeed, were made with sufficient care to
HEAT.

First Proposition.—Invisible radiant heat may in some circumstances pass directly through glass.

Different philosophers, and particularly Mr. Leslie, conceive that they have proved the falsehood of this proposition; but the experiments of Professor Prevost of Geneva, have lately established its truth in an incontrovertible manner. He obtained his result by separating the immediate effects of transmitted heat from those produced by the heating of the glass, by a process equally simple and ingenious; namely, by employing movable screens of glass, which he renewed continually, and of course did not give them time to become heated before I have myself, since I became acquainted with the memoir of Mr. Prevost, made a great many experiments, which appear to me to prove the same thing. The nature of these will be stated in support of the second proposition.

Second Proposition.—The quantity of radiant heat which passes directly through glass is so much greater, relative to the whole heat emitted in the same direction, as the temperature of the source of heat is more elevated.

M. Delaroché shows, in the first place, by some ingenious experiments, that a thermometer, (of the temperature of the surrounding atmosphere,) exposed to the action of radiant heat, rises in a given time, ceteris paribus, a quantity proportional to the rays which it receives. If a certain number of rays make it rise 1 degree, double the numberwill make it rise 2 degrees; triple the number 3 degrees; and so on. This being established, he placed two parabolic metallic mirrors at the distance of rather more than three feet from each other. In the focus of one mirror he placed a thermometer; and in the focus of the other, a hot body, gradually increasing its temperature. The thermometer was allowed to rise to its maximum without any screen; then a screen of transparent glass was interposed, and the experiment repeated. Lastly, a screen of blackened glass was interposed, and the experiment repeated a third time. By the blackened screen all the radiant heat would be intercepted, and the effect on the thermometer would be owing to the rise in the temperature of the screen. Hence, the rise of the thermometer, when the blackened screen was used, subtracted from the same rise, when the transparent screen was used, leaves the effect produced by the radiant heat passing through the glass. The following table shows the ratio between the rays passing through the clear glass, and the rays acting on the thermometer, when no screen was interposed, at different temperatures.

Third Proposition.—The calorific rays which have already passed through a screen of glass, experience in passing through a second glass screen of a similar nature, a much smaller diminution of their intensity than they did in passing through the first.

This proposition was proved by interposing first one glass screen, and then two, and observing the difference in the effect. The experiments appear conclusive.

Fourth Proposition.—The rays emitted by a hot body differ from each other in their faculty to pass through glass.

This proposition is an obvious consequence from the third, which can hardly leave a doubt that the calorific rays (like those of light,) are of different kinds.

Fifth Proposition.—A thick glass, though as much or more permeable to light than a thin glass of worse quality, allows a much smaller quantity of radiant heat to pass. The difference is so much the less, as the temperature of the radiating source is more elevated.

This proposition is proved by experiments made with glasses of different thickness, employed as a screen; and its truth is sufficiently established, if these experiments be accurate. This curious fact, that radiant heat becomes more and more capable of penetrating glass, as the temperature increases, till at a certain temperature the rays become luminous, leads to the notion that heat is nothing else than a modification of light, or that the two substances are capable of passing into each other.

Sixth Proposition.—The quantity of heat which a hot body yields in a given time by radiation, to a cold body situated at a distance, increases ceteris paribus, in a greater ratio than the excess of temperature of the first body above the second.

This proposition being at variance with the opinion of Mr. Leslie, and of several other philosophers, M. Delaroché thought it necessary to establish it by a great variety of experiments. These leave no doubt of the fact; though they are not sufficient to enable us to deduce the rate at which the increase takes place.

(187.) In this matter, however, it may be as well to Berard's give a short abstract of the report made by MM. Berard, M. Malus from a very distinguished and too short career of scientific pursuits. This immediate object, however, was prosecuted and completed by M. Berard. The main object of Berard's researches had been, in conjunction with Malus, to repeat the experiments of Herschell and Englefield, and to examine the properties of heat, with some reference to the phenomena of polarization. During these researches death removed M. Malus from a very distinguished and too short career of scientific pursuits. This immediate object, however, was prosecuted and completed by M. Berard. The advantage of an heliostate, by which a beam of solar light could be reflected to one constant point for any length of time, greatly facilitated these researches. The experiments of Herschell, relative to the progressive heating power of the rays from the violet to the red, were fully confirmed; but the greatest heating power seemed to be within the red ray, and not beyond the spectrum. He fixed it at that point where the bulb of the thermometer was entirely covered by the red ray; and when the thermometer was placed beyond the visible spectrum at the point where Herschell obtained the greatest heat, "its elevation above the ambient air was
HEAT

295

The following observations by M. Berthollet turn so much upon the general features of this question, that we cannot forbear from quoting them, although we are most scrupulously anxious not to intrude upon the province of physical optics; a subject at present under preparation for this work, in hands better qualified for the task than any others which this country could produce.

The report goes on to state, “without attempting to decide between two opinions, which both go beyond the facts observed, we may at least weigh their relative probabilities, and compare the number of hypotheses necessary in each, to represent the same number of facts. If we wish to consider solar light as composed of three distinct substances, one of which causes light, another heat, and the third chemical combinations, it will follow that each of these substances, is separable by the prism into an infinity of different modifications, like light itself; since we find by experiment that each of the three properties, chemical, colorific, and calorific, is spread, though unequally, over a certain extent of the spectrum. Hence we must suppose, on that hypothesis, that there exist three spectra, one above another, viz. a calorific, a colorific, and a chemical one. We must likewise admit that each of the substances which compose the three spectra, and even each molecule of unequal refrangibility which constitutes these substances, is endowed, like the molecules of visible light, with the property of being polarized by reflection, and of escaping from reflection in the same positions as the luminous molecules.

“Instead of this complication of ideas let us conceive simply, according to the phenomena, that light is composed of a collection of rays unequally refrangible, and of course unequally attracted by bodies. This supposes original differences in their size and velocity, or in their affinities. Why should those rays which differ already in so many things, produce upon thermometers, or upon our organs, the same sensations of heat or light? Why should they have the same energy to form or separate combinations? Would it not be quite natural that vision should not operate on our eyes, except within certain limits of refrangibility; and that too little or too much refrangibility, should render it equally incapable of producing that effect? Perhaps these rays may be visible to other eyes than ours; perhaps they are so to certain animals; which would account for certain actions that appear to us marvellous. In a word, we may conceive the calorific and chemical faculty to vary through the whole length of the spectrum, at the same time with the refrangibility, but according to different functions; so that the calorific faculty is at its minimum at the violet end of the spectrum, and its maximum at the red end; while, on the other hand, the chemical faculty expressed by another function, is at its minimum at the red end, and at its maximum at the violet end, or a little beyond it. This simple supposition, which is only the simple statement of the phenomena, equally agrees with all the facts hitherto observed, and accounts for those established by M. Berard, and even perhaps by Mr. Powell, and, as the shortest possible abstract of his views, we present the following from his own paper in the Philosophical Transactions.

1. “That part of the heating effect of a luminous hot body which is capable of being transmitted in the way of direct radiation through glass, affects bodies in proportion to their darkness of colour, without reference to the texture of their surfaces.
in fluids or vapours, we must take care that the surfaces of the vessels containing them be of bright metal; such of the pipes for conveying steam; and the well-known excellence of a bright silver teapot affords another familiar illustration. On the contrary, if heat is to be given out with rapidity, as in the case of pipes for communicating warmth to rooms or hothouses, the surfaces must be covered with some rough black pigment, in order that they may produce the greatest possible effect. Where heat is to be reflected the metals must be resorted to with the best polish that can be given to them. And if we wish to intercept heat by a screen, a very thin plate of polished metal is found sufficient for the purpose; thus the fireman’s mask is covered with tin or tin-foil.

(197.) Thus have we described the effects of radiant heat, or rather, perhaps, the methods according to which, as far as observation has yet taught us, those effects are produced. But throughout all this chapter, we have spoken of the communication of heat by radiation, as if an excess of heat possessed by one body, naturally tended to flow into all surrounding bodies, until an equilibrium of temperature should be established. That, in short, the heated body does nothing but give out caloric, and the comparatively cooler bodies do nothing but receive it. Whether this be or not the case is at present an uncertainty; but it is a question highly important to those suppositions or theories which have been brought forward to explain the modus operandi of radiation.

Professor Leslie supposed radiant heat to be propagated by serial pulsations; but the existence of radiation in vacuo, and, in short, the whole tenour of Dulong and Pictet’s results, seems quite fatal to such an hypothesis. M. Pictet’s theory of radiation is somewhat analogous to the received doctrines of Electricity. He conceived heat to be a subtle fluid, the particles of which tended towards the establishment of equilibrium; that the excess of heat which one body had over another was a manifestation that this equilibrium did not exist, and that all effects were due to this inequality of tension. (p. 83.)

The more generally received theory of radiant heat, Prevost’s theory was advanced by M. Prevost, of Geneva. According to the views of this able philosopher, the radiation of heat is a process perpetually going on between all bodies in nature. Those which are at equal temperatures make a mutual and equal interchange; but in the radiation which takes place between bodies unequally heated, the emanations proceeding from the warmer to the colder body are greater than those which proceed in the contrary direction; and hence the universal tendency to an equilibrium of temperature is accounted for. This theory is now pretty generally adopted; there may be yet slight difficulties which embarrass its explanations when subject to the interferences of colour, surface, &c.; but it seems to abide well the application of that admirable touchstone, Mathematical Analysis. (p. 15.)

Dr. Brewster however refers it to aerial pulsations; but the application of the views of this able philosopher, the radiation of heat is a process perpetually going on between all bodies in nature. Those which are at equal temperatures make a mutual and equal interchange; but in the radiation which takes place between bodies unequally heated, the emanations proceeding from the warmer to the colder body are greater than those which proceed in the contrary direction; and hence the universal tendency to an equilibrium of temperature is accounted for. This theory is now pretty generally adopted; there may be yet slight difficulties which embarrass its explanations when subject to the interferences of colour, surface, &c.; but it seems to abide well the application of that admirable touchstone, Mathematical Analysis. (p. 15.)

Heat. 

CHAPTER IV.

ON THE CONDUCTING POWERS OF BODIES.

(198.) The phrase, Conducting power, though now so familiar as to be readily understood by everyone, and therefore as we hope secure from inducing any false notion of the operation of caloric, must nevertheless be admitted to be logically objectionable. In strict language it seems to imply some active property in the particles of matter, by which the effect or substance of caloric (be it which it may) is passed on from each molecule in succession to the one next adjoining to it: while in fact it is possible that the true case may be one of resistance, that the particles of matter oppose the free motion of heat which otherwise would take place, and compel it to undertake the more tedious process of inducing a certain effect upon the first particle acted upon, which is in turn to act upon the next adjoining one, and so on.

Whether the molecules of matter be or be not in contact, and consequently whether all the effects even in solids are necessarily those of radiation at small distances from one particle to another, from so many screens placed consecutively, is a point quite beyond our present knowledge, but is also, happily, immaterial to our purpose.

It seems to be the general tendency of caloric to become so diffused among matter of every kind as to produce uniformity of temperature. In the preceding chapter we have treated of the motions of caloric in free space and in aeriform fluids, where it moves by radiation. We here therefore consider its motion in homogeneous bodies, which, as we have seen, is estimated by their conducting power, or to use a better word, proposed by M. Fourier, their specific permeability: a property peculiar in degree for each substance, and independent of the state of its surface.

Corresponding to the three physical states of ponderable matter, we shall now consider the specific permeability or conducting power of heat, in solids, liquids, and gases.

(199.) If heat or cold be applied to the surface of any body, that is to say, if caloric be added to or abstracted from the exterior molecule of any mass of matter, this effect will be continued to the molecule next adjoining, and so on. Thus the change of temperature is transmitted through the mass of matter. In this illustration we do not consider whether the first molecule exerts any influence upon the third, other than through the medium of the second, or not; neither is this a question which we are able to resolve; for if we were, the doubts which have been expressed at the beginning of this chapter, respecting the mode of the transmission of heat, would be at an end.

That bodies differ greatly in the facility with which they permit the motion of caloric or transmit its effects, is a matter of daily observation. If two rods, the one of metal and the other of earthenware, have each an end placed in the fire, the metal rod will become heated much sooner, and the caloric effect will be transmitted along it much further than in the earthenware one. If the rods be of considerable length, there will be found a point in each, (the focus of heat remaining constant) at which the increment of temperature received from the next preceding heated molecule being exactly equal to the decrement produced by the effect of radiation, and the contact of the air; no further elevation of temperature will beyond that point be produced.

Although it is not, as we shall shortly show, a law of rigid accuracy, yet it may be roughly stated, that those substances which possess the greatest density have also the greatest conducting power. Thus the metals are the best conductors, then the hard woods, and so on.

(200.) The relative conducting power has been the subject of many experiments, with a view to ascertain whether any connection could be traced between that and their other physical or chemical properties. The metals seem to offer the most promising subject for such researches, in consequence of their uniform nature and continuity. How near their solidity approaches to perfection we are however ignorant; and in the case of woods and other porous bodies, the presence of air, a notoriously bad conductor, must materially interfere with the process.

On this principle alone, if not from any other, we may account for the very different conducting power of the same substance in different states of aggregation. Thus a mass of iron filings conducts heat much more slowly than an integral mass of iron; and saw-dust much worse than the wood from which it has been formed.

(201.) Amongst the earliest comparative experiments those of M. Richman have been thus briefly described. "He enclosed the bulb of a thermometer in similar hollow balls of the metals, which were plunged into boiling water until the thermometer in each rose to the same point. They were then removed and exposed to the atmosphere, and the time which elapsed, while the enclosed thermometer cooled a certain number of degrees, was marked: the relative conducting power was supposed to be as the times of cooling." His results need not be stated, as they are rendered quite nugatory by considering that in fact the cooling would greatly depend upon the radiation of the surfaces of these metallic shells. (a)

(202.) Franklin's method as employed by Ingenhousz in 1780 is more direct and simple. Equal wires of the several ductile metals were passed through a flat horizontal disc of wood, and all left standing at a considerable but equal height above its surface. This
Heat. The portion of all the wires above the board was equably coated with wax, while the lower extremities of the wire beneath the disc were immersed in olive oil, heated to about 219° Fahrenheit. The height in each rod to which the wax was melted above the board, was considered a measure of the conducting power of the metal. The experiment was repeated twelve times, and the following series presents the order of the conducting powers of the metals according to this method, the best standing at the top of the list. (b.)

Morveau. On the authority of Morveau (d) the conducting power of charcoal to that of fine sand is as 2 to 3, but the ratio is probably one of greater disparity, for charcoal is in fact one of the worst conductors known. In some experiments of Count Rumford, the conducting powers of pure dry wood ashes, charcoal in fine powder, and lamp black, were as the numbers  v 9 16 1 v 9 17 1 v 9 18 1 v 9 19 1 v 9 20 1 v 9 21 1 v 9 22 1 v 9 23, respectively.

Rumford. (204.) To Count Rumford also we are indebted for a series of experiments on the conducting power of substances of several other kinds, especially those which form the material of dress, &c. "His method was to suspend a thermometer in a cylindrical glass tube, the extremity of which had been blown to a globe of 1.6 of an inch in diameter, the bulb of the thermometer being placed in the centre of the globe. It was then surrounded with the substance, and the instrument was heated in boiling water, and afterwards being plunged into a mixture of pounded ice and water, the times of cooling were observed. The following are the results, the number of seconds being marked during which the thermometer cooled from 70° to 10° in Reaumur's scale: Air 576°; raw silk 1284°; wool 1118°; cotton 1046°; fine lint 1082°; beaver's fur 1296°; hare's fur 1315°; eider down 1305°. The relative conducting powers being inversely as the times of cooling. Hare's fur and eider down are the worst conductors, lint the best.

The relative conducting powers of these substances appeared to depend on the quantities of air enclosed within their interstices, and the force of attraction by which this air is retained or confined. If their imperfect conducting power depended on the difficulty with which caloric passes through their solid matter, the relative degree of that power would be as the quantity of that matter. The reverse, however, is the case. It was found that by varying the arrangement of the same quantity of matter the conducting power was varied. The thermometer being surrounded with 16 grains of raw silk, the time of cooling from 70° to 10° of Reaumur amounted to 1284°; with ravellings of taffeta (16 grains) 1169°; and with cut sewing silk 16 grains 917°. Here it was obvious that the more dense the same matter was, or the less air it contained, diffused through its interstices, the caloric passed with more celerity. It is evident also, that the air remaining in the globe in these experiments, if the motion of its parts had not been impeded, would have been sufficient of itself to have carried off the caloric more quickly than it actually was; for air in motion conveys changes of temperature with celerity, and hence the interposition of the fibrous matter must have acted principally by retarding the motions of the included air, partly also, probably, by retarding the discharge of heat by radiation.

The former effect will be in a great measure proportionate to their sponginess, and to the force of attraction with which the air is retained in their interstices. That such an attraction exists, is proved by the force with which they retain the air which adheres to them even when immersed in water, or exposed under the exhausted receiver of an air-pump. It is to this cause principally that the property which all porous bodies, such as furs, feathers, wool, and down, have of retarding the passage of caloric is owing." (e.)

(205.) The experiments which have now been recited although of considerable interest, are not strict solutions of the problem touching the conducting power of the substances themselves, because the interference of some other important properties has not been guarded against. Thus the effects of radiation have always continued to operate, and yet no account has been taken of them, nor any correction made for them. And further, the different absolute quantities of caloric added or abstracted, in order to produce a known change of sensible temperature, have been disregarded. Humboldt still believed, though with little success, to remove this source of error in certain results which he published. (f.) Imperfect as our knowledge upon these points confessedly is, we still are gainers by these researches, because so long as the conditions of experiment remain the same, the
HEAT.

Thus we are taught the reason why wool and down, feathers and furs, are such warm articles of clothing; because in the ordinary state in which we employ them, the effect of their own bad conducting property, and that of the air retained in their interstices, prevents the abstraction of caloric from our bodies. From its porous nature, snow is a very bad conductor; and thus a mantle producing uniformity of temperature is provided for the protection of vegetables from the more intense colds of winter.

Heat and cold when referred to our sensations are but comparative terms, and depend upon the temperature of our bodies at the time of experiment. This admits of a very familiar illustration. Let a hand be dipped into a basin of water at about 90° Fahrenheit, and it will feel warm; then let the hand be plunged into another basin at about 70°, this will produce the sensation of cold. But if the same basin of water at 70° be made use of after a bath of spring water, it will produce the sensation of warmth. Thus the same water is warm or cold to our sensations, according to the state of bodily temperature at which we make the experiment.

But by the conducting powers of bodies we readily explain another branch of our sensations. In a room of uniform temperature all substances in it would produce equal indications upon the scale of the thermometer. But if we touch these different substances in succession, very different sensations will be produced; a piece of metal will feel much colder in the ordinary state of the atmosphere than any marble or stone or glass, and these colder than a table of wood or a mass of paper. The contrary will take place if all these bodies be heated in the sun to a temperature beyond that of our animal heat. The reason is apparent, each of these substances has a different conducting power, and that which is the best conductor will carry off heat from our bodies with the greatest rapidity, and therefore will produce in us the greatest sensation of cold.

Again, it is in consequence of bad conducting power that glass and earthenware vessels are so easily broken by the sudden application of heat. The exterior portion which is first affected undergoes expansion, but as this effect has not been carried on by the progress of heat towards the interior of the substance, the equilibrium of cohesion between the particles is destroyed, and the vessel is broken.

These principles also are of frequent application in the arts and in domestic economy. If we wish to keep any body hot or cold, speaking comparatively with reference to the mean temperature of the air, or in other words to cut off the radiation and conducted transmission of heat, which tends to produce equilibration of temperature in all bodies, we must employ clothing or screens of the worst conductors we can find. To keep the substance warm we wrap it in flannel, to keep a piece of ice from melting we do the same. Air is, as we shall see, a very bad conductor; therefore, in building an ice-house, in which the object is to prevent the access of caloric, a double wall having a hollow space within is found to be very effectual. Furnaces also are coated with a paste of clay and sand, to prevent the dissipation of heat. Wine coolers have recently been constructed for the purpose of confining the cooling effects of ice, or an artificial refrigerant mixture,—allowing as little loss as possible from the heating influence of the external air. To effect this, the outer tin case is made double, so as to leave a space of half an inch between the two plates of which it is formed. This space is either filled with powdered charcoal, or left vacant; and in either case, a vessel is produced of which the temperature within will remain many hours below that of the external air.

M. Pictet's experiment made with a view to ascertain whether heat were conducted more readily in one direction than in another, by the same substance, is worthy of observation. He contrived to enclose a metallic bar vertically in a vacuum, and then heated it exactly in the centre. Thermometers having been placed at the upper and lower extremities, it was found that the upper one manifested an increase of temperature more speedily than the lower one.

The problem of the communication of heat in solid bodies, has, like every other branch of the subject, been submitted to rigorous analysis by Laplace, Biot, Fourier, and Poisson. Of these, M. Biot is the only one who, as far we know, has compared actual experiment with numerical calculation, and this only in the case of a metal bar heated at one extremity. For the details we must refer to his work. The formula investigated is

\[ \log y = \log Y - \frac{x}{M} \sqrt{\frac{b}{a}} \]

where \( y \) represents the temperature of the air surrounding the bar in degrees of the thermometer. The temperature of the focus of heat being \( Y + y \). The distance of the point examined from the focus of heat is \( x \), and \( a \), \( b \), are two coefficients constant for the whole length of any one bar only, and determinable by experiment; \( a \) is dependent on the specific permeability of the bar; and \( b \) represents the velocity of cooling for each point in the surface of the bar considered alone.

In speaking of the effects of caloric communicated to the surface of a body, and thence passing along through its substance, no limit has been assigned to the mode in which it may be imparted. Neither is any such of consequence, for the effect is the same as far as is known, whatever be the source from which the caloric emanates. Such at least is the case, wherever heat is communicated from the exterior of a substance, but of course the heat developed by percussion, or by Voltaic action, is differently excited and propagated.

The differences existing between the transmission of heat by the contact of two substances possessing unequal temperatures, seems simply to resolve itself into the case of those bodies before mentioned, (200.) which differ in the state of their aggregation: the filings and the saw-dust. In such cases the rapidity with which the one abstracts, and the other parts with its excess of caloric, follows, probably, a law arising out of the conducting power and capacity of each body respectively.

References from (198) to (210) inclusive:

§ 2. Conducting Power of Liquids.

(211.) From the facility with which liquids are heated in common vessels, it may at first sight appear that their conducting power is considerable. The very opposite, however, is the true state of the case; strictly speaking, they are such bad conductors of heat that many experiments were made before a complete conviction was obtained of their possessing that property at all.

The physical constitution of fluids, by which their molecules enjoy complete mobility among themselves, is the chief source of their apparent conducting power. For if we suppose the lowest stratum of particles in a vessel of fluid to receive caloric from any source of heat applied beneath: the first effect produced will be the expansion of these particles, by which their specific gravity being diminished, they will ascend through the mass of fluid, and a fresh stratum of molecules will descend to occupy their place. By a repetition of this process the whole body of fluid soon becomes heated.

But if the upper surface of a fluid be heated, no such effect can take place; the heated and lighter particles continue at the surface, and caloric if it proceed downward in the fluid at all, must do so by a legitimate process of conducting power as in solids.

(212.) Among the earliest in prosecuting this subject of inquiry, was Count Rumford; he felt assured that the diffusion of heat through a fluid mass took place in consequence of this carrying process only, and that this class of substances, the liquids, possessed no true conducting power. He discovered and beautifully exemplified the process by which a vessel of fluid receives heat from any source over which it may be placed.

"In a set of experiments on the communication of heat, he made use of thermometers of uncommon size. Having exposed one of these (the bulb of which was near four inches in diameter) filled with alcohol, to as great a heat as it could support, he placed it in a window to cool, where the sun happened to be shining. Some particles of dust had by accident been mixed with the alcohol; these being illuminated by the sun became perfectly visible, and discovered that the whole liquid in the tube of the thermometer was in a most rapid motion, running swiftly in opposite directions, upwards and downwards at the same time. The ascending current occupied the axis, the descending current the sides of the tube. When the sides of the tube were cooled by means of ice, the velocity of both currents was accelerated. It diminished as the liquid cooled; and when it had acquired the temperature of the room, the motion ceased altogether. This experiment was repeated with linseed oil, and the result was precisely the same. These currents were evidently produced by the particles of the liquid going individually to the sides of the tube, and giving out their caloric. The motion they did so, their specific gravity being increased, they fell to the bottom, and of course pushed up the warmer part of the fluid, which was thus forced to ascend along the axis of the tube; and so on in continuity."

He exhibited this result more conveniently by forming a solution of potash and water, so that it should have exactly the specific gravity of amber; and then by placing this solution, with some roughly powdered amber dispersed in it, within a proper glass vessel, the currents became more apparent.

"These observations naturally led Count Rumford to examine, whether the heating and cooling of fluids be not very much retarded by every thing that diminishes the fluidity of these bodies? He took a large linseed oil thermometer with a copper bulb and glass tube; the bulb was placed exactly in the centre of the brass cylinder; so that there was a void space between them all around, 0.2575 of an inch thick. The thermometer was kept in its place by means of four wooden pins projecting from the sides and bottom of the cylinder, and by the tube of it passing through the cork stopper of the cylinder. This cylinder was filled with pure water, then held in melting snow till the thermometer fell to 32°, and immediately plunged into a vessel of boiling water. The thermometer rose from 32° to 200° in 597 seconds. It is obvious that all the caloric which served to raise the thermometer must have made its way through the water in the cylinder. The experiment was repeated exactly in the same manner, but the water in the cylinder, which amounted to 2276 grains, had 192 grains of starch boiled in it, which rendered it much less fluid. The thermometer now took 1109° to rise from 32° to 200°. The same experiment was again repeated with the same quantity of pure water, having 192 grains of eider down mixed with it, which would merely tend to embarrass the motion of the particles. A quantity of stewed apples were also in another experiment put into the cylinder. These substances retarded the rate of cooling rather more than the starch.

"Now the starch and eider down diminished the fluidity of the water. It follows from these experiments, that the more completely the internal motions of liquid are impeded, the longer is that liquid before it arrives at a given temperature. Therefore when heat is applied to liquids, they acquire the greatest part of their temperature, in common cases, by their carrying power. If liquids then be conductors, their conducting power is but small when compared with their carrying power." (a.)

(218.) As a source of fallacy in these experiments, wherein heat was said to be conveyed downwards, and therefore fairly conducted through a fluid, it was suspected that the sides of the vessel might in reality be the conductors of the heat. To obviate this objection, several series of experiments have at different times been performed by Dr. Hope, (b.) Professor Thomson, (c.) Mr. Nicholson, (d.) Mr. Dalton, (e.) and Mr. Murray, (f.) All these experimentalists arrived at the same conclusion; that though the conducting power is very feeble in fluids, nevertheless it does exist.

We limit ourselves to a description of Mr. Murray's Mr. Mur.experiment, as being the most decisive, and shall ray, describe it in his own words.

"It occurred to me," says he, "that the source of uncertainty, arising from the supposed conducting power of the sides of the vessel, might be obviated by a simple contrivance, employing a vessel of ice, in which a fluid at 32° should be placed. Ice cannot have its temperature raised above 32° Fahrenheit, for if heat be communicated to it, it is spent merely in melting it. Hence it cannot communicate any temperature above that point, and therefore if a fluid contained in a vessel of ice be heated downwards, by a hot body being..."
Heat. applied to its surface, we may conclude with certainty, that the caloric has been conveyed by the conducting power of the fluid. In a hollow cylinder of ice, a thermometer was placed horizontally at the depth of one inch, its bulb being in the axis of the cylinder, and the part of the stem to which the scale was attached entirely without. As water could not be employed at the temperature at which it is requisite to make the experiment, on account of the property it possesses of becoming more dense in the rise of its temperature from 32° to 40°, oil was used. A quantity of almond oil at 32° was poured into the ice cylinder, so as to cover the bulb of the thermometer \(\frac{1}{2}\) of an inch. A flat-bottomed iron cup was suspended, so as to touch the surface of the oil, and two ounces of boiling water were poured into it. In a minute and a half the thermometer had risen from 32° to 32°.75; in three minutes to 34°.5; in five minutes to 36°.25; in seven minutes to 37°.5; when it became stationary, and soon began to fall. When more oil was interposed between the bottom of the cup and the bulb of the thermometer, the rise was less; but even when its depth was three quarters of an inch the rise amounted to 1°.5. With mercury the same results were obtained, the thermometer rising only with much more rapidity, from the mercury being a better conductor than the oil. (f)

(f) Few experiments have been made upon the relative conducting powers of fluids, and little is at present known on the subject, in consequence of the difficulty already adverted to, of separating the transportation by motion from the true conducting property. Obviously those substances which undergo the greatest expansion from heat will possess the most rapid carrying power, (fluidity being equal,) because in them currents will be formed with the greatest ease. Now since alcohol suffers a greater expansion from a given increment of temperature than mercury does; the circulation of its carrying currents must be more rapid than those in the metallic fluid; but yet as mercury adopts the temperature of a medium in which it is placed with greater rapidity than alcohol does, it must in reality be the better conductor.

(g) Count Rumford found that when a thermometer was surrounded with a body of quicksilver, it required to be immersed in boiling water 36; seconds to produce a rise of a certain number of degrees; but that to produce the same rise when surrounded in the same manner with water, 117 seconds were necessary. In this, which is obviously only a particular case of the general question, the conducting power of water is to that of mercury as \(\frac{1}{117}\) to \(\frac{1}{36}\) or as 313 to 1000.

Dr. Traill. endeavoured to ascertain the conducting power of different liquids, by finding the times requisite to produce an increment of 3° of temperature in a mercurial thermometer placed in the liquid submitted to trial. The caloric was transmitted downwards, from the extremity of a cylinder of iron, one inch in diameter, heated to 212°, and suspended in the liquid, so as to be half an inch distant from the bulb of the thermometer. The following are the results in minutes and seconds: (g)

- **Mercury** .......................... 0' 15"
- Saturated solution of sulphate of soda .......... 6 30
- **Water** .................................. 7 5
- Proof spirit ................................ 8 0 nearly
- Solution of sulphate of iron (1 salt 5 water) ........ 8 0
- **Alcohol** (London Pharmacopeia) .......... 10 45

(217.) Dr. Thomson states, that according to his experiments the conducting powers of mercury, water, and linseed oil are in the following ratio: (k.)

- Water ........................................ 1
- Mercury ........................................ 2 {equal volumes.
- Linseed oil .................................... 1.111
- Water ........................................... 1
- Mercury ........................................ 4.8 {equal weights.
- Linseed oil .................................... 1.085

(218.) The conducting property of liquids has also Dr. Brewster been proved on optical principles by Dr. Brewster, whose very curious experiments we most reluctantly commit to our readers through a reference only. (i.)

(i.) References from (211) to (216) inclusive:

§ 3. Conducting Power of Gases.

(219.) With regard to the conducting power of aerial Gases, fluids, in the sense to which we have hitherto applied it, we are inclined to think that nothing at all is at present known. Count Rumford supposed them not to possess conducting power at all. If, however, we were to speak of permeability we arrive at the actual subject of the last Chapter, Radiation; for in this sense, the gases are highly permeable, as we have shown. The experiment made by Sir Joseph Banks and others, by venturing into a room heated to the temperature of 260°, and remaining there some time, must prove that in such a practical case as is an extremely bad conductor. Water at a much lower temperature would not have been tolerable.

Experiments towards ascertaining the conducting power of gases have been made by Mr. Dalton, Sir H. Davy, and perhaps by others. They ascertained the times of cooling required for thermometer bulbs placed in different airs. But a little consideration will teach us, that this mode of cooling does not apply to our present question, because many other incidental causes must have interfered with the results, or, in truth, the whole investigation refers to radiation. How can we separate the effects due to that action? or how much power of the fluid is dependent upon the currents of the gases? These questions it seems impossible to answer, and without an absolute correction could be obtained for these disturbing causes, we feel that the real question at issue remains quite undecided.

Although perhaps the effect of currents might be guarded against, as in the case of liquids, yet we do not see how the process of radiation is to be prevented in media of such tenuity; and no experiments had until very recently been made, enabling us to ascertain how much of effect might be ascribed to conducting.
We terminate this Chapter with the following passage from Dr. Murray.

"In concluding this subject, it may be observed, that it is principally by the agency of fluids, elastic and non elastic, that the distribution of caloric over the globe is regulated, and great inequalities of temperature guarded against; and that this agency is exerted chiefly by the circulation of which their mobility renders them susceptible.

"Thus the atmosphere, with which the earth is surrounded, serves the important purpose of moderating the extremes of temperature in every climate. When the earth is heated by the sun's rays, the stratum of air reposing on it receives part of its caloric, is rarified, and ascends. At the same time, from a law which attends the rarefaction of elastic fluids, that they become capable of containing a larger quantity of caloric at a given temperature, as they become more rare; this heated air, though its temperature falls as it ascends, retains the greater part of its heat; its place at the surface is supplied by colder air pressing in from every side; and, by this constant succession, the heat is moderated that would otherwise become intense. The heated air is by the pressure of the constant ascending portions, forced towards a colder climate; as it descends to supply the equilibrium, it gives out the heat it had received, and this serves to moderate the extremes of cold. There thus flow a current from the poles towards the equator, at the surface of the earth, and another superior current from the equator to the poles; and though the directions of these are variously changed, by inequalities in the earth's surface, they can never be interrupted, but produced by general causes must always operate, and preserve more uniform the temperature of the globe. Water is not less useful in this respect in the economy of nature. When a current of cold air passes over the surface of a large collection of water, it receives from it a quantity of caloric; the specific gravity of the water is increased, and the cooled portion sinks. Its descent forces up a portion of warmer water to the surface, which again communicates a quantity of caloric to the air passing over it; and this process may be continued for a considerable time, proportioned to the depth of the water. If this is not very considerable, the whole is at length cooled to 40°, below which, the specific gravity not increasing, the circulation ceases, and the surface is at length so far cooled as to be covered with ice. If the depth is much greater, the application of the cold air may be continued longer without this result; and in this, and other countries not intensely cold, it often happens that deep lakes are not frozen in the course of the winter. The depth of the ocean being greater, and the body of water larger, while from its saline impregnation, its points, both of freezing and maximum density, are lowered; it resists freezing still more effectually, and is scarcely frozen indeed, except in latitudes where the most intense cold prevails.

"The quantity of caloric thus communicated by water is exceedingly great. "The heat," Count Rumford remarks, "given off to the air by each superficial foot of water, in cooling one degree, is sufficient to heat an incumbent stratum of air 44 times as thick as the depth of the water, 10 degrees. Hence we see how very powerfully the water of the ocean, which is never frozen over except in very high latitudes, must contribute to warm the cold air which flows in from the polar regions." From this cause, currents must exist in the ocean similar to those formed in the atmosphere. The water, which in the colder regions is cooled at the surface, descends, and spreading on the bottom of the sea, flows towards the equator, which must produce a current at the surface in an opposite direction; and thus the ocean may be useful in moderating the excessive heats of the torrid zone, as well as in obviating the intense colds of the polar climates." (a.)

(220.) It is found that if a number of bodies of the same initial temperature be so disposed that they may each receive equal quantities of caloric from some extrinsic source, the heating effects produced upon each of them are not equal. That is to say, equal quantities of caloric, when communicated to different bodies, do not produce equal increments of temperature upon the thermometric scale. Or, if heat be communicated to several bodies, so that they shall all at length manifest the same apparent temperature, the quantities which they are severally found to have imbibed are dissimilar.

This will appear more familiar by an example. Let 1 pound of mercury at 40°Fahrenheit be mixed with 1 pound of water at 156°F, and it will be found that the temperature after mixture is about 152°F Fahrenheit. Now as the quantities are equal, it might possibly have been expected that the temperature after mixture should be the mean of the temperatures of the substances mixed, or $\frac{156 + 40}{2} = 98°$. By the result, however, it appears that the water has only lost 3°.7 of temperature, which being added to that of the mercury, has raised its temperature 112°.3 to 3°.7 is that of 30.35 to 1. Hence, we say, the specific heat of water is to that of mercury, estimated in equal weights, as 30.35 to 1.

Again, conversely, let 1 pound of water at 40°Fahrenheit be mixed with 1 pound of mercury at 156°F: the calculated mean would be 98° as before, but the observed temperature of the mixture is found to be only 43°.7. Here the water has only gained 3°.7, but to supply this, the mercury has lost 112°.3. By which result we arrive at the same ratio as before.

By this or other modes of experiment, bodies are found to differ greatly in the ratios of their specific caloric. If instead of employing in this comparison the weights of bodies we make use of their volumes, a different series of ratios is of course obtained. In general the weight of the substances has been considered in preference to their volume, as being more capable of accurate admeasurement. Tables of both sorts have however been drawn up, and the numbers of the one sort are easily reducible to those of the other, as circumstances may require. Experiments of this nature have been diligently made, with the hope of discovering some general connection existing between this and other physical properties of bodies. The research was long a fruitless one, but by the introduction of the atomic theory, a clue seems to have been found and certain properties discovered, which, should they receive full confirmation, will stand among the most successful instances of philosophical generalization. From these general views we obtain the following definition.

Def. The relative specific caloric of bodies, sometimes also called their relative capacity for heat, is described by a numerical series, expressing the ratios of the different quantities of caloric necessary to be communicated to, or abstracted from, a given weight, or a given volume of each substance, in order to produce in it a given change of temperature.

Some writers have endeavoured to obtain an expression for absolute specific heat, the expression, however, necessarily requires the assumption of some measure of effect; to this subject we shall recur hereafter.

(221.) As an illustration of this definition, we have shown in the last Article that the specific caloric of water is to that of mercury (referring to equal weights) as 30.35 to 1, which is as 1 to .033. Similarly the capacities of other bodies may be compared with that of water; and if we always express its capacity by unity in these comparisons, we obtain a series of ratios having the capacity of water for the unit of the scale.

(222.) It is obvious that this question may be Three applied to substances under three distinct views.

1. When the substances to be compared are chemically dissimilar, but have all the same initial temperature.
2. When the same substance is considered at different temperatures, though in the same physical state.
3. When the same substance is considered, but under changes in its physical condition.

In attempting to give a succinct abstract of the researches of philosophers into the two first cases simultaneously, a chronological order may be preserved with convenience; while all that relates to the third case, or, as it is termed, the doctrine of latent heat, may be reserved for a similar, but independent mode of continuous description.

Method of Mixtures.

(223.) It would appear that Boerhaave was the first to infer from experiment that caloric is not distributed to bodies in proportion to either their density or their volume (b.) and some researches were made by Fahrenheit under his direction. The conclusions, however, at which he arrived were quite erroneous, and it is to Dr. Black that we are indebted for the first accurate views upon this subject. In his lectures at Glasgow between 1760 and 1765, he taught that the specific heat of bodies differed. (c.) Dr. Irvine pursued the subject between 1765 and 1770. (d.) About this time Wilcke of Stockholm applied himself to these investigations, and quotes Klingenstjerna as the author who first recognised the difference between the specific heats of bodies. Professor Thomson, however, states that the late Professor Robison had told him that Wilcke's information was originally obtained from a Swedish.
general experiments were published in 1781. Wilcke's experiments were published in 1781. (e) Wilcke mixed equal weights of glass heated to 86° centigrade and of water at 0°. The temperature after mixture was found to be 12°.75 centigrade.

Generally \( (m \, c + m' \, c') \, T = m \, c \, t + m' \, c' \, t' \) (Art. 224.)

\[
\frac{c'}{c} = \frac{m}{m' \, (T' - T)}
\]

Here \( m = m' \), \( t = 0 \), \( t' = 86° \), \( T = 12.75 \)

\[
\frac{c'}{c} = \frac{12.75}{86 - 12.75} = 0.174
\]

that is if \( c = 1 \) \( c' \) the specific capacity of glass \( = .174 \).

(227.) Another very convenient incidental application of this formula is for the purpose of obtaining the temperatures of substances, either by the temperature, or by the great elevation of temperature, preclude the use of the thermometer. M. Coulomb had recourse to this method for estimating the heat at which he tempered his metallic bars in a series of magnetic experiments, and M. Delaroche thus estimated the temperature of heated masses of metal placed in the focal plane of the reflecting mirrors in his experiments on the radiation of heat.

For the sake of an example, let us take the last experiment of Wilcke, varying only our object. Let us state that into water at 0° centigrade, an equal weight of heated glass was introduced; and that the temperature after mixture was 12°.75. And let it also be known that the specific capacities of water and glass are as 1 to .174.

Generally, \( (m \, c + m' \, c') \, T = m \, c \, t + m' \, c' \, t' \) (Art. 224.)

\[
\frac{t'}{t} = \frac{(m \, c + m' \, c') \, T - m \, c \, t}{m' \, c'}
\]

Here therefore

\[
m = m' \quad t = 0 \quad c = 1 \quad c' = .174 \quad T = 12.75
\]

By substitution, therefore, \( t' = 86° \) centigrade, the temperature to which the glass must have been heated.

(228.) In this method of mixture there are certain precautions to be most carefully observed. As the mixtures of whatsoever kind it is made in some vessel, a portion of calorific is communicated to the vessel, and therefore more heat is expended than would be sufficient to raise the mixture to the observed temperature \( T \). Hence \( T \) is always less than it would be were it not for this interference, and some correction must be devised to exclude this source of inaccuracy.

Let the vessel be of a substance as thin as conveniently possible. Let its mass \( = (m) \), its capacity \( = (c) \). Then it is evident that in all temperatures it will produce the same effect as a mass of water of the same temperature with itself, weighing \( \frac{(m)}{(c)} \), this then is the expression for the quantity to be added to the mass of water \( m \), in order that the effect of the vessel may be taken into account.

(229.) But it may happen that the specific heat \( (c) \) of the substance of the vessel is not known, and therefore must be determined.

For this purpose we may again employ the general formula of mixture,

\( (m \, c + m' \, c') \, T = m \, c \, t + m' \, c' \, t' \) (Art. 224.)

In which if the vessel be considered the heated body \( B \), the notation for this case requires the substitution of \( (m) \) for \( m' \) and \( (c) \) for \( c' \).
Heat.

whence

\[ \frac{m}{c} \left( \frac{T}{t} - \frac{t'}{t'} - \frac{T}{t} \right) \]

and the formula sought

\[ \frac{m}{c} \left( \frac{T}{t} - \frac{t'}{t'} - \frac{T}{t} \right) \]

In a series of experiments this, however, admits of

further simplification; for as the expression for the effect

of the vessel is constant in a comparative series of

results, we may by using the same vessel for several

experiments save some trouble. For though in this case

the mass of the water \( m \), may vary in each experiment,

yet the mass of the vessel \( m \) remains constant, and

therefore the value of

\[ \frac{m}{c} \]

so conducted will be constant. Hence in each expe-

riment it will only be necessary to add to the mass of

water \( m \) a constant correction obtained from the substi-

tution of the actual values of \( m \) \( c \) and \( c \). This

addition will of course be made in terms of that unit

of weight to which \( m \) refers. And hence in order to a

correct result, as much of the heated water is to be made

use of beyond the nominal quantity, as will give to

the vessel its due share of heat, which otherwise

would be stolen from the purposes of the experiment.

M. Biot has selected an example from the experi-

ments of Crawford. He put 40 ounces of water,

temperature 20°.0833 centigrade, into a tin vessel

which itself had a temperature of 42°.916. The

common temperature when established was 20.555.

Here \( m = 40 \) ounces; \( t = 20.0833 \); \( t' = 42.916 \);

\( T = 20.555 \); \( m \) refers to English ounces; and hence

\( c \) might be determined by substitution of values.

But it has been shown that the value of

\[ \frac{m}{c} \] a con-

stant quantity is sufficient for our purpose, and from

the formula

\[ \frac{m}{c} \left( \frac{T}{t} - \frac{t'}{t'} - \frac{T}{t} \right) \]

By substitution

\[ = 0.84 \]

that is to say, the vessel takes up as much heat from

the experiment as will require to be compensated by

an additional 0.84 of an English ounce of hot water.

In order to heat the tin vessel equally in Dr. Craw-

ford’s experiment, it was fitted exactly into a similar

tin vessel of tin, which was then plunged into a water

bath until the full effect had taken place, and the tempera-

ture of the bath was of course estimated by a

thermometer.

(231.) Another source of error in this method of

mixtures arises from the loss of temperature between

the instant at which the mixture is made, and that at

which uniformity of temperature is established and

measured. Crawford endeavoured to obtain a correc-
tion for this error by observing the law of progressive

cooling of the mixture for some time, and harassed

by calculation a correction to be added to the

observed value \( T \), to make up for the loss. This, how-

ever, is a matter of great difficulty and delicacy; and

even were the operation easy, there is no certainty that

the law of increment is the same for the mixing, as for

the mixed substances.

Method by melting of Ice.

Calorimeter (231.) We now proceed to the experiments of M.

Lavoisier in 1777, and those made in conjunction with

M. Laplace, and published in 1780. (f.) In these

a new instrument and a new method of investigation

were adopted. This method consists in employing the

heat to be given out by the body, for the liquefation

of ice. The water thus obtained is the measure of the

heat produced. This method was employed by M.

Lavoisier and Laplace, and the calorimeter contrived

for these experiments has been already described in

article (150.).

It may be well to remark, that the principle of

this instrument chiefly consists in the influence of the

exterior case of ice contained between the two metallic

vessels A B C D, A'B'C' D', fig. 18; for it is that

envelope which by its presence continues the tempera-

ture of the ice within at zero \( C^\circ \), and hinders it from

fusing, except by the action of the body introduced

within its central space.

Suppose this body a solid, and of a nature not to

change its state between the temperature of melting

ice and boiling water; then having brought it to any

temperature \( t \) comprised between these limits, and

measured in degrees of the mercurial thermometer; let

it be placed in the calorimeter, and left to cool down to

0°C. Arrived at this point we shall find that the quantity

of ice which it has melted, is proportional to the number

of degrees \( t \); so that if in cooling from 10° to 0° it has

melted 1 kilogramme; it will in passing from 20° to 0°
melt 2 kilogrammes, and 3 in cooling from 30° to 0°,
and so on throughout the thermometric scale. But

the constancy of this ratio will be different for different

bodies of the same given mass. For example, if a cer-

tain weight of sheet iron heated to 30° has fused

11 kilogrammes of ice, the same weight of mercury

raised to the same temperature will only fuse 3 kilo-

grammes. Quantity is here an essential element; for

a double or triple mass of the same substance melts

a double or triple quantity of ice under the same

circumstances.

That we may form a clear idea of these results, and

deduce accurate consequences from them, let us take

for the unit of caloric the unknown quantity of that

principle which is requisite to fuse a kilogramme of ice

at 0°; and let \( x \) represent the total and unknown num-

ber of such units, which at the temperature of melting

ice are contained in each kilogramme of a body \( A \), in

whatsoever mode that caloric may exist, whether fixed

and in combination; or free and capable of undergo-

ing change by radiation with other bodies in free space;

or even by portions in all these different states. If

now we raise the temperature of \( A \) to \( T \) degrees on the

mercurial thermometer, and then leave it to cool to 0°
in the calorimeter, there will be melted a certain num-

ber of kilogrammes of ice, which we may represent by

\( N \); then, according to our previous assumption, \( N \)

expresses also the new quantity of heat necessary to be

introduced into the body to elevate its temperature to

\( T \). But experiment proves that between 0° and 100°

the number \( N \) is proportional to the number \( T \) of

degrees, at least as long as the body does not change its

physical state. Consequently, if we divide \( N \) by \( T \),

the quotient \( \frac{N}{T} \), which we may call \( c \), will express

between these limits the number of kilogrammes of

ice which the body is capable of melting in lowering its

temperature one degree; and the same quotient will

express also in terms of our primary unit, the quantity

of caloric necessary to raise or lower its temperature
Heat.

On the same assumptions for every other temperature \( t \), comprised also between the limits of the thermometric scale, \( x + t \) will express the total quantity of caloric contained in \( A \), and \( c t \) will be the number of kilogrammes of ice at \( 0^\circ \), which it is capable of melting in cooling down to \( 0^\circ \). If the mass of the body instead of being 1 kilogramme be \( m \), its nature remaining the same, it will be necessary to consider it as consisting of \( m \) kilogrammes, exactly similar to the preceding. Then the initial quantity of caloric which it will contain at \( 0^\circ \) will be \( mx + mct \); and \( mct \) will express the number of kilogrammes of ice at \( 0^\circ \), which it is able to melt in the calorimeter in passing from \( t^\circ \) to \( 0^\circ \).

Hence, it appears sufficient to reason upon the unit of mass, taking care to multiply the result by the number of those units which the body under consideration contains.

From the comparison already mentioned between sheet iron and mercury, we perceive that the number \( c \) varies for different substances: and we have already stated (129) that it varies for each identical substance when that substance changes its physical state, that is to say when from solid it becomes liquid, or from liquid it becomes aeriform, or conversely. It is probable that these variations begin to be perceptible even before the change of state is effected. The number \( c \) therefore must be ascertained by observations made under those different circumstances. By doing this, \( c \), the specific heat of bodies is determined.

If the body be solid, a given mass \( m \) is raised to a known temperature, \( t \); and having placed it in the calorimeter, we find the number \( n \) of kilogrammes of ice at \( 0^\circ \), which it has melted in cooling down to \( 0^\circ \). This number being known we have the equation

\[
mct = n,
\]

whence

\[
c = \frac{n}{mct}.
\]

That is to say, the capacity for the heat of the unit of mass is expressed by the quantity of ice melted, divided by the product of the mass into the initial temperature.

For example, 3.772640 kilogrammes of sheet iron were heated in a water bath to 97.5°, and then placed in the calorimeter. At the expiration of eleven hours the whole mass had cooled to 0°, and the calorimeter furnished 0.542004 of melted ice. Hence, by substitution in our formula, the capacity of iron plate \( c = 0.542004 \times 97.5 = 0.00147235 \).

This experiment was actually made by MM. Lavoisier and Laplace, but with different units of weight and temperature. They estimated the weight in pounds, and the temperatures in degrees of Reaumur's thermometer. They employed 7.7070319 pounds of iron raised to 78° of Reaumur; and obtained 1.109705 pounds of melted ice. Hence, the specific heat of the iron in this system of units is \( c = \frac{1.109705}{7.7070319 \times 78} = 0.001841875 \).

By this example we perceive that the numerical value of \( c \) is independent of the unit of weight which may be chosen; because the same denomination is found both in the numerator and denominator of the fraction which expresses it. But this is not the case with the thermometric division that may be made use of; this really does affect the value of \( c \), of which it is only a divisor. Having remarked this fact, it is easy to convert results of one sort into those of the other sort, by multiplying each value of \( c \) obtained on one scale of division, by the ratio which this scale bears to that into which we wish to transpose it. For example, if we multiply our first value of \( c \) by \( \frac{100}{80} \), we shall find our second value; because in so doing we replace in the denominator the factor 97.5, which expresses the centesimal temperature, by the factor \( \frac{97.5 \times 80}{78} \) or \( \frac{78}{100} \) which expresses the octogesimal temperature.

But it is possible to render these numerical values of \( c \) independent of any such reduction, by expressing all of them in terms of some one adopted from among them as the unit. In this case the thermometric division of temperature disappears also, and the results become common to all systems of graduation. To this notation and result we have already arrived by other methods, (221,) and it is the method in common use at present. But to be able to deduce also from these results the absolute quantities of ice, which each body may melt in cooling down through certain limits, it is essential that we obtain the actual value of \( c \) for that substance to which all others are referred, and then it is necessary to specify the mode of division adopted for the expression of the temperature.

To ascertain the specific caloric of liquids, they are introduced into the calorimeter, by placing them in vessels; the specific heat of which is already determined by their having been placed alone in the calorimeter. Let the mass of the vessel = \( m \); that of the liquid = \( m' \); \( c \) and \( c' \) be the specific caloric of the substances respectively; and \( t \) the common temperature to which they are elevated. If \( n \) be the number of kilogrammes of ice which their cooling liquefies, we have evidently

\[
mct + m'c't = n,
\]

whence

\[
c' = \frac{n - mct}{m't}.
\]

That is to say, the capacity \( c \) equals the total weight of ice melted, minus the weight melted by the vessel alone, all divided by the product of the mass of the liquid into its temperature.

For example, MM. Lavoisier and Laplace wishing to determine the specific heat of nitrous acid, put 4 pounds of acid into a glass flask, weighing 0.53125 pounds, and of which the specific caloric \( c \) referred to the octogesimal scale is 0.008215 for the unit of mass. By means of a water bath the flask and acid were raised to a temperature of 80°, and then placed in the calorimeter. After twenty hours the cooling being completed, the machine well drained gave 3.66406 pounds of melted ice. In this example then \( n = 3.66406 \); \( m = 0.53125 \); \( c = 0.008215 \); \( t = 80° \); \( m' = 4 \); and hence \( c' = 0.0110292 \).

This is the absolute specific heat of the nitrous acid employed in that experiment, using the division of Reaumur. To adopt the centigrade division we must multiply by \( \frac{80}{100} \), whence we obtain 0.00881856.

(232.) By operating upon liquid water in the same manner, MM. Lavoisier and Laplace found that 1 pound of liquid water raised to 60° R or 75° Cent. would just melt 1 pound of ice in cooling down to 0°. Consequently the absolute specific heat of water on the octogesimal division = \( \frac{1}{60} = 0.0166666 \); or if we adopt the centigrade scale = \( \frac{1}{75} = 0.013333 \).
HEAT.

As these numbers are so constantly referred to for comparison with other substances, we shall do well to remember, that the absolute specific heat of water equals unity divided by the temperature of that water which just melts an equal volume of ice. And that this result comes out in degrees of whatever scale may be used for the estimation of the temperature.

(233.) If we divide the absolute specific heats of bodies estimated on either scale by these quantities respectively, we shall obtain the series of relative specific heats, referred to that of water adopted as the unit of the scale. But in order that we may repass from these values to absolute results, it is always necessary to include the absolute specific heat of water. The following are a few results of this sort given by Lavoisier and Laplace:

<table>

</table>

According to the signification which we have attributed to the coefficient c, the ratios contained in this table may immediately serve to estimate numerically the transfer of heat from one substance to another included therein. Thus the number 0.0290 corresponding to mercury, shows that a mass of mercury in cooling 1° gives out a quantity of caloric sufficient to raise the temperature of an equal mass of water 0.029°. A mass of quick lime in cooling 1° might raise the temperature of an equal mass of water, 0.21699°. Hence it follows, that the caloric given out by a mass of mercury in cooling 1° would be equal to elevate the same mass of quick lime 0.029/0.21699 = 0°.134. Here the scale on which the degrees are counted is unimportant, because it is the same in both valuations.

(234.) Moreover, if we multiply the numbers of this table by 60 1/4, which expresses the absolute specific heat of water in degrees of Reaumur, we shall have the weights of ice which one unit weight of each of these substances could melt in cooling through 1° upon that scale. If we made the multiplication by 75 or 300, we should obtain the analogous result for 1 centesimal degree. These then would be the absolute specific heats of the substances included in the table. For example, dividing thus the number 0.66139 (which belongs to nitrous acid) by 60, we again find the number 0.010232 which we obtained before as the absolute value of its specific heat.

(235.) It seems that mercury has a very low degree of specific heat. To raise the temperature of this liquid 1°, there only requires 29/1000 of that which a mass of water of equal weight would require. The almost absolute constancy of the value of c for mercury throughout that part of the thermometric scale between the freezing and boiling of water is a fact worthy of notice; for it hence follows, that within those limits the quantities of heat introduced into that substance are justly proportional to the elevation of temperature measured in degrees upon the scale. But these degrees themselves are measured by the dilatations of the mercury, and are proportional to those dilatations; therefore the dilatations of mercury within the limits of the thermometric scale are proportional to the increments of caloric received.

(236.) It were unjust to pass by the name of Crawford without acknowledging him to have been one of the most laborious and praiseworthy experimentalists in this department of science. The objects to which his researches tended were of first rate importance, for he thought that he had obtained an elucidation of the source of animal heat, by investigating the changes of capacity which attended the effects of respiration upon the blood. In 1788 his Essay on Animal Heat appeared, and though the whole foundation of his reasoning has been proved to be unstable, yet the numerous experiments which he made upon the specific heats of bodies were conducted with great care, and are still justly regarded with interest. (g.)

Meyer's Process.

(237.) About this time Meyer devised another process for comparing the specific heats of bodies. The times were observed, which were requisite to cool down equal volumes through a given interval on the thermometric scale. These times were considered to be as the capacities directly. But of course this estimation is referred to volume, so that if we wish to deduce the specific heats with reference to mass, we must divide the numbers thus obtained by the specific gravities of the substances respectively.

Hence Sp. Cal. by mass = \( \frac{\text{Sp. Cal. by vol.}}{\text{S. G.}} \)

This method is highly approved by Professor Leslie, who recommends it strongly in his interesting work upon heat. (m.) There is also the authority of Mr. Dalton in its favour, who conceives that it has an advantage over the method of mixture, being independent of any inaccuracy in the mercurial thermometer. (a.) This method seems chiefly adapted to substances in the liquid form; but the following remarks upon it by the late Mr. Murray are not unworthy of attention. "The principle however, on which it rests, is not just, for the cooling of bodies depends on other circumstances than their capacities. It is influenced both by their radiating and conducting powers. Any error indeed from the former, may be avoided by the mode in which the experiment has been performed by Leslie and Dalton, giving the same external surface to the body while cooling, by including it in a glass globe. But it is not possible entirely to obviate the latter. It is obvious, in the example of a mass of matter at a high temperature, communicating the excess of its heat to the surrounding medium, whether by the intervention of a vessel containing it, or not, that if it be an imperfect conductor of caloric, the caloric passing more slowly from the internal mass to the surface, the time...
of cooling will be longer than if it were the reverse, the capacity being the same. In liquids, too, the degree of mobility and expansibility influencing the motions of their parts, must influence their times of cooling. Hence, an accurate conclusion cannot be formed of the quantities of caloric which a body evolves, as its temperature falls, compared with that given out by another, by observing their respective times of cooling, but only by measuring these quantities by the effects they produce on another body to which they are communicated." Syst. Chem. i. p. 384.

Of some researches conducted in this manner, we shall, however, give an account hereafter. Gay Lussac's experiments on the specific caloric of gases may be noticed, together with those of Delaroche and Berard. (c.)

(238.) The order which we have adopted, will now lead us to a more elaborate series of experiments made by MM. Delaroche and Berard upon the specific heat of gases. Their Essay obtained the prize proposed by the French Institute, for the investigation of this subject, in 1811. After an attentive examination of this admirable Memoir, we have only to regret that its extreme length should preclude the possibility of our giving it entire in this place. Some abstracts of its contents, and the entire results obtained, however, to be laid before our readers, and as we are convinced we cannot improve upon that analysis, we extract the copious summary made by M. Biot, in his admirable Traité de Physique. No one, we are convinced, will ever notice in succession.

For this reason, the preceding result was regarded as peculiar to the circumstances under which it was obtained: and to render it applicable to other experiments, the authors reduced it to the proper pro-
HEAT.

portion for the difference between the temperatures of the calorimeter and the tube.

The method of determining by means of ascending and descending series, the maximum temperature which each current of gas would communicate to the calorimeter, has been already described; but as it would have been tedious to obtain this maximum by the sole influence of the current of gas, the calorimeter was brought nearly to that point, by applying the heat of a small spirit of wine lamp; the action of the gas was then allowed to proceed until the slowness of the heating or the cooling of the calorimeter showed that the maximum effect was not distant more than three or four tenths of a degree. This difference, though small, was nevertheless very perceptible in the experiments; for as the temperature of the calorimeter was measured by a thermometer, on the scale of which one centesimal degree occupied a length of ten millionths, which permitted the measurement of tenths and the estimation of hundredths of a degree. This thermometer had a cylinder, in length equal to the depth of the calorimeter, so that it accurately measured the mean temperature of the various strata of water contained in it.

It was essential to determine most accurately the temperature of the current of gas at its entrance into the calorimeter. This temperature was always rather below 100°; for however short the glass conducting tube might be, we may easily suppose that the gas must cool a little in passing through it. To estimate that cooling, a very sensitive thermometer was placed within the tube itself, at the point where it entered the calorimeter, and this thermometer continued steadily between 95°.6, and 92°.6, according to the nature of the gas. But certain trials proved that the temperature thus indicated was always rather inferior to that of the gas itself; and as that temperature could not possibly exceed 100°, it seemed not far distant from the truth to take the mean of these two values, that is to say, to consider the temperature of the gas as intermediate between 100°, and the temperature indicated by the thermometer in the tube. Another thermometer, placed at the very point from which the gas issued, proved that it escaped exactly at the temperature of the water in the calorimeter.

Finally, it remained to bring all the results into a comparable state; for it was of course physically impossible to operate always upon gases at the same temperature and pressure, even if there were no other cause beyond the ordinary changes of the atmosphere. With this view the authors made two auxiliary experiments upon atmospheric air, under different pressures. These pressures were easily obtained by means of the gasometers employed. It was only necessary to alter the height of the tubes which permitted the introduction of air into the vessels. In an experiment of this sort, the gasometers were so adjusted, as to give a pressure of 1°.0058; for, to the natural pressure of the atmosphere, which was 0°.7527, there was an additional one of a column of water, 3°.44 in height, equivalent to 0°.2531 of mercury. The current was such as to convey in 10 minutes through the calorimeter 31.1 litres of air, taken originally at the temperature 5°; which is equivalent to 30°.53, if taken at 0° originally. This current, heated to 100°, and then employed as in the other experiments, raised the temperature of the calorimeter to 16°.117 above the surrounding air; the heat communicated by the conducting tube being properly deducted. This air entered the calorimeter at 96°.90; it issued at 22°.632; therefore it suffered a depression of temperature of 74°.683. Let C be the total quantity of heat disengaged from it; and if we suppose that the specific heat of each gas remains constant throughout the range of the thermometrical scale, when the pressure is constant, it is clear that one litre of air, under a pressure of 1°.0058, as in the present case, and cooled in a similar manner, would have disengaged 30.55 being in proportion to its mass; whence it follows that it would only have disengaged

\[
\frac{30.53 \times 74.683}{1.6117} \quad \text{or} \quad \frac{0.0071274}{1°}.
\]

But we have seen that the quantity C is proportional to the permanent excess of the temperature of the calorimeter above that of the surrounding air. Therefore excess may be taken for the measure of the heat disengaged, representing it by the number of degrees of the thermometer to which it corresponds: then the actual value of C will be 16°.117, and the number

\[
\frac{30.53 \times 74.683}{16.117} \quad \text{or} \quad \frac{0.0071274}{1°}
\]

elevation of temperature at which the calorimeter may be maintained by the passage of one litre of air, taken originally at the temperature of 0°. C, under a pressure of 1°.0058, and cooled at 1°. But in another experiment, made at a pressure of 0.7405, it appeared that 35.99 of air measured also at 0° in cooling through 72°.415, had continued the elevation of the calorimeter at 15°.423, which by a similar mode of calculation

\[
\frac{35.99 \times 72.415}{15.423}
\]
gives 0.00591778 for the quantity of heat disengaged under these new conditions, by one litre of air cooling one degree. Dividing the former result by the latter, we have

\[
\frac{0.00591778}{1°.0058} = 1.20441
\]

for the ratio of the quantities of calorific disengaged by two equal volumes of air, at equal temperatures when the ratio of the pressures is 1°.0058 or 1.35927. A series of similar experiments gave for the mean ratio of the quantities of calorific 1.2396 instead of 1.20441. So that a variation of 0.35827 in the density, produces only a variation of 0.2396 in the quantities of calorific. Now, let us suppose a given volume of air, taken at a pressure p, has disengaged a quantity of heat C, measured by the number of degrees which it raises the temperature of the calorimeter above that of the air; if we represent the number of degrees which the same volume of air would have produced under the same circumstances as to temperature, but under some other pressure p', by the quantity C (1 + z); we may by a sufficiently near approximation suppose the proportion

\[
0.35827 : 0.2396 = \frac{p' - p}{p} : z
\]

whence

\[
z = 0.2396 \cdot \frac{p' - p}{p} \cdot 0.35827
\]

Thus did our authors proceed, and they were the more justified in doing so, because all their experiments took place under the natural pressure of the atmosphere, and therefore presented but slight variations of pressure. We perceive also from the same reason, that the assumption of the constancy of the specific heats could not produce any appreciable error in the reduction;
since they only made use of it between very confined limits, in consequence of the slight difference of temperatures to which the calorimeter was raised, and at which it was maintained by the different gases. Lastly, the same reason allowed them to consider the same scale of reduction as applicable to other gases as well as to air; because their specific heats differing but slightly, the reduction, if not strictly identical, must be but slightly dissimilar for each of them. After these explanations it will be easy to comprehend the following table, in which the circumstances of the experiments are recorded, together with the results deduced from them.

<table>

(240.) The last column of the table expresses the excess of the stationary temperature of the calorimeter, above that of the external air, supposing it to be heated successively by some given number of litres of different gases, taken originally at the same temperature, and under the same pressure, and reduced in temperature the same number of degrees. By dividing all these numbers in succession by the first among them, we obtain the specific heats of the different gases compared with that of air, under equal volumes and equal pressures; and if we divide these results by the specific gravity of each gas, calling that of atmospheric air unity, we obtain the specific heats of the gases under equal weights, that is to say, the relative quantities of caloric which a given weight of each gas, under a given pressure, would give out in cooling down through a given number of degrees. The following are the results as given by the authors of the memoir.

</table>
To deduce the second column from the first, the specific gravities are employed which are given in p. 381, book i. Biot's Physique; the specific heat of the vapour of water was obtained by comparing the cooling of the calorimeter effected by dry air, with that produced by air saturated with moisture at a temperature of 40°. This required that the atmosphere surrounding the calorimeter should be kept rather above that temperature, in order that no precipitation of vapour might take place; for the great evaporation of caloric that must accompany any such precipitation, would have produced very considerable error in the result.

These results are only relative. To make them absolute, we must obtain the actual value of some one among them; that is to say, we must ascertain for some one gas, atmospheric air for example, the quantity of ice which a given volume, under a given pressure, is capable of fusing by cooling down 10°; or which is the same thing, the quantity of water which it would boil; or, lastly, the increment of temperature which it could produce in a given mass of water. But the last result may be deduced from the experiments themselves. In fact we know the weight m of water contained in the calorimeter, as also the mass of the sheet copper and the solder of which it is made. The copper, according to Crawford, has a relative specific heat of 0.112; and solder, an alloy of lead and tin, may be considered as having a specific heat intermediate between those of its two metals, that is of 0.038. From these data we may calculate the number of grammes of water to which the sides of the instrument are equivalent; and adding this to the mass m, we have m + μ, the grammes of water represented by the whole instrument. Here the number was 5964.8. But in the first experiment above cited 35.99 of air, measured at 0° C, and under a pressure 0.7405, if heated to 100°, produced a current which in cooling down 72.415 maintained the calorimeter stationary ten minutes at a temperature of 15.734 above the surrounding air; whence it follows, that such a current then furnished to the calorimeter just as much heat as it lost to the surrounding air. This loss it is easy to estimate; for we have only to stop the current of gas, and allow the calorimeter to cool spontaneously, and observe the law of its refrigeration, calculate the logarithmic curve that represents it, and obtain from the formula the initial velocity of refrigeration. In fact if we call (y) + T the initial temperature of the calorimeter, (y) being that of the surrounding air, and find that after t minutes the former quantity is reduced to (y) + α y we know that the law of cooling will be

\[ \log y = \log T - \frac{a T}{t} \]

In this formula M is the modulus of the common logarithmic tables, or 2.302585; and the coefficient a, as in electric experiments, expresses the proportion of refrigeration in the unit of time; that is to say, the number of degrees which the refrigeration would take away from a body continued during that whole time at an elevation of 1° above the temperature of the surrounding air. This proportion from the nature of the law remains the same as long as the refrigeration continues.

If we wish to ascertain the effect upon the initial temperature T, we must obtain the value of a T from our equation: thus

\[ a T = M (\log T - \log y) \]

Whence we perceive that this value is known when we know, in addition to the initial value of T, any single value of y observed after any time t. But in the experiment on atmospheric air, above mentioned, Delaroche and Berard had at first the initial excess T = 15.734; and by a subsequent observation they found t = 20 minutes, y = 12°.847;

whence a = 0°.0101365, and a T = 0°.159474.

Knowing that the number of degrees communicated to the calorimeter by the gas in one minute, we have for 1° ten times that quantity = 0°.159474; a similar series of experiments gave 1°.5996. But the 35.99 of air employed to produce the current weighed 454.49, as may be calculated from the data in Biot, Phys., book i. p. 387; and the effect produced was upon 5964.8 of water, by the air cooling down 72.415. The relative specific heat of air, under the pressure above mentioned = 5964.8 × 1.5996

\[ 45.49 \times 72.415 \]

or = 0.2898.

Other processes gave results almost exactly identical, though always rather inferior. By taking a mean, and reducing the effects to what they would have been if the refrigeration had taken place under a pressure of 0°.76, the authors decided upon the number 0.2669, as representing (under that pressure) the specific heat of air referred to water as unity. By multiplying all the relative specific heats obtained for a given weight of each gas, by this common factor, they obtained the following table:

<table>

</tbody>
</table>

Each of these results expresses the elevation of temperature which one gramme of each gas would produce in one gramme of water, by itself cooling one centesimal degree. By dividing each number by 75 we obtain the number of grammes of ice at 0° which the same refrigeration could melt; and by dividing them by 100, we obtain the number of grammes of water which it would bring from the temperature of melting ice to that of ebullition.

It must be remarked, however, that these results are the expressions for a very complicated phenomenon. By the method in which the experiments are made, the gases contract as they cool, since they have to become always equivalent to the same pressure; and thus their density, when they enter into the calorimeter, is less than when they issue from it. The calorific effect then which they produce upon that instrument, is the effect compounded of the heat which they disengage both in cooling, and in contracting at the same time; instead of which, in order to obtain the simple results, we ought to be able to observe these effects separately; first having determined the quantity of heat which each gas disengages in cooling down within a given space,
and of course under a constant volume; and then also the quantity which it disengages, when its volume changes, the exterior temperature remaining constant. The separation of these two phenomena appears extremely difficult; but it is indispensable, in order to obtain simple results, and to investigate the exact laws which regulate these operations. A similar inconvenience presents itself in experiments upon the specific heats of liquid and solid bodies, as they also necessarily contract as they cool; but as the variation of their volume is much less considerable, we may suppose that the evolution of heat which it occasions is also very small, compared with that which arises from the diminution of temperature. (§) and (cc.)

(241.) The question of capacity, as referring to gases and vapours, has been submitted to mathematical analysis by M. Laplace in the XIth Book of the Mécanique Céleste, and perhaps still more successfully and comprehensively by M. Poisson. For these investigations, which are not susceptible of abridgement, we must refer to the original memoir; but as it may be a matter of convenience to some to have the formula at hand, we here subjoin those which are of practical utility.

\[
\begin{align*}
q &= A + B \left(266.67 + \theta\right) - 1 \\
\frac{m'}{m} &= (\frac{p'}{p})^{1/\gamma}
\end{align*}
\]

The former expresses the augmentation of heat of a gas, and the latter the ratios of the quantities of heat lost by a gramme of air, \( \theta \) being the number of centigrade degrees, \( p \) and \( p' \) the pressures for a unit of surface, \( A \) and \( B \) constant coefficients, and \( k \) a coefficient which varies for different gases, which has been found = 1.3750 for atmospheric air, by MM. Gay Lussac and Wether, and which expresses the specific gravity, under a constant pressure, and at a constant volume.

In the second paragraph, M. Poisson applies the first of the above formulae to the vapour of water, \( C \) being the quantity of heat necessary to reduce to vapour a gramme of water under a pressure of 76°, at the temperature 100°, the formula then becomes,

\[
Q = C + y \left(\frac{266.67 + \theta}{\frac{0.76}{\theta}} - 266.67\right)
\]

The coefficient \( C \) has been found = 650; the coefficient \( y = 0.8470 \), according to MM. Delaroche and Berard; and as to the coefficient \( k \), it has been found by remarking that the quantity of heat contained in each gramme of vapour is sensibly the same at all temperatures, when a certain space is saturated with vapour; thus it has been found, that when \( \theta = 50^\circ \), the tension of the vapour \( H = 0.085742 \), whence it appears that by substituting this value for \( k \), and making the coefficient of \( y = 0 \), \( k = 1.073 \). The author then refers to this formula, that which expresses the quantity of heat necessary to form a volume \( V \) of vapour at the temperature \( \theta \), and at the tension \( h \); it is

\[
V = \frac{0.76}{266.67 + \theta} \cdot Q
\]

and it shows that the quantity \( Q \) does not undergo an appreciable variation for steam engines.

In the third paragraph, the author considers the mixture of two gases, of which the volumes \( n \) and \( n' \) are different, filling a volume \( v \) at the temperature \( \theta \); \( c \) and \( c' \) being the specific heats of a gramme of these gases under a constant pressure \( p \), \( c'' \) the specific heat of the mixture, \( c' \), \( c'' \) and \( c''' \) representing the same specific heats respectively under a constant volume, \( k' \) and \( k'' \) the ratios of the former specific heats to the second ones; the author deduces this formula,

\[
k'' = n' k' + n'' k''
\]

from which it appears that the ratio \( k'' \) with reference to the mixture is not independent of the pressure \( p \), and that therefore the same formula do not apply both to simple gases and mixtures of gases, this ratio not being apparently constant, except for air and the vapour of water.

(242.) In order of time we next find some experiments on the specific heat of a few liquids made by Dr. Ure, throughout a considerable range of temperature. Of these we shall give the author's own description, abstracted from his paper on muriatic acid. (x.)

"A thin glass globe, capable of holding 1800 grains of water, was successively filled with this liquid, with strong muriatic acid S. G. 1.192, and with that of S. G. 1.152; and being in each case heated to the same degree, was suspended with a delicate thermometer immersed in it, in a large room of uniform temperature. The comparative times of cooling through an equal range of the thermometric scale were carefully noted by a watch in each case. The following were the results:

<table>
<thead>
<tr>
<th>Description</th>
<th>Temperature</th>
<th>Time</th>
</tr>
</thead>
<tbody>
<tr>
<td>Globe, with water cooled from 124° to 66° Fahrenheit, in 122 minutes.</td>
<td>0°</td>
<td>122 do.</td>
</tr>
<tr>
<td>Ditto dilute acid</td>
<td>124 to 66</td>
<td>102 do.</td>
</tr>
<tr>
<td>Ditto strong acid</td>
<td>124 to 66</td>
<td>88 do.</td>
</tr>
</tbody>
</table>

"The glass itself had a capacity for heat equal to that of 150 grains of water. Hence in the three cases we have the following relations between the quantities of matter cooled and the times of cooling:

\[
\begin{align*}
\text{Water} & \cdot \frac{122^\circ \times 100}{1800 + 150} = 62'6 \\
\text{Dilute acid} & \cdot \frac{122^\circ \times 100}{2090 + 200} = 46' \\
\text{Strong acid} & \cdot \frac{88^\circ \times 100}{2154 + 250} = 36'4
\end{align*}
\]

"If water be called unity, or 1,000, then the dilute acid is 0.735, and the strong acid is 0.586. These numbers represent the specific heats by experiment. But the dilute acid ought, from calculation, to have the mean capacity for heat, corresponding to 6 strong acid + 4 of water = \( \frac{-0.586 + 4 \times 1.00}{10} \) = 0.7516.
We see, therefore, that the capacity is diminished in the ratio of \(0.735\) to \(0.7516\), to which cause the evolution of heat is due.

"Conceiving that I observed in the successive stages of cooling of the several liquids indications of the relative specific heats, varying at different temperatures, I made the following experiments to decide this interesting point. The same glass globe and thermometer were employed.

Hence, including the specific heat of the vessel, and the difference of density of the liquids, we get the following equations:

<table>

"The ratios of the sulphuric acid and of the two oils are obviously proportional to one another in both ranges; but the specific heat of the water, compared with these bodies, increases in a remarkable ratio as its temperature falls. Had I continued the experiments to still lower degrees of the thermometer, this difference would probably have become greater. But when the substance operated upon approached the temperature of the atmosphere, which was then from 55° to 60° Fahrenheit, the cooling was too slow to permit the intervals of time to be marked with the requisite precision.

"Hitherto the specific heats of bodies have been compared with that of water, either at the freezing temperature, as in the calorimeter of Lavoisier and Laplace, or by admixture, or rate of refrigeration at very moderate heats. In all these cases the capacity of water, being at a maximum, has caused other bodies to stand relatively low upon the capacity scale. The mean capacity of water, between that of freezing and boiling, is probably to be placed at about the hundredth degree of Fahrenheit's scale.

"By thus possessing at ordinary atmospheric heats its maximum specific caloric, water is peculiarly fitted for performing its important function of a magazine and equalizer of temperature to the terrestrial globe." (x.)

Dulong and Petit.

(243.) Proceeding towards the close of this branch of our subject, we have yet one more very important series of experiments to examine. These were made by MM. Dulong and Petit, and published in 1817. In the part which concerns us at present, they refer to the experiments of Crawford and De Luc, made with a view to ascertain whether the specific heats of liquids remained constant at all temperatures, measured upon the scale of the mercurial thermometer. Crawford convinced himself that there was a slight variation in the capacity of water during the first 100 degrees, while De Luc considered that there was no such variation.

Mr. Dalton, who has exerted great labour and ingenuity upon all the doctrines of heat, considered that the capacity of a mass of matter did not remain constant, because one portion of heat is employed in producing dilatation; but that if a given volume were estimated, the capacity might be considered as constant.

This point MM. Dulong and Petit investigate by employing the method of mixtures as in (220) and (224), extending their observations to an interval of from 0° to 350° upon the thermometric scale. The experiments were made upon metals difficult of fusion; wherein the excellence of the conducting power, and the homogeneity of the substances formed additional recommendations. The metals were formed into circular discs, weighing from about 2 to 8 English pounds. The baths employed for the immersion and heating of the metals were of boiling water, boiling mercury, or oil heated to a given temperature. After the metals had been heated in these baths, they were instantly plunged into water, and the temperature thus communicated measured with extreme care. For all the minute details of these experiments we must refer our readers to the memoirs of the authors themselves.

The high capacity of iron compared with other metals, and the power of heating it most accurately in boiling mercury, made them select this substance for their first experiments. The capacity of water is considered unity, and the following table shows the general result of several experiments which accorded well with each other:

<table>
<thead>

It is, then, with the capacities of solid bodies as with their dilatabilities, both increase with their temperatures, as measured upon the air thermometer. They would increase still more if the mercurial thermometer were employed, which is contrary to the opinion of
Heat.

Crawfurd. If the experiment had been made upon a substance which could not vary in point of volume, there could remain no doubt about the result; but the gaseous state is the only one upon which the experiment can be made, and in this case the experiment would present insurmountable difficulties. Moreover, if the dilatation of solids were uniform, we could not ascribe the increase of the capacities to the quantity of heat which causes the augmentation of volume; because this quantity being always in proportion to the temperatures, could not affect the ratio of the capacities. The same does not take place when the dilatations are increasing quantities. Doubtless, in that case the capacities estimated at different heights upon the thermometric scale ought to be affected by the irregularity of the law of dilatation. We are unable to form any conjecture upon the intensity of the effects due to that accidental cause; but the fact which renders it probable that they are not to be neglected, and that the observed increase of capacity depends upon them in part at least; is that the metals of which the expansion follows the most rapid law, are at the same time those whose capacities are most variable. This question, however, cannot be finally settled but by observations taking in an interval of temperature much greater than that within which the experiments were made.

Hence it would appear, that one of Mr. Dalton's laws, viz. "that the capacity of bodies remains constant under the same volume," is not supported by these experiments; for it has been proved that the capacity augments about one-tenth part in many substances, while the volume does not vary one-hundredth part; and if the capacities were estimated upon the mercurial scale only, this law would appear still less to coincide with experiment.

(244.) It is evident that researches of this sort bear upon the construction of the thermometer on this principle of MM. Dulong and Petit remark, "We have shown in speaking of the dilatation of solids, that in constructing thermometers with the most infusible metals, and supposing them regulated by the ordinary method from the fixed points of melting ice and boiling water, the temperatures indicated by each of these instruments would be very dissimilar. The same discordance ought only to be found upon the thermometer of combination, and which Crawfurd made the basis of his augmentation of the capacities. The same doesn't take place when the dilatations are increasing quantities. Doubtless, in that case the capacities estimated at different heights upon the thermometric scale ought to be affected by the irregularity of the law of dilatation. We are unable to form any conjecture upon the intensity of the effects due to that accidental cause; but the fact which renders it probable that they are not to be neglected, and that the observed increase of capacity depends upon them in part at least; is that the metals of which the expansion follows the most rapid law, are at the same time those whose capacities are most variable. This question, however, cannot be finally settled but by observations taking in an interval of temperature much greater than that within which the experiments were made.

Hence it would appear, that one of Mr. Dalton's laws, viz. "that the capacity of bodies remains constant under the same volume," is not supported by these experiments; for it has been proved that the capacity augments about one-tenth part in many substances, while the volume does not vary one-hundredth part; and if the capacities were estimated upon the mercurial scale only, this law would appear still less to coincide with experiment.

(245.) We now proceed to another memoir, subsequently published by the same distinguished author, and we are convinced that we cannot serve the cause to which we have devoted ourselves, viz. the diffusion of sound knowledge, in a better manner than by communicating to our readers a very considerable portion of these observations. It will not be denied that the subjects entered upon are of first rate importance, and whether the theory advanced prove alternately stable or unfounded, there is enough of the verum to demand the earnest attention of philosophers.

Many experimentalists, they say, have attempted to confirm by their researches certain consequences deduced from the ideas they had formed upon the nature of heat, and upon its mode of existence in bodies. Thus Irvine and Crawfurd, admitting that the quantity of heat contained in substances is proportional to their capacities, have thence concluded that whenever the specific heat of a compound is greater or less than the sum of those of its elements, there ought at the moment of combination to be either an absorption or a disengagement of heat. But this principle, which Irvine applied to circumstances accompanying changes of aggregation, and which Crawfurd made the basis of his theory of animal heat, is found to be in opposition to too great a number of facts for it ever to be adopted. The same happens to the very ingenious hypothesis proposed by Mr. Dalton. According to the notions of this celebrated philosphe, the quantities of heat united to the elementary particles of elastic fluids, are the same for each of them. Hence by knowing the number of molecules contained in the same given weight, or in the same given volume of different gases, we may calculate the specific heats of these substances. This is what Mr. Dalton has done. But the numbers which he obtained, and those even which might be deduced from many other facts, are not in agreement with the constitution of the gases, are so widely distant from the results of experiment, that it is impossible to admit the principle upon which these determinations are founded. It was, however, brought forward by Mr. Dalton on grounds purely theoretical. The attempts hitherto made for ascertaining some general law existing among the specific heat of bodies, have therefore been quite fruitless. This can scarcely be a matter of surprise, when we consider the extreme inaccuracy of many of the existing estimates of the specific heats of bodies.

The process adopted by MM. Dulong and Petit for obtaining new estimates of the capacities of solids, is founded upon the laws of cooling. "We know that certain relations exist between the rate of cooling of different bodies, placed under similar circumstances, and the specific heats of the same bodies, by the help of which the ratio of the capacities may be deduced from that of the times of cooling. Meyer first applied this principle, and satisfied himself that the capacities given by this method, differed little from those obtained by the method of mixtures. Mr. Leslie, who adopted..."
the process of Meyer, pointed out a necessary precaution, of the importance of which Meyer was not aware, that of always enclosing the body in a vessel of one kind of matter, for the sake of avoiding the error arising from inequalities in the radiating power of the surfaces. But of all the sources of error, there is one which it is most important to avoid, and which has not been regarded by either Meyer or Leslie; it is that which arises from the unequal conducting power of the substances compared. The influence of this cause is less in proportion as the volume of the substance operated upon is diminished, and the loss of heat slowly carried on. These two are important conditions to be observed; but they seem difficult to act upon simultaneously, for by diminishing the mass of any substance, we augment the velocity with which its heat is dissipated. By endeavoring, however, to unite all those causes, which for any given mass conspire to retard the cooling, we may (as experiments have proved) obtain such conditions that the different conducting power of the bodies operated upon shall have no sensible influence upon the estimate of their capacities.

The first method which presents itself for attaining this object, consists in making the experiments, with the substance itself elevated only a few degrees above that of the surrounding bodies. Thus all the experiments referred to hereafter, were made within an interval of temperature comprised between 10° and 5° centigrade of excess above the ambient medium. In this case the utmost nicety in the measure of the temperatures is requisite: for even a slight error in this estimate might occasion a much more serious one in the final result. By making the experiments upon all substances at the same temperature, we avoid all uncertainty arising from the graduation of the thermometer; and by observing that instrument with a lens of considerable power, MM. Dulong and Petit say that they are confident of having no error above 3½ of a degree, which cannot produce any appreciable error in the calculated specific heat of the body. It is evident, however, that all these precautions would be insufficient, if the temperature of the surrounding medium were not precisely the same in all cases, and during the whole time of each experiment. This condition, however, was fulfilled, by placing the body in a vessel of very thin substance, blackened within, and covered on all parts with a thick envelope of melting ice.

"To this first mode of retarding the refrigeration, without removing from the admeasurements that precision which they ought to maintain, another is added, the influence of which may be calculated by knowing the laws of the communication of heat. It results from these laws that the rate of a substance cooling, may be ceteris paribus much diminished when the surface possesses only a very slight radiating power; and is placed in a highly diluted atmosphere. To comply with these conditions, the experiments were made upon solids reduced to extremely fine powder. In this state they were strongly pressed into a cylindrical vessel made of very thin silver, and of small capacity, having in the axis the bulb of a thermometer serving to indicate the progress of refrigeration. This vessel was then placed in the centre of the enclosure, and the air within diluted to a very slight degree of tension, (about 2 millimetres,) taking care to reproduce exactly the same in each experiment."

By precautions like these, even when the most dense substances, such as gold and platinum were examined, the masses did not exceed 30 grammes (about 9 English ounces,) and in the most rapid instances of cooling the duration was at least 15 minutes.

By comparing the specific heats thus obtained, for substances the worst conductors, with those estimated by the method of mixtures or by the calorimeter, the coincidence of the results gave a very convincing proof of the exactness of the process adopted.

Dulong and Petit, An. de Ch. et de Ph., x. 403.

This table represents the capacities of certain simple bodies, and is limited to those cases, of the accuracy of which the authors felt perfectly convinced. The column expressing the atomic weights (see Chemistry) of the substances, is given for the purpose of bringing forward the very important law which the authors think they have established. By a bare inspection of the table it appears that (allowing for the unavoidable errors of experiment) the capacity of each simple body, multiplied by the weight of the atom, is a constant quantity.

"We may," say they, "by means of this table easily calculate the ratios which exist between the capacities of atoms of different kinds. To pass from the specific heats furnished by observations to the specific heats of the atoms themselves, it is enough to divide the former by the number of atoms contained in a given weight of the substances to be compared. But it is obvious that these numbers of particles are for equal weights of matter reciprocally proportional to the densities of the atoms. Hence our result is obtained by multiplying each of the capacities obtained by experiment by the weight of the corresponding atom. Such are the products contained in the last column of the table. The number and the diversity of the substances we have operated upon do not permit us to consider our results fortuitous, and we think we are authorized to deduce the following law from them.

"The atoms of all simple substances have exactly the same capacity for heat.

"By remembering the uncertainty which as yet attends the fixing the specific weights of the atoms, we may easily conceive that the law just established would change the form of its enunciation, if we adopted a supposition concerning the density of the atoms different from that which we have admitted; but under all circumstances this law would involve the expression of
The law we have announced seems to be independent of the form which bodies may affect, so that we always examine them under the same circumstances.

Such at least is the conclusion which may be drawn from the experiments of MM. Delaroche and Berard on the specific heat of the gases. The numbers which they give for oxygen and azotic gas do not differ from what they ought to be to accord strictly with our law, but by a quantity less than the probable errors of experiments of this sort. The number for hydrogen gas is, it is true, rather too low; but by attentively examining all the corrections which the authors have been obliged to make for the observed data, we easily perceive that the rapidity with which hydrogen gas places itself at an equilibrium of temperature with the surrounding bodies, compared with other elastic fluids, must of necessity introduce into the determination with regard to this gas, an inaccuracy from which they did not endeavour to protect themselves; and by estimating this error, as well as seemed possible, we may explain the discrepancy in question without being reduced to make any gratuitous assumptions.

The law of specific heats once established for elementary bodies, it became very important to examine the specific heats of compound substances under the same point of view. Our process applying indifferently to all bodies, whatever might be their conductivity or the law of their aggregation, we were able to submit to this sort of trial a great number of substances, of which the proportions might be considered as fixed invariably; but when from these data we attempted to advance to the specific heat of each compound atom, by a method analogous to that which we pointed out for the simple substances, we soon found ourselves checked in the instant of their combination, bear no ratio to the capacities of the elements, and that, in the greater number of cases, this loss of heat is not followed by any diminution of capacity in the resulting compound. Thus, for example, the combination of oxygen with hydrogen, or of sulphur with lead, by which so much heat is evolved, is not accompanied by a greater alteration in the capacities of water and of sulphuret of lead, than the combinations of oxygen with copper, lead, silver, or sulphur with carbon, produce in the capacities of the oxides of those metals, or of sulphuret of carbon. (246) "It will be difficult to reconcile these facts with the ideas generally received about the production of heat in chemical phenomena; for, to this end we must admit the very improbable supposition, that heat exists in bodies under two different forms, and that that which we regard as united to the material particles, is entirely independent of the ratios of specific heats. Besides, there is so much that is vague and incoherent in the explanations relative to the class of phenomena in question; there exist on this point such discordant opinions, that it seems impossible to subject them to regular discussion, or to bring forward a total refutation of them. It may not, however, be useless to recapitulate in few words the principal facts and inductions which belong to this important branch of the science.

Of all chemical actions, considered as sources of heat, combustion alone was recognised as such until lately. It will, therefore, be useless to seek for a plausible theory of this mode of producing heat, before the period marked by the memorable researches of Lavoisier. That illustrious chemist, having more particularly studied the action of oxygen in the state of gas, adopted an opinion concerning the cause of the phenomenon in question, which was naturally suggested to him by the observations of Black upon latent heat. Hence the idea, that the heat evolved during combustion proceeded from the change of state which the oxygen gas underwent. The determination which he made in conjunction with M. de Laplace, of the quantities of heat developed by the combustion of certain substances, appeared to furnish him with a powerful argument in favour of his conjecture. In fact, experiment proved that a given quantity of oxygen in combining successively with phosphorus, hydrogen, and carbon, evolved more heat in the first case than in the second, and more in the second than in the third; but this the theory led them to expect, for the result is in the first case a solid, in the second a liquid, and in the third a gas. But by considering that the two elements which go to the formation of water both lose the gaseous state, and that, nevertheless, the heat evolved is much inferior to that which results from the combustion of phosphorus, naturally a solid, we are compelled to admit that the latent heat of oxygen gas ought to be superior to that of other elastic fluids. A new difficulty shortly presents itself. Nitric acid, in which the oxygen has already lost the form of an elastic
S-N- produce by their decomposition with combustible bodies, heat fluid; nay more, nitre where it is in the solid state; forming a communication between the two poles of a Voltaic pile with a small bit of charcoal placed in a gas free state, or to that which we regard as combined with the material molecules. We have the greater reason for rejecting this entirely gratuitous hypothesis, because we are able to explain the phenomenon in a much more satisfactory manner.

In fact, Sir H. Davy long since showed that by forming a communication between the two poles of a Voltaic pile with a small bit of charcoal placed in a gas unfiltered for combustion, this substance may be kept in a state of vivid ignition as long as the pile remains in activity, without the charcoal undergoing the slightest alteration. On the other hand, we may conclude from the extensive series of galvanic experiments made by MM. Hissinger and Berzelius, and also from those of M. Davy, that all substances which do combine, find themselves with regard to each other at the instant of combination exactly in the same electrical condition as the two opposite poles of the pile respectively. Is it not then probable that the same cause which produces the incandescence of the charcoal in the beautiful experiment above cited, is identical with that which to a greater or less degree elevates the temperature of the substances in the act of combination? This is at least a supposition founded upon the strongest analogies, and which deserves to be pursued through all its consequences.

"At the same time we are far from arguing that those changes of physical constitution which result from chemical combinations perform no part in the development of the heat which accompanies them; we only wish to assert that in the case of very energetic combinations, this cause generally produces only a very small portion of the total effect."

"In terminating this memoir we cannot silently pass by another very important application to which the exact knowledge of the specific weight of the atoms, would lead us. If, as we have every reason to hope, we shall arrive by means of the preceding considerations at the determination of that element with certainty, we shall be enabled, setting out with the true densities of bodies, to calculate the ratios which exist between the distances of their atoms; and, it is easy to perceive of what consequence it would be, in the midst of a number of philosophical theories, to be able to establish a comparison between the distances of the atoms, and certain phenomena which it is reasonable to suppose are connected with that new element. It is in examining under this view the question of dilatations, that we may hope to arrive at some simple laws, which as yet are entirely unknown. Some attempts founded upon the observations of different philosophers, and upon some which we had made for a different purpose, have led us to consider it extremely probable, that some very simple relation exists between the dilatability of liquids and the distances of their molecules. The beautiful observation of M. Gay Lussac, of the identity of the contractions of carburet of sulphur and alcohol, setting out from their respective points of ebullition, comes in confirmation of our opinion; for these two liquids present this remarkable peculiarity, that at the temperatures at which they have been compared, the distances between their atoms are almost exactly the same; but previously to the extending those researches which might be made upon this subject, it is absolutely essential that the question of specific heats should be cleared up as much as possible, and that all those consequences to which it may lead, touching the knowledge of the constitution of bodies, should be primarily deduced." (u.)

(248.) We are convinced that the importance of the subject, and the novelty of these views, will appear to all our readers a sufficient reason for the length of the above extract. It is true these are but the opinions of two individual experimentalists, but these are well known as of the highest order in ability and research; whether this beautiful step towards generalization may safely be admitted as a fact proved, future researches must decide, and it is with a view to call the attention of English experimentalists to this point, that so ample a view of the question has here been brought forward.

A general table of the specific heat of various substances is given in the appendix, No. XV.

Class 3.

(249.) We have now to proceed to our remaining class of results, viz. "those in which the same substance is examined; but under changes in its physical condition."

In this department we find some of the most striking and valuable properties arising out of that mysterious system of operations to which the great author of nature has subjected every form and atom of material substance. It will easily be conceived that we refer to the great discoveries of Dr. Black, which made known to us the most familiar examples. In them we shall have a still further illustration that the thermometer is only a measure of apparent temperature; and that it can only indirectly give us any information as to the real quantity of caloric contained in the various kinds or states of matter. In short, it appears, that for body to undergo one of the great physical changes from one form of matter to another form, a very considerable change takes place in its specific caloric, though its sensible temperature may not be at all affected. To pass from the solid to the fluid, or from the fluid to the gaseous state, a very considerable quantity of heat is absorbed and rendered latent, or imperceptible to the thermometer; and in the converse operations of passing from the gaseous to the fluid, or from the fluid to the solid state, this heat is again liberated, and becomes sensible. Black's illustrations are as follows:

(250.) Let a mass of ice of the temperature 20° Fahrenheit be brought into a warm room; the temperature of the ice gradually rises to 32°; it then begins to melt, but during the process of melting, which occupies several hours, the temperature of the mass never rises above 32°. Doubtless the ice continues to receive caloric throughout the whole time as rapidly as at first, and therefore as no increase of sensible temperature above 32° is apparent, the heat added must have been employed in transforming the ice from the solid to the fluid state.

(251.) Two thin glass globes of nearly the same weight were suspended in a large room, at a distance from all other bodies. The one contained water at 33° Fahrenheit, the other a solid mass of ice. The temperature of the air in the room was 47° Fahrenheit. In half an hour the thermometer in the water rose to 40°; but it required 10½ hours to produce the entire liquefaction of the ice, and to raise the water in that glass to 40°. Supposing roughly that in the first half-hour the water gained 7°, and that the ice globe continued through all the time of the experiment to receive heat at the same rate, it must in all have obtained 21 × 7 = 147° of heat, of which 7° only were sensible to the thermometer.

(252.) That in this, and such cases, the heat is rendered latent, but not destroyed, the following converse experiment proves. When the exposed thermometer is at 22°; let two vessels, the one filled with brine, the other with water, both at 52°, with a thermometer in each, be exposed till both are cooled down to 32°. The water freezes slowly, while its temperature remains 32°. The brine (not freezing but at a temperature 4° Fahrenheit) gradually cools down to 32°. From this it seems fair to infer, that both liquids are continually imparting caloric to the surrounding air; the one, as it undergoes no physical change, gives out caloric at the expense of its sensible temperature; the other is enabled to undergo a physical change by the loss of its caloric; and in making that change, one portion with a sufficient quantity of caloric superfluous to, or inconsistent with its new state, which goes to the remaining water from which it must be abraded by the surrounding air, that a further portion of the liquid may be enabled to undergo the same process.

(253.) Again, Dr. Black mixed together 59¾ drams of ice and 67½ drams of water. The effect of the glass vessel in which the experiment was made, he estimated as equal to that of 4 drams of water; so that the experiment may be considered as 59¾ ice + 71½ hot water. The water was 19° Fahrenheit, the ice 32°. When the ice had melted the temperature of the water was 53°. The loss upon the 71½ drams of water was 137°, and the gain to 59½ of ice 21°. But the heat of the mixture should be 118°, according to calculation for a mean, so that the rise of heat upon the ice should be 86°. Hence, it seems, that a quantity of heat which might have been expected to have produced an elevation of 65° more of temperature in the ice water, has totally disappeared or become latent.

From these data the absolute specific heat of water may also be determined.

Let \( m \) be the mass of water.

\( t \) its temperature.

\( c \) its specific caloric to be determined.

\( m' \) the mass of ice.

\( T \) the common temperature after mixture.

The caloric contained in this mixture above freezing point will \( = (m + m') \, c \, T \), because it has then all become liquid. To this we must add the caloric absorbed by the mass of ice \( m' \) in order to its fusion, which by the conditions of the experiment equal \( m' \).

Hence \( (m + m') \, c \, T + m' = \) the total caloric of the mass of hot water at first above 32° \( i.e. = m \, c \, t \).

Hence \( (m + m') \, c \, T + m' = \) the total caloric of the mass of hot water at first above 32° \( i.e. = m \, c \, t \).

And substituting Black's numbers

\[
\begin{align*}
& m = 143; \quad t = 190 - 32 = 158 \\
& m' = 119; \quad T = 53 - 32 = 21 \\
& c = 119 \quad \frac{143 \, \times \, 158 - 262 \, \times \, 21}{17132} = 0.0069 \, \text{F.}
\end{align*}
\]

or on centigrade scale = 0.0124 C.

(254.) In another experiment Dr. Black added together equal weights of ice at 32° and water of 176° Fahrenheit. In this mixture the ice was just melted, and the temperature of the liquid did not rise above 32°. That is to say, in the process of liquefaction renders latent 144° of apparent heat in an equal weight of water.

But according to MM. Lavoisier and Laplace a volume of water at 167° Fahrenheit is sufficient for the fusion of an equal volume of ice at 32° Fahrenheit. The difference between these results is not very considerable.

Black's experiment gives \( \frac{1}{176} = 0.0056 \) for the absolute specific heat of water; while that of the French experimentalists reduces the expression to \( \frac{1}{167} = 0.00598 \) on
232

HEAT.

the scale of Fahrenheit; or $\frac{1}{75} = 0.013333$ centigrade.

(255.) The calorimeter of ice may be conveniently employed in measuring the caloric which bodies give out in passing from the fluid to the solid state, at least in those which congeal above 0°. Let $t'$ be the freezing point of the substance. Below this term it will be solid, above that liquid. In these two conditions let $c'$ and $c''$ be the absolute specific heats which may be determined by independent experiments. Let the temperature of the body be raised to $t' + t''$, and having placed it in the calorimeter leave it to cool down to 0°. It is evident, that during the first $t'$ degrees it will cool as a liquid, and during the last $t''$ degrees as a solid; then, if the specific heat remains constant during each of these two states, the quantity of ice melted during the former will be $m'c' t'$, calling the mass $m'$; and in the latter will be $m'c'' t''$. The sum $m'c' t' + m'c'' t''$ would represent the total quantity of ice melted, if there were no extraordinary disengagement of heat at the instant of solidification. But in consequence of that phenomenon, the quantity of ice melted is found to be more considerable, and equal for example to $a''$. Hence if from $a''$ we subtract the preceding sum, the remainder will exhibit the quantity of caloric sought for; and calling it $m'z$, since it ought to be proportional to the mass, we have $m'z = a'' - m'c' t' - m'c'' t''$.

But we have yet to find the values of $c'$ and $c''$. To obtain $c'$, let the temperature of the body be raised to $t'' - t''$ degrees, such that it shall remain solid, and then let it cool down to 0° in the calorimeter. Let $a$ be the quantity of ice which it thus melts; then clearly we have $m'c' (t'' - t') = a$, whence $m'c' = \frac{a}{t'' - t'}$.

Again, in order to obtain $c''$, let the body be heated to $t'' + t'''$ degrees, by which it shall be rendered liquid; then let it be introduced by a glass tube, so as to remain in the calorimeter to cool down to 0°. Let $a''$ be the quantity of melted ice resulting. If from this we deduct $a''$; the difference $a'' - a''$ evidently expresses the quantity of ice which the body could have melted in its liquid state by cooling down through a number of degrees $= t''' - t''$; and as we have called $c''$ its specific heat, in that state we have

$m'c'' (t''' - t''') = a'' - a''$

whence $c'' = \frac{(a'' - a''')}{(t''' - t''')}$

Thus $c'$ and $c''$ are obtained, and by substituting them in the expression for $m'z$, we learn the quantity of caloric disengaged during the solidification of the mass $m'$, that is to say, the number of kilogrammes of ice at 0° which the caloric is capable of melting. If we divide this result by $m'$ we shall have the measure of the same effect for the unit of mass.

(256.) The following is an experiment of Fahrenheit. Let a quantity of water in a tall glass be exposed when the atmospheric temperature is 22°. A thermometer is placed in the water and the whole lightly covered. By suffering the glass to remain quite quiet, the water may cool down to 22° without freezing; but if the whole be slightly agitated, a portion of the water congeals, and the thermometer instantly rises to 32°. It seems an incontestable inference, that this sudden rise of 10° of temperature is due to caloric evolved by the water in the act of passing from the liquid to the solid state. The following remarks of Professor Thomson are to our present purpose.

"From a good many experiments which I have made on water in these circumstances, I have found reason to conclude that the quantity of ice which forms suddenly on the agitation of water cooled down below the freezing point, bears always a constant ratio to the coldness of the liquid before agitation. Thus I find that when water is cooled down to 22°, very nearly $\frac{1}{5}$ of the whole freezes; if the previous temperature is 32°, $\frac{7}{10}$ of the whole freezes. I have not been able to make satisfactory experiments in temperatures lower than 22°; but from analogy I conclude, that for every 5 degrees of diminution of temperature below the freezing point, without congelation, $\frac{1}{5}$ of the liquid freezes suddenly on agitation. Therefore if water could be cooled down 28 times 5° below 32° without congelation, the whole would congeal instantaneously on agitation, and the temperature of the ice would be 32°. Now it deserves attention, that 5 x 28 = 140; gives us precisely the quantity of heat which, according to Dr. Black's experiment, enters into ice in order to convert it into water. Hence it follows, that in all cases when water is cooled down below 32°, it loses a portion of the caloric which is necessary to constitute its liquidity. The instant that such water is agitated, one portion of the liquid seizes upon the quantity of caloric in which it is deficient at the expense of another portion, which, of course becomes ice. Thus when water is cooled down to 22°, every particle of it wants 10° of the caloric necessary to keep it in a state of liquidity. Thirteen parts of it seize 10° each from the fourteenth part. Thirteen of course acquire the temperature of 32°; and the other part being deprived of 10 x 13 = 130, which with the 10° that it had lost before constitute 140°, or the whole of the caloric necessary to keep it fluid, assumes of consequence the forms of ice." Syst. Chem., i. p. 54.

"It is rather difficult to ascertain the precise number of degrees of heat that disappear during the melting of ice. Hence different statements have been given. Mr. Cavendish, who informs us that he discovered the fact, before he was aware that it was taught by Dr. Black, states the number of 150°; Wilcke at 140°; Black at 140°; and Lavoisier and Laplace at 135°. The mean of the whole is very nearly 140°.

"Water then after being cooled down to 32°, cannot freeze till it has parted with 140° of caloric; and ice after being heated to 32°, cannot melt till it has absorbed 140° of caloric. This is the cause of the extreme slowness of these operations. With regard to water, then, there can be no doubt that it owes its fluidity to the caloric it contains; and the caloric necessary to give fluidity to ice is equal to 140°.

"To the quantity of caloric which thus occasions the fluidity of solid bodies by combining with them Dr. Black gave the name of latent heat, because its presence is not indicated by the thermometer: a term sufficiently expressive, but other philosophers have rather chose to call it caloric of fluidity." Ibid. p. 56.

(257.) Observations of this nature have been extended to the fusion of other bodies, and with results in general conformity to the same physical law. The following table is given by Dr. Murray, as deduced from the essay on latent heat by Dr. Irvine Junior.
The latent heat of each substance being measured by the capacity of the solid instead of by that of the liquid, which in the greater number of cases is more difficult to determine,—with the exception of spermaceti, wax, and mercury.

Numerous instances of the evolution, or of the absorption of latent heat might be adduced from the action of compound bodies. Certain acids have such avidity for water as to dissolve snow and ice, not by their superior degree of free caloric, but by their strong affinity compelling the solid to a rapid change of state for the purpose of combination. Certain salts also for the purpose of combination. Certain acidshave such affinity compelling the solid to a rapid change of state mutual liquefaction. An amalgam of bismuth being mixed with an amalgam of lead, liquefaction of all the ingredients ensues. In all these cases a body passes from the solid to the liquid state, and to this end a certain portion of caloric is essential; which, if obtainable from no other source, must be abstracted from the sensible caloric of the mixture. On this principle we explain the instances of the artificial production of cold given. Chap. ii. sect. 4 and 5. All these facts tend to prove that the disappearance of heat is a general phenomenon accompanying liquefaction: and the evident proof that this process is the true cause of the reduction of temperature, is, that if the substances mixed be previously cooled below the temperature which the resulting liquid can support, that is to say, that the liquid be frozen, the mixture produces no refrigerant effect.

**Latent Heat of Vapours.**

(258.) We have spoken hitherto of the passage of a solid to the liquid state or the converse, let us now pursue matter and heat through their relations under another physical condition. We shall find the same laws to be continued, and that in a body's passage from the liquid state to that of vapour, heat is absorbed or rendered latent; while in the contrary operation, of passing from the aeriform to the liquid condition, the opposite effect takes place.

Let us first cite examples in which the liquid passes to the state of vapour, and in which of course heat is absorbed.

(259.) Dr. Black placed several cylindrical tin vessels containing equal quantities of water upon an iron plate, equally heated from beneath. The initial temperature was 50°. In 4 minutes the water boiled, and

in 20 minutes had entirely passed off in the state of vapour. As in 4 minutes the water had passed from 50° to 212°, equivalent to a gain of 40°.5 per minute, it seems fair to infer that during the whole operation the water had required 20 x 40°.5 or 810° to enable it to assume the state of vapour: and yet the temperature of the steam escaping never exceeded 212°.

(260.) Mr. Watt heated a quantity of water in a copper digester furnished with a valve, and as soon as ebullition commenced he closed the valve, and suffered it to remain on the fire half an hour. The vessel was then removed, and upon opening the valve a quantity of vapour issued out with great force. Much as it was heated however, only one-third of the water escaped in the form of steam, and the temperature of the remainder was immediately reduced to 212°. When not confined, water then passes off in vapour as soon as it exceeds 212°, but under pressure it may be more strongly heated; and again upon the removal of that pressure the escape of a comparatively small quantity of vapour causes the disappearance of a considerable quantity of sensible heat.

(261.) Dr. Black found that when hot water is placed within the vacuum of an air-pump, its temperature falls rapidly to even 70°F. This can only be accounted for on the ground of the great quantity of heat taken up by the rapid evolution of aqueous vapour, under the circumstances of the experiment.

Many instances which have already been cited for their practical effects in the production of cold, Chap. ii. sect. 4, depend upon this principle. Such are the evaporation of ether, sulphuret of carbon, and other volatile fluids.

It has been proved by Lavoisier also, that when an aeriform fluid is disengaged from a state of combination, the attendant chemical action is productive of much less heat than if the same chemical action take place, but without the evolution of gas.

(262.) To proceed to the converse mode of action, in which the condensation of an aeriform fluid is effected, and with an opposite result; viz. with considerable disengagement of free caloric: and for a most succinct and comprehensive view of this matter, we shall be indebted to Professor Thomson's Chemistry.

If one part of steam at 212° be mixed with nine parts by weight of water at 62°, the steam instantly assumes the form of water, and the temperature after mixture is 176°.6; consequently each of the nine parts of water has received 116°.6 of caloric; consequently the steam has lost 9 x 116°.6 = 1049°.4 of caloric. But as the temperature of the steam is diminished by 38°.3, we must subtract this sum. There will remain rather more than 1000°, which is the quantity of caloric which existed in the steam without increasing its temperature. This experiment cannot be made directly, but it may be made by passing a given weight of steam through a metallic worm, surrounded by a given weight of water. The heat acquired by the water indicates the heat which the steam gives out during its condensation.

Mr. Watt was the first person who attempted to determine accurately the latent heat of steam with precision. His experiments were made in 1781; but the account of them has been only published very recently in Mr. Watt's edition of the articles Steam and Steam Engine, by Professor Robison, (p. 61.) The result of their experiments is, that the latent heat of steam is 950°. This agrees nearly with the determination of Mr.
Southern in 1802. He found it in three experiments made at very high temperatures, 948°, 945°, and 950°. (Rob. Mech. Phil. p. 165.) The experiments of Lavoisier make it rather more than 1000°. According to Rumford it amounts to 1040°.8. Dr. Ure, in a set of experiments lately published, states it at 967°. (Phil. Trans., 1818, p. 388.) Thus we have the latent heats of steam as follows:

</tr>
</tbody>
</table>

The above determinations are all from Dr. Ure's paper (Phil. Trans., 1818), with the exception of alcohol, which is by Rumford, in Gilb. An., xlv. p. 312.

Dr. Black's law, then, is very general, and comprehends every change in the state of the body. The cause of the conversion of a solid into a liquid is the combination of the solid with caloric; that of the conversion of a liquid into an elastic fluid is the combination of the liquid with caloric. Liquids are solids combined with caloric; elastic fluids are liquids combined with caloric. This law, in its most general form, may be stated as follows: whenever a body changes its state, it either combines with caloric, or separates from caloric.

No person will dispute that this is one of the most important discoveries hitherto made in chemistry. Science seems indebted for it entirely to the sagacity of Dr. Black. Other philosophers, indeed, have laid claim to it; but these claims are either without any foundation, or their notions may be traced to Dr. Black's lectures, or their opinions originated many years posterior to the public explanation of Dr. Black's theory in the chemical chairs of Glasgow and Edinburgh. (aa.)

Se also Despretz on the latent heat of vapours. (dd.)

(263.) Count Rumford's estimation of the latent heat Count Rumford of steam affords another elegant application of his ford calorimeter. (157.) A given quantity of water was boiled in a long necked flask, which was bent so as to terminate under the mouth of the reflected tube. The extremity of this flask was joined by a cork fitting accurately into the mouth of the calorimeter tube; the cork had four apertures opening horizontally within the tube, but so elevated above the bottom of the tube as not to be blocked up by the return of vapour condensed within the tube. The flask was heated by a small portable furnace at some distance from the calorimeter, which was also well defended by certain screens. The weight of the condensed vapour was deducted from that of the flask weighed before and after the operation,
The following table of the results in two such experiments is given by M. Biot, who reduced the calculations to the centigrade scale.

To calculate these experiments, and obtain the numbers in the last column, it is necessary to remember that the introduction of vapour to the calorimeter heats it from two causes: 1st, by the disengagement of caloric in the passage from steam to water; and 2dly, by the caloric which that water parts with in cooling down to the actual temperature of the calorimeter. To estimate the former effect, it is essential that we know at what temperature the steam passed to the liquid state. This temperature might be calculated if we knew the pressure which the steam supported at the time. This Rumford unfortunately has not mentioned, but as the experiments were made at Paris, and under the ordinary atmospheric pressure, we may suppose this pressure equal to 0.76, and therefore the temperature 100° centigrade. The water resulting will then enter the tube at 100° centigrade, which it will retain to the temperature t at the commencement of the experiment, and at the end at the temperature t'. So that supposing the heating of the calorimeter uniform as it ought, being so inconsiderable, we obtain the mean of all these results, by considering the water produced as being cooled down to the temperature t'. This being assumed let m' = the total weight of the steam condensed, and c' the quantity of caloric which the unit of weight of this steam would part with by condensing itself in water at 100°; then m'c' will be the quantity disengaged by the mass m' under similar circumstances. Now let c be the quantity of caloric which one unit of weight of water parts with in cooling down one degree. The liquid mass m', in cooling down to \( t + t' \); will part with m'c \( 100° - \frac{1}{2} (t + t') \). If we added this result to the preceding the sum m'c' + m'c \( 100° - \frac{1}{2} (t + t') \) will represent the caloric communicated to the calorimeter from the steam, and by virtue of which the temperature of the apparatus is raised t' - t degrees. Let m represent a mass of water equivalent to the water and vessel together; then the variation of temperature t' - t will correspond to a quantity of caloric equal to m c (t' - t). Hence we ought to have

\[
\frac{m'}{m} \cdot C = \frac{100° - \frac{1}{2} (t + t')}{100° - \frac{1}{2} (t + t')}
\]

whence

\[
c' = \frac{c}{m'} \left( m (t' - t) - m' \left( 100° - \frac{1}{2} (t' + t) \right) \right)
\]

If in this equation we substitute for m, m', t, t' their respective numerical values in the two experiments of Rumford; m being equal to 2751 grammes.

We find in 1st experiment c' = 568.484 c. 1°
2nd experiment c' = 565.906 c. 1°

\( \therefore \text{mean...} \)
\( \therefore \text{c' = 567.195 c. 1°} \)

That is to say, one gramme of steam in its condensation to water of 100° gives out a quantity of heat 567 times as great as is necessary to raise the temperature of one gramme of liquid water one degree; or in other words, this caloric would heat 567 grammes of water one centessimal degree.

The factor 1° is left in the formula to show that c' is expressed in terms of the product of c into 1°. Consequently, if we wished to express this result in degrees of some other scale, it is necessary to multiply by the value of a centessimal degree in terms of the other scale. For example, to express it in degrees of Fahrenheit, multiply by \( \frac{180}{100} \) or 1.8; by which means the factor 567.195 will become 1020.951. Thus the quantity of caloric given out by one gramme of steam, condensed at 212° Fahrenheit, would heat one gramme of water 1021° on the same scale; or what is the same thing, it would heat 1021 grammes of water one of these degrees. It is common in England to express this result by saying that steam condensed at 212° Fahrenheit gives out 1021° of heat.

(264.) If we wished to ascertain how many grammes of water at 0° this heat would make to boil, we have only to take our first value of c', and divide it by the number of centessimal degrees which expresses the temperature of boiling water, that is to say by 100. Thus we obtain c' = 5.67195 c. 100°. That is to say, the caloric disengaged by 1 gramme of steam would raise 5.67195 grammes of water from the freezing to the boiling point.

(265.) Lastly, if we wished to express the same result in grammes of melted ice, we have only to introduce into the centesimal expression for c', in place of c, its numerical value \( \frac{1}{75} \) which expresses in the fraction of a gramme the quantity of ice that one gramme of liquid water can melt in parting with one centesimal degree of heat. Here c' = 7.5626; that is to say, the caloric given out in the condensation of one gramme of steam would melt 7.5626 grammes of ice at 0°.

(266.) The general law deducible from all these facts is, that in every physical change of condition which any substance undergoes, there is either an evolution of caloric, which becomes sensible heat, or an absorption of caloric, which then becomes latent or insensible. And as heat is always absorbed in the passage of a body from the solid to the liquid, or from the liquid to the gaseous state, and again given out in the converse operation, the caloric thus taken up is either the actual cause, or at least the essential condition of liquid and aeriform fluidity.

(267.) Certain observations of Dr. Black have also gone far towards showing that the absorption of caloric is the cause of malleability.

(268.) We shall now find ourselves enabled to present a summary of what takes place with regard to the three classes of bodies mentioned in Art. 229.
Heat.

1. Substances chemically dissimilar, have different capacities for heat, which may be investigated, and then represented in a tabular form.

2. With regard to the second class, we use the following quotation from M. Thenard.

"In mixing together, under ordinary atmospheric pressure, two portions of the same gas, equal in weight, unequal in temperature (20° to 25°) and consequently in volume, we obtain a mixture of which the temperature is always more elevated than the mean of the two; whence it follows, that the capacity of a gas for heat increases with the temperature, dilatation being permitted." (Gay Lussac, An. de Ch., lxxxi. p. 96.)

"It is probable, that if the volume varied but little, the augmentation of capacity would not become sensible but when the two portions of gas differed greatly in temperature. At least such is the observed fact in bodies of the same nature in the liquid state, and especially in the solid state, a property which they doubtless owe to their slight degree of dilatability.

"In fact the capacity of water for caloric is nearly the same from 10°C to 30°C, as from 30°C to 50°C; also when we mix one kilogramme of water at +10°C with another of +50°C there results 2 kilogrammes at +30°C. The same is true of the capacities of mercury, zinc, &c. for similar intervals of temperature; while from 0°C to 100°C we find that the capacities are less than from 100°C to 200°C; and still less from 200°C to 300°C." (a)

3. And with regard to the third class, we have but to cite the law announced in Art. 266, that in every physical change of condition which any substance undergoes, there is either an evolution of caloric, which becomes sensible heat, or an absorption of caloric, which then becomes latent or insensible.

It is not in our power here to enter so fully into the theory of latent heat as we could desire, but a very short statement of the two opinions on this subject, which have excited the most attention, may be made as follows. Dr. Black considers the absorption of caloric in liquefaction and vapourisation, as the cause of those changes of form; and that, therefore, the latent heat existing in a liquid or vapour, is that which preserves it in these states. And he considered, says (Professor Robison) latent heat "as united with the substance of a body in a way very much resembling many chemical combinations." Irvine on the contrary supposed the phenomena of latent heat to arise from changes of capacity accompanying the changes of physical state. A very excellent comparative review of these opinions may be found in Murray's Chemistry, vol. i. p. 420, to 456.

Chap. V.

(269.) From this change in the distribution of caloric, which takes place when bodies change their forms, many chemical and natural phenomena are explained.

The absorption of heat, accompanying the change from the solid to the liquid form, explains the fixity of the point in the thermometrical scale at which bodies melt. Ice melts at 32° of Fahrenheit, and whenever any mass of ice is heated to that temperature, the farther communication of heat, however rapid, has no effect in raising its temperature, till the whole is converted into water; since, as quickly as the ice is melted by the caloric, as quickly is a portion of it absorbed by the fluid formed. This is exemplified in the long time before large masses of ice, or collections of snow, are melted by a thaw. Were it not for this absorption of heat, the liquefaction of masses of ice and snow in the colder climates, at the approach of spring, would take place almost instantaneously, when the temperature of the atmosphere rose above 32°; whereas, from this circumstance, it is gradual and progressive, by which the water formed is distributed more slowly, and the too sudden rise of temperature, which would prove fatal to vegetables, is prevented.

The reverse of this, or the extrication of heat, when water is converted into ice, is equally beneficial; since, were it otherwise, the freezing of large collections of water would be extremely rapid, whenever the temperature of the atmosphere was at or below 32°. But from this extrication the freezing is gradual, and, at the same time, a large quantity of heat is given out by the water in passing to the solid state, by which the approaching cold is moderated, and the congelation rendered more slow.

Similar general effects arise from the operation of this law in vapourisation. When the earth is much heated by the sun's rays, water is evaporated from its surface, and from rivers and the ocean, and the conversion of this into vapour is necessarily accompanied with the absorption of caloric. Hence evaporation is the most powerful agent employed by nature to moderate excessive heat. On the contrary, when the vapour of the atmosphere is condensed by cold, and descends in rain or snow, it gives out the caloric it had received, which is then beneficial rather than hurtful. Much of this vapour must even be wafted from the torrid zone, where evaporation must be most rapid, towards the polar regions; and being condensed in its progress in colder climates, will prove a source of heat.

The process of artificial refrigeration is explained on the same principle. By allowing water to filtrate slowly through porous earthen vessels, so as to present an extensive humid surface to the atmosphere, it passes rapidly into vapour, and in this vapourisation absorbs so much caloric as to produce considerable cold. Liquors are cooled, and in warm climates ice is formed, by arrangements of this kind, and this even when the temperature of the atmosphere is several degrees above 32°. This artificial formation of ice is carried on in Bengal to a considerable extent. The cold from the evaporation is no doubt considerably accelerated by the rapidity of that process from the dryness of the atmosphere, and hence, in a humid atmosphere, the process would not succeed at a similar average temperature. A considerable part of the effect too depends, as Dr. Wells has shown, on radiation from the surface of the water, and hence the success is always greatest in nights which are calm and serene.

The theory of freezing mixtures is deduced from the doctrine of latent caloric. These are mixtures of saline substances, which, at the common temperature, by their mutual chemical action, pass rapidly into the fluid form, or are capable of being rapidly dissolved in water, and by this quick transition to fluidity absorb caloric, and produce degrees of cold more or less intense.

In other cases of chemical action, substances pass from the gaseous to the fluid, or from the fluid to the solid form, and the rise of temperature which attends these transitions is referred to the evolution of latent caloric, which must be their result.

The use of steam, as a vehicle and source of heat, affords an example of the scientific application of these,
principles. By conveying steam into water, it is condensed, and by the evolution of the latent heat by the condensation, the temperature of the water is raised, so as soon to arrive at 212°. In certain arts, as in that of dyeing, where large quantities of water are to be heated in separate vessels, this method has superior advantages. By having a common boiler, from which the vapour is conveyed by tubes, the loss of heat is less than if fire was applied to each vessel, and the vessels are subject to less wear, and may be constructed at less expense. This method has accordingly been employed with success. Another application of the same principle is that of heating rooms by conveying steam through tubes, proposed in an early volume of the Philosophical Transactions, and since revived. The steam in its progress is condensed gradually, and gives out its latent heat, so as to produce an equable warmth. A well-constructed apparatus for this purpose has been described by Mr. Snodgrass, by whom the mode of heating apartments by the introduction of warm air, may in particular situations be preferred. The mode of applying heat from the condensation of steam, has been proposed to be applied to the drying of gunpowder, as attended with less risk than the same principle is that of heating rooms by conveying steam through tubes, proposed in an early volume of the Philosophical Transactions, and since revived. The steam in its progress is condensed gradually, and gives out its latent heat, so as to produce an equable warmth. A well-constructed apparatus for this purpose has been described by Mr. Snodgrass, by whom the mode of heating apartments by the introduction of warm air, may in particular situations be preferred. The mode of applying heat from the condensation of steam, has been proposed to be applied to the drying of gunpowder, as attended with less risk than the common mode. The modern improvements in the steam engine, as they originated from Dr. Black's discovery, so they afford the most important practical application of the doctrine of latent heat. In the engine wrought previous to the improvements of Mr. Watt, the steam was received into a cylinder, to which a piston was adapted; the piston by the weight attached to its arm being elevated to the top of the cylinder, and the cavity beneath filled with steam. This was condensed by a jet of cold water, and the piston was of course forced down by the pressure of the atmosphere. To raise this, steam was again introduced from beneath, and thus the alternate elevation and depression of the piston were effected. But in this way, it is obvious, that there was an immense waste of heat, and this altogether concealed, while the facts relating to latent caloric were unknown. By the jet of cold water, not only is the steam condensed, but the cylinder is cooled, as it is also by the entrance of the atmospheric air. When, therefore, the steam from beneath is again introduced, a great part of it must be condensed and lost, by its heat being abstracted by the cold cylinder and piston, and its elasticity cannot operate with effect until the whole is again elevated to 212°. At each stroke of the engine this waste is repeated; and thus, according to Mr. Watt's calculation, at least half of the steam produced in the boiler is lost.

Mr. Watt's principal improvements consisted: first, in condensing the steam, not in the cylinder, but in a vessel communicating with it by a pipe with a valve, which being exhausted of air, the steam rushes into it when the communication is opened, and is condensed by the vessel being kept cold by immersion in water; and, secondly, by excluding from the cylinder the atmospheric air, and depressing the piston by steam introduced above it, and condensed in the condensing vessel alternately with the steam beneath. Thus the whole may be kept at the temperature of 212°, and the waste of heat in the old method obviated. Dr. Black justly characterises the engine in this state as the master-piece of human skill, and no less justly observes, that it has not been "the production of a chance observation, but the result of deep thought and reflection, and really a present by philosophy to the arts." (bp.)

References from (220) to (269) inclusive.

CHAPTER VI.

THEORETICAL OPINIONS ON THE NATURE OF HEAT.

Heat. (270.) In the five preceding chapters we have given as copious an abstract of those facts which experiment has developed concerning heat, as it is consistent with the plan of this work to allow. The very short chapter now before us will contain a statement of the two great systems of belief which philosophers have adopted with regard to the nature or cause of heat. As advocates for each of these theories, there will be found some of the most distinguished names that have ever done honour to the intellect of man; but, after all, their speculations have produced little that is convincing to others, or even satisfactory to themselves. For these reasons we have filled our pages chiefly with experiments, and hasten to conclude this already extended article.

Of these two principal theories the one admits the materiality of heat; while the other, denying that it is substance, considers it a property of matter producing its effects by an actual vibration among the molecules of that matter.

The vibratory hypothesis which is usually attributed to Bacon is thus explained in his own words, "Calor est motus expansivus, cohibitus, et nitens per partes minores." Perhaps this is the same as if he had said that caloric is a force which is opposed to molecular attraction; and that heat is the effect of a vibration produced by these conflicting forces. Of this opinion also were Boyle and Newton; while Rumford and Sir Humphrey Davy have been its most recent and able advocates.

The material hypothesis, in which heat is considered a substance of extreme tenuity, of great elasticity, imponderable and invisible, is said to have been proposed by Boerhaave, and was advocated by Hamberg and Lemery. It seemed, in fact, much the most consistent with the notions of chemists; and can by no means be a matter of surprise that Black's discovery of latent heat should have been by them deemed a strong confirmation of this hypothesis.

(271.) In favour of the hypothesis that heat is material, it has been urged, that as its addition to bodies produces their expansion, it is most natural to suppose that this effect is owing to the actual insertion of a material substance between the molecules. But this, perhaps, is not quite conclusive; for if the magnitude of a body depend upon the arrangement of its molecules, and if these (as there is every reason to suppose) be endowed with polarity, then any change in the state of this polarity, producing a new arrangement of molecules, will produce a new magnitude of volume, providing the molecules be not spheres in strict contact.

The transfer of measured quantities of heat (to use a common phrase) to effect given purposes of expansion, fusion, vapourisation, or the contrary, has been urged with reason as a good argument on this side of the question. Those inclined to dispute, may say that it is only the application of a force accurately estimated, and of course producing from given quantities the same effects under given circumstances.

The passage of heat through a vacuum is also advanced, on the same side; because it is not possible to conceive how, if heat be a property of matter, it should be freely propagated where no matter exists. Let this also have its due weight; but let us remember that we are quite unable to produce an absolute vacuum, for that even in that which is called after Torricelli, there is an atmosphere of mercurial vapour, though of great tenuity.

If the experiments of Herschel and others have proved the distinct separation of heat from light in any case, and that the laws which they obey are analogous, though not identical; then the materiality of heat stands much upon the same evidence with that of light.

(272.) That heat is merely a property of matter, and that it may arise from vibrations of the molecules, has thus been urged:

Because the most careful experiments made for that purpose never could prove it to be ponderable. (a.) Thus it seems not to possess the ordinary sensible properties of matter, weight and obedience to the laws of mechanical motion.

On these grounds Count Rumford strongly urged the immateriality of heat, and also from the evidence of his own experiments, in which friction seemed an inexhaustible source of heat in the same given substance. With regard to the former proof arising from the absence of certain mechanical properties, it might be urged that these, being inappreciable by our experiments, is not a sufficient evidence of their non-existence.

The following sentences must serve to give an idea Davy's hypothesis.

The immediate cause of the phenomenon of heat, then, is motion; and the laws of its communication are precisely the same as the laws of the communication of motion. Since all matter may be made to fill a smaller volume by cooling, it is evident that the particles of matter must have space between them; and since every body can communicate the power of expansion to a body of a lower temperature; that is, can give an expansive motion to its particles, it is a probable inference that its own particles are possessed of motion; but as there is no change in the position of its parts, as long as its temperature is uniform, the motion, if it exist, must be a vibratory or undulatory motion, or a motion of the particles round their axes, or a motion of particles round each other.
Heat.

"It seems possible to account for all the phenomena of heat, if it be supposed that in solids the particles are in a constant state of vibratory motion, the particles of the hottest bodies moving with the greatest velocity, and through the greatest space; that in liquids and elastic fluids, besides the vibratory motion, which must be conceived greatest in the last, the particles have a motion round their own axes, with different velocities, the particles of elastic fluids moving with the greatest quickness; and that in ethereal substances, the particles move round their own axes, and separate from each other, penetrating in right lines through space. Temperature may be conceived to depend upon the velocities of the vibrations; increase of capacity on the motion being performed in greater space; and the diminution of temperature, during the conversion of solids into fluids or gases, may be explained on the idea of the loss of vibratory motion in consequence of the revolution of particles round their axes, at the moment when the body becomes liquid or aeriform; or from the loss of rapidity of vibration, in consequence of the motion of the particles through greater space."

Professor Leslie is also an advocate for the hypothesis of vibrations, but under certain modifications, which are not very clearly defined in his work.

(273.) It is supposed by many that heat and light are modifications of the same matter or property; susceptible under variations of condition of producing the sensation of heat or the visual sensation of light. Both are imponderable. Neither the one nor the other is ever found cohering together in a mass: and whenever the particles of either are forcibly accumulated they tend to fly off in all directions with immense rapidity. Hence the particles (if such they be) are highly idio-repulsive. Heat and light are both emitted from the sun in rays issuing and proceeding with great velocity; both are refracted by transparent media, reflected by polished surfaces, and capable of an analogous operation termed polarization.

Light when sufficiently accumulated seems always to produce the sensation of heat; and heat on the other hand, when communicated to material substances of considerable density, invariably gives to them the power of emitting light. The identity of heat and light is however yet far from being established, and there is great room for a well directed series of experiments on this subject. (b.)

(274.) It was an ingenious notion formed by Dr. Irvine to ascertain from the data in his possession, the absolute zero of temperature, that is to say, that point to which if a substance were reduced it would be absolutely deprived of all caloric.

He reasoned thus: supposing the specific heat of ice to that of water as 8 to 10 at temperature 32° Fahrenheit, and that in order to liquefy a given weight of ice, as much heat is required as would raise the same weight of water to 140° Fahrenheit. Then 140° Fahrenheit equals one-fifth of the whole heat of fluid water. Hence that total heat = 5 x 140 = 700° below 32. This subject will be found treated at length in Mr. Dalton’s chapter upon absolute zero: and from the following references; but we do not pursue the question further here, because we feel that it is at best one of great uncertainty at present. Besides, the proof by MM. Dulong and Petit of the variation in the specific heat of the same substance, fairly leads to their conclusion (172) that the absolute zero is at infinity; in other words, that bodies can never be altogether deprived of heat: and this we are inclined to think is most likely to be a just representation of the law of nature on this point. (c.)

</table>

In order to produce these effects, the salts employed must be fresh crystallized, and newly reduced to a very fine powder. The vessels in which the freezing mixture is made should be very thin, and just large enough to hold it, and the materials should be mixed together as quickly as possible. The materials to be employed, in order to produce great cold, ought to be first reduced to the temperature marked in the table, by placing them in some of the other freezing mixtures; and then they are to be mixed together in a similar freezing mixture. If, for instance, we wish to produce a cold = -46°, the snow and diluted nitric acid ought to be cooled down to 0°, by putting the vessel which contains each of them into the first freezing mixture in the second table, before they are mixed together. If a still greater cold is required, the materials to produce it are to be brought to the proper temperature by being previously placed in the second freezing mixture. This process is to be continued till the required degree of cold has been procured.

</table>
The following Table, No. XV., presents a comparative view of the quantities of heat which different bodies contain at a given temperature; these are referred to water as a standard, calling its capacity 1.000. As the capacities of bodies are different, according as they exist in the solid, liquid, or aeriform state, the Table is divided according to those forms: the results obtained by different modes of experiment are placed in distinct classes. The Table from 1 to 151 contains the results obtained by the method of mixture and by the calorimeter; these agreeing in principle, the capacities found by them being inferred from measuring the quantity of caloric given out by a body in suffering a certain change of temperature, by the effect that quantity produces on another body to which it is communicated. Dr. Crawford's results form the basis of this Table, to which are added those established by Irvine, Wilcke, Gadolin, Lavoisier and Laplace, and Kirwan, and also the capacities of some solids ascertained by Mr. Dalton by this method. The Table from 152 to 175 comprises the capacities of bodies estimated from observing their times of cooling, established by the experiments of Leslie and Dalton. And the table from 175 to the end denotes the capacities of aerial fluids ascertained by Delsart and Beranek. The initial letter of the name of each author is annexed to the numbers; and where a difference exists in the capacity of any body, as ascertained by different Chemists, it is given according to each, with a reference by numbers within brackets, so that the authorities may be compared, and that selected on which it may be supposed most reliance is to be placed. (Murray.)

LIGHT.

PART I.

Of unpolarized Light.

§ 1. INTRODUCTION.

In this article we propose to give an account of the properties of light; of the physico-mathematical laws which regulate the direction, intensity, state of polarization, colours, and interferences of its rays; to state the theories which have been advanced for explaining the complicated and splendid phenomena of optics; to explain the laws of vision, and their application, by the combined ingenuity of the philosopher and the artist, to the improvement of our sight; and the examination and measurement of those objects and appearances which, from their remoteness, minuteness, or refinement, would otherwise elude our senses.

2. The sight is the most perfect of our senses; the most various and accurate in the information it affords us; and the most delightful in its exercise. Apart from all considerations of utility, the mere perception of light is in itself a source of enjoyment. Instances are not wanting of individuals debarred from infancy by a natural defect from the use of their eyes, whose highest enjoyment still consisted in that feeble glimmering a strong sunshine could excite in their obstructed organs; but when to this we join the exact perception of form and motion, the wonderous richness and variety of colour, and the ubiquity conferred upon us by just impressions of situation and distance, we are lost in amazement and gratitude.

3. What are the means and mechanism by which we receive this inestimable benefit? Curiosity may well prompt the inquiry, but a more direct interest urges us to pursue it. Knowledge is power; and a careful examination of the means by which we see, not only may, but actually has led us to the discovery of artificial aids by which this particular sense may be strengthened and improved to a most extraordinary degree; giving to man at once the glance of the eagle, and the scrutiny of the insect—by which the infirmities of age may be deferred or remedied—may, by which the sight itself when lost may be restored, and its blessings conferred after long years of privation and darkness, or on those who from infancy have never seen. But as we proceed in the inquiry we shall find inducements enough to pursue it from purely intellectual motives. A train of minute adaptation and wonderful contrivance is disclosed to us, in which are blended the utmost extremes of grandeur and delicacy; the one overpowering, the other eluding, our conceptions. In consequence of those peculiar and singular properties which are found to belong to light in its various states of polarization, it affords to the philosopher information respecting the intimate constitution of bodies, and the nature of the material world, totally distinct from the more general impressions of form, colour, distance, &c. which it conveys to the vulgar. Its notices, it is true, in this respect, are addressed rather to the intellect than the sense; but they are not on that account less real, or less to be depended on. Polarized light is, in the hands of the natural philosopher, not merely a medium of vision; it is an instrument by which he may be almost said to feel the ultimate molecules of natural bodies, to detect the existences and investigate the nature of powers and properties ascertainable only by this test, and connected with the more important and intricate inquiries in the study of nature.

4. The ancients imagined vision to be performed by a kind of emanation proceeding from the eye to the object seen. Were this the case, no good reason could be shown why objects should not be seen equally well in the dark. Something more, however, is necessary for seeing than the mere presence of the object. It must be in a certain state, which we express by saying that it is luminous. Among natural bodies some possess in themselves the property of exciting in our eyes the sensation of brightness, or light; as the sun, the stars, a lamp, red-hot iron, &c. Such bodies are called self-luminous; but by far the greater part possess no such property. Such bodies in the dark remain invisible, though our eyes are turned directly towards them; and are therefore termed dark, non-luminous, or opaque, though this word is also used occasionally to express want of transparency. All bodies, however, though not luminous of themselves, nor capable of exciting any sensation in our eyes, become so on being placed in the presence of a self-luminous body. When a lamp is brought into a dark room, we see, not only the lamp, but all the other bodies in the room. They are all, so long as the lamp remains, rendered luminous, and are in their turn capable of illuminating others. Thus a sunbeam passing into a darkened room renders luminous, and therefore visible, a sheet of paper on which it falls; and this, in its turn, will in like manner illuminate the whole apartment, and render visible every object it contains, so long as it continues to receive the sunbeam. The moon and planets are opaque bodies; but those parts of them on which the sun shines become for the time luminous, and perform all the offices of self-luminous bodies. Thus we see, that the communication which we call light, subsists not only between luminous bodies and our eyes, but between luminous and non-luminous bodies, or between luminous bodies and each other.
Many bodies possess the property of intercepting this peculiar intercourse between luminous bodies and our eyes, or other bodies. A screen of metal interposed between the sun and our eyes prevents our seeing it; interposed between the sun and a sheet of white paper, or other object, it casts a shadow on such object; i.e., renders it non-luminous. By this power of bodies to intercept light, we learn that the communication which constitutes it takes place in straight lines. We cannot see through a bent metallic tube, nor perceive the least glimpse of light through three small holes in as many plates of metal placed one behind the other at a distance, unless the holes be situated exactly in one straight line. Moreover, the shadows of bodies, when fairly received on smooth surfaces perpendicular to the line in which the luminous body lies, are similar in figure to the section of the body which produces them, which could not be, except the light were communicated in straight lines from their edges to the borders of the shadow. We express this property by saying that light emanates, or radiates, or is propagated from luminous bodies in straight lines; by which expressions nothing more is to be understood than the mere fact, without in any way prejudging the question as to the intimate nature of this emanation. Moreover, it emanates from them in all directions, for we see them in all situations of the eye, provided nothing intervene to intercept the light. This is the essential distinction between luminous bodies and optical images; from which, as we shall see, light emanates only in certain directions. Whether it emanates equally in all directions will be considered farther on.

Light also radiates from every point (at least from every physical point) of a luminous body. This may, perhaps, be regarded as a truism; for those points of a luminous body from which (as from the spots in the sun) no light emanates, are, in fact, non-luminous, and the body is only partially so; the figure of the spots is only seen, because it is also necessarily that of the luminous surface which surrounds them. Still it should be borne in mind, for reasons which will appear when we come to speak of the formation of images. It is possible (say, probable) that a luminous surface, such as that of the flame of a candle, may consist only of an immense but finite number of luminous points, surrounded by non-luminous spaces; but it is not ocular demonstration this idea admits of; and it is sufficient for our purpose that, so far as our senses inform us, every physical point of a luminous surface is a separate and independent source of light. We may magnify in a telescope the sun's disc to any extent, and intercept all but the very smallest portions of it, (spots excepted,) yet the visibility of one part is no way impaired by the exclusion of the rest. In this sense the proposition is no truism, but an important fact, of which we shall hereafter trace the consequences.

When the sun shines through a small hole, and is received on a white screen behind at a considerable distance, we see a round luminous spot, which enlarges as the screen recedes from the hole. If we measure the diameter of this image at different distances from the hole, it will be found that (laying out of the question certain small causes of difference not now in contemplation) the angle subtended by the spot at the centre of the hole is constant, and equal to the apparent angular diameter of the sun. The reason of this is obvious; the light from every point in the sun's disc passes through the hole, and continues its course in a right line beyond it till it reaches the screen. Thus every point in the sun's disc has a point corresponding to it in the screen; and the whole circular spot on the screen is, in fact, an image or representation of the face of the sun. That this is really the case, is evidently seen by making the experiment in the time of a solar eclipse, when the image on the screen, instead of appearing round, appears horned, like the sun itself. In like manner, if a pin-hole in a card be held between a candle and a piece of white paper in a dark room, an exact representation of the flame, but inverted, will be seen depicted on the paper, which enlarges as the paper recedes from the hole; and if in a dark room a white screen be extended at a few feet from a small round hole, an exact picture of all external objects, of their natural colours and forms, will be seen traced upon the screen; moving objects being represented in motion, and quiescent ones at rest. (See fig. 6.) To understand this, we must recollect that all objects exposed to light are luminous; that from every physical point of them light radiates in all directions, so that every point in the screen is receiving light at once from every point in the object. The same may be said of the hole; but the light that falls on the hole passes through it, and continues its course in straight lines behind. Thus the hole becomes the vertex of a conoidal solid prolonged both ways, having the object for its base at one end, and the screen at the other. The section of this solid by the screen is the picture we see projected on it, which must manifestly be exactly similar to the object, and inverted, according to the simplest rules of Geometry.

Now if in our screen receiving (suppose) the image of the sun we make another small hole, and behind it place another screen, the light falling on the space occupied by this hole will pass beyond it, and reach the other screen; but it is clear that it will no longer dilate itself, after passing through the second hole, and form another image of the whole sun, but only an image of that very minute portion of the sun which corresponds to the space occupied in his image on the first screen by the hole made there. The lines bounding the conoidal surface will in this case have much less divergency, and, if the holes be small enough, and very distant from each other, will approach to physical lines, and that the nearer, as the holes are smaller and their distance greater. (See fig. 7.) If we conceive the holes reduced to mere physical points, these lines form what we call rays of light. Mathematically speaking, a ray of light is an infinitesimal pyramid, having for its vertex a luminous point, and for its base an infinitely small portion of any surface illuminated by it, and supposed to be filled with the luminous emanation, whatever that may be. This pyramid, in homogeneous media, and when the course of the ray is not interrupted, has, as we have seen,

* In the eclipse of September 7, 1820, this horned appearance was very striking in the luminous interstices between the shadows of small irregular objects, as the leaves of trees, &c. It was noticed by those who had no idea of its cause.
**LIGHT.**

9. Light requires time for its propagation. Two spectators at different distances from a luminous object, suddenly disclosed, will not begin to see it at the same mathematical instant of time. The nearer will see it sooner than the more remote; in the same way as two persons at unequal distances from a gun hear the report at different moments. In like manner, if a luminous object be suddenly extinguished, a spectator will continue to see it for a certain time afterwards, as if it still continued luminous, and this time will be greater the farther he is from it. The interval in question is, however, so excessively small in such distances as occur on the earth's surface, as to be absolutely insensible; but in the immense expanse of the celestial regions the case is different. The eclipses and emersions of Jupiter's satellites become visible much sooner (nearly a quarter of an hour) when the earth is at its least distance from Jupiter than when at its greatest. Light then takes time to travel over space. It has a finite, though immense velocity, viz. 192500 miles per second; and this important conclusion, deduced by calculation from the phenomenon just mentioned, and which, if it stood unsupported, might startle us with its vastness, and incline us to look out for some other mode of explanation, receives full confirmation from another astronomical phenomenon, the *aberration of light*, which (without entering into any close examination of the mode in which vision is produced) may be explained as follows:

10. Let a ray of light from a star $S$, at such a distance that all rays from it may be regarded as parallel, be received on a small screen $A$, having an extremely minute opening $A$ in its centre; and let that ray which passes through the opening be received at any distance $AB$, on a screen $B$ perpendicular to its direction; and let $B$ be the point on which it falls, the whole apparatus being supposed at rest. If then we join the points $A$, $B$ by an imaginary line, that line will be the direction in which the ray has really travelled, and will indicate to us the direction of the star; and the angle between that line and any fixed direction (that of the plumb-line, for instance) will determine the star's place as referred to that fixed direction. For simplicity, we will suppose this angle nothing, or the star directly vertical; then the point $B$ on which the ray falls will be precisely that marked by a plumb-line let fall from $A$; and the direction in which we judge the star to lie will coincide precisely with the direction of gravity. Such will be the case, supposing the earth, the spectator, and the whole apparatus at rest; but now suppose them carried along in a horizontal direction $AC$, $BD$, with a uniform and equal velocity, of whose existence they will therefore be perfectly insensible, and the plumb-line will hang steadily as before, and coincide with the same point of the screen. At the moment when the ray $SA$ from the star passes through the orifice $A$, let $A$, $B$ be the respective places of the orifice, and the point on the screen vertically below it. When the ray has passed the orifice, it will pursue its course in the same straight line $SA$ as before, independent of the motion of the apparatus, and in some certain time ($\frac{\text{distance } AB}{\text{velocity of light}} = t$) will reach the lower screen. But in this time the aperture, screens, and plumb-line will have moved away through a space

$$Aa = BB' \left(= t \times \text{velocity of motion} = AB \times \frac{\text{earth's velocity}}{\text{velocity of light}}\right)$$

At the instant, then, that the ray impinges on the lower screen, the plumb-line will hang, not from $A$ on $B$, but from $a$ on $b'$; and $a$ being the real orifice, and $B$ the *real point of incidence* of the light on the screen, the spectator, judging only from these facts, will necessarily be led to regard the ray as having deviated from its vertical direction, and as inclining from the vertical, in the direction of the earth's motion through an angle whose tangent is

$$\frac{Aa}{AB} \times \frac{\text{earth's velocity}}{\text{velocity of light}}$$

11. The eye is such an apparatus. Its retina is the screen on which the direction of the light of the star or luminary falls, and we judge of its place only by the actual point on this screen where the impression is made. The pupil is the orifice. If, the eye preserving a fixed direction, the whole body be carried to one side with a velocity commensurate to that of light, before the rays can traverse the space which separates the pupil from the retina, the latter will have shifted its place; and the point which receives the impression is no longer the same which would have received it had the eye and spectator remained at rest; and this deviation is the *aberration of light*.

12. Every spectator on the earth participates in the general motion of the whole earth, which in its annual orbit about the sun is very rapid, and though far from equal to that of light, is by no means insensible, compared to it. Hence the stars, the sun, and planets, all appear removed from their true places in the direction in which the earth is moving.

13. This direction is varying every instant, as the earth describes an orbit round the sun. The direction therefore of the apparent displacement of any star from its true situation continually changes, i.e. the apparent place describes a small orbit about the true. This phenomenon is that alluded to. It was noticed as a fact by Bradley, while ignorant of its cause, that the stars appear to describe annually small ellipses in the heavens of about 40° in diameter. The discovery of the velocity of light by the eclipses of Jupiter's satellites, then recently made by Roemer, however, soon furnished its explanation. Later observations, especially those of Brinkley and Struve, have enabled us to assign, with great precision, the numerical amount of this inequality, and thence to deduce the velocity of light, which by this method comes out 191515 miles per second, differing
from the former only by a two hundredth part of its whole quantity. This determination is certainly to be preferred.

But this is not the only information respecting light which astronomical observations furnish. We learn from them also, "That the light of the sun, the planets, and all the fixed stars, travels with one and the same velocity." Now as we know these bodies to be at different and variable distances from us, we hence conclude that the velocity of light is independent of the particular source from which it emanates, and the distance over which it has travelled before reaching our eye.

The velocity of light, therefore, in that free and perhaps void space which intervenes between us and the planets and fixed stars, cannot be supposed other than uniform; and the calculations of the eclipses of Jupiter's satellites, and the places of the distant planets made on this supposition agreeing with observation, prove it to be so. In entering such media as it traverses, when arrived within the limits of the atmospheres of the earth and other planets, we shall find reason hereafter to conclude that its velocity undergoes a change; but, at all events, we have no reason to suppose it to differ in different parts of one and the same homogeneous medium.

The enormous velocity here assigned to light, surprising as it may seem, is among those conclusions which rest on the best evidence that science can afford, and may serve to prepare us for other yet more amazing numerical estimates. It is when we attempt to measure the vastness of the phenomena of nature with our feeble scale of units, such as we are conversant with on this our planet, that we become sensible of its insignificance in the system of the universe. Demonstrably true as are the results, they fail to give us distinct conceptions; we are lost in the immensity of our numbers, and must have recourse to other ways of rendering them sensible. A cannon ball would require seventeen years at least to reach the sun, supposing its velocity to continue uniform from the moment of its discharge. Yet light travels over the same space in \( \frac{7}{2} \) minutes. The swiftest bird, at its utmost speed, would require nearly three weeks to make the tour of the earth. Light performs the same distance in much less time than is required for a single stroke of his wing; yet its rapidity is but commensurate to the distances it has to travel. It is demonstrable that light cannot possibly arrive at our system from the nearest of the fixed stars in less than five years, and telescopes disclose to us objects probably many thousand times more remote.

But these are considerations which belong rather to astronomy than to the present subject; and we will, therefore, return to the consideration of the phenomena of emitted light.

§ II. Of Photometry.

Of these, one of the most striking is certainly the diminution of the illuminating power of any source of light, arising from an increase of its distance. We see very well to read by the light of a candle at a certain distance: remove the candle twice, or ten times as far, and we can see to read no longer.

The numerical estimation of the degrees of intensity of light constitutes that branch of optics which is termed Photometry. (ποιμομετρία.)

If light be a material emanation, a something scattered in minute particles in all directions, it is obvious that the same quantity which is diffused over the surface of a sphere concentric with the luminous points, if it continue its course, will successively be diffused over larger and larger concentric spherical surfaces; and that its intensity, or the number of rays which fall on a given space, in each will be inversely as the whole surfaces over which it is diffused; that is, inversely as the squares of their radii, or of their distances from the source of light. Without assuming this hypothesis, the same thing may be rendered evident as follows. Let a candle be placed behind an opaque screen full of small equal and similar holes; the light will shine through these, and be intercepted in all other parts, forming a pyramidal bundle of rays, having the candle in the common vertex. If a sheet of white paper be placed behind this, it will be seen dotted over with small luminous specks, disposed exactly as the holes in the screen. Suppose the holes so small, their number so great, and the eye so distant from the paper that it cannot distinguish the individual specks, the will still receive a general impression of brightness; the paper will appear illuminated, and present a mottled appearance, which, however, will grow more uniform as the holes are smaller, and nearer, and the eye more distant; and if extremely so, the paper will appear uniformly bright. Now, if every alternate hole be stopped, the paper will manifestly receive only half the light, and will therefore be only half as much illuminated, and ceteris paribus, the degree of illumination is proportional to the number of the holes in the screen, or to the number of equally illuminated specks on its surface, i. e. if the specks be infinitely diminished in size, and infinitely increased in number, to the number of rays which fall on it from the original source of light.

Let a screen, so pierced with innumerable equal and very small holes in the manner described, be placed at a given distance (1 yard) from a candle; and in the diverging pyramid of rays behind it place a small piece of white paper of a given area, (1 square inch, for instance,) so as to be entirely included in the pyramid. It is manifest that the number of rays which fall on it will be fewer as it is placed farther from the screen, because the whole number which pass the screen are scattered continually over a larger and larger space. Thus were it close to the screen it would receive a number equal to that of the holes in a square inch of the screen, but at twice the distance (2 yards) from the candle this number will be spread over four square inches by their divergence, and the paper can therefore receive only a fourth part of that number. If, therefore, its illumination when close to the screen be represented by \( I \), it will at twice the distance be only \( \frac{I}{4} \), and...
20. As this reasoning is independent of the number and size of the holes, and therefore of the ratio of the sum of their areas to that of the unperforated part of the screen, we may conceive this ratio increased ad infinitum. The screen then disappears, and the paper is freely illuminated. Hence we conclude that when a small plane object of given area is freely and perpendicularly exposed to a luminary at different distances, the quantity of light it receives, or the degree of its illumination, is inversely as the squares of its distance from the luminary, ceteris paribus.

21. If a single candle be placed before a system of holes in a screen, as before, and the rays received on a screen at a given distance, (1.) the degree of illumination may be represented by a given quantity, I. Now if a second candle be placed immediately behind the other, and close to it, so as to shine through the same holes, the illumination of the screen is perceived to be increased, though the number and size of the illuminated points on it be the same. Each point is then said to be more intensely illuminated. Now, (the eye being all along supposed so distant, and the illuminated points so small as to produce only a general sense of brightness, without distinguishing the individual points,) if one candle be shifted a little sideways, without altering its distance, the illumination of the paper will not be altered. In this case the number of illuminated points is doubled, but each is illuminated with only half the light it had before. The same holds for any number of candles. Hence we conclude that the illumination of a surface is constant when the number of rays it receives is inversely as the intensity of each, and that consequently the degree of illumination is proportional to the number and intensity of the rays jointly.

Now if for any number of candles placed side by side we substitute mere physical luminous points, each of these will be the vertex of a pyramid of rays, and the number of equally illuminated points in the paper, and therefore illuminations will be proportional to the number of such points. If we conceive the number of these increased, and their size diminished ad infinitum, so as to form a continuous luminous surface, their number will be represented by its area. Hence the illumination of the paper will be, ceteris paribus, as the area of the illuminating surface, (supposed of uniform brightness.)

22. Uniting all these circumstances, we see that when a given object is enlightened by a luminous surface of small but sensible size, the degree of its illumination is proportional to the area of the luminous surface x intensity of its illuminating power divided by the square of the distance of the surface illuminated.

23. Oblique illumination.

The foregoing reasoning applies only to the case when the luminous disc is a small portion of a spherical surface concentric with the illuminated object, in which case all its points are equidistant from it, and all the light falls perpendicularly on the object. When the object is exposed obliquely, conceive its surface divided into equal infinitely small portions, and regard each of them as the base of an oblique pyramid, having its vertex at any one point of the luminary; then will the perpendicular section of this pyramid at the same distance be equal to the base x sine of inclination of the base to the axis, or the element of the illuminated surface x by the sine of the inclination of the ray. But the number of rays which falls on the base is evidently equal to those which fall on the section, and being spread over a larger area their effect will be to illuminate it less intensely in the proportion of the area of the section to that of the base, i.e. in the proportion of the sine of inclination to radius. But the illumination of the section is equal to the area of the luminary x intrinsic brightness divided by the square of the distance of the section to the luminary.

24. Therefore that of the elementary surface equals this fraction multiplied by the sine of the rays' inclination; or, calling A the area of the luminary, I its intrinsic brightness, D its distance, and $\theta$ the inclination of the ray to the illuminated surface $A \cdot I \sin \theta \frac{D^2}{D^2}$ will represent the intensity of illumination.

25. If L represent the absolute quantity of light emitted by the luminary in a given direction, which may be called its absolute light, we have $L = A \times I$, provided the surface of the luminary be perpendicular to the given direction. If not, A must represent the area of the section of a cylindroidal surface bounded by the outline of the luminary, and having its axis parallel to the given direction; consequently $\frac{L \cdot \sin \theta}{D^2}$ represents in this case the intensity of illumination of the elementary surface.

To illustrate the application of these principles we will resolve the following problem.

To illustrate the application of these principles we will resolve the following problem.

26. A small white surface is laid horizontally on a table, and illuminated by a candle placed at a given (horizontal) distance: What ought to be the height of the flame, so as to give the greatest possible illumination to the surface?

Fig. 2. Let A be the surface, B C the candle. Put $AB = a$, $AC = D$; $BC = \sqrt{D^2 - a^2}$. Then, since the illumination of A is, ceteris paribus, as $\frac{\sin C A B}{A C^2}$, or as $\frac{CB}{AC^2} = \frac{\sqrt{D^2 - a^2}}{D^2}$ $(= F)$ we have to make this

**Light.**

Quantity a maximum; consequently $dF = 0$, or $d^2F = 0$, that is,

$$d \left( \frac{1}{D^4} - \frac{a^8}{D^6} \right) = 0, \quad \text{or} \quad - \frac{4}{D^2} + \frac{6a^8}{D^7} = 0, \quad 2D^2 - 3a^8 = 0,$$

or $D = a \cdot \sqrt{\frac{3}{2}}$ and $BC = \sqrt{D^2 - a^8} = \frac{a}{\sqrt{2}} = 0.707 \times A B$.

27. Definition. The apparent superficial magnitude, or the apparent magnitude of any object, is a portion of a spherical surface described about the eye as a centre, with a radius equal to 1, and bounded by an outline being the intersection of this spherical surface with a conoidal surface, having the object for its base and the eye for its vertex.

Hence the apparent superficial magnitude of a small object is directly as the area of a section (perpendicular to the line of sight) of this conoidal surface, at the place of the object, and inversely as the square of its distance. If the object be a surface perpendicular to the line of sight, this ratio reduces itself to the area of the object divided by the square of its distance.

**Definition.** The real intrinsic brightness of a luminous object is the intensity of the light of each physical point in its surface, or the numerical measure of the degree in which such a point (of given magnitude) would illuminate a given object at a given distance, referred to some standard degree of illumination as a unit. When we speak simply of intrinsic brightness, real intrinsic brightness is meant.

**Corol. 1.** Consequently the degree of illumination of an object exposed perpendicularly to a luminary is as the apparent magnitude of the luminary and its intrinsic brightness jointly.

**Corol. 2.** Conversely, if these remain the same, the degree of illumination remains the same. For example, the illumination of direct sunshine is the same as would be produced by a circular portion of the surface of the sun in diameter, placed at about 10 feet from the illuminated object, and the rest of the sun annihilated; for such a circular portion would have the same apparent superficial magnitude as the sun itself. This will serve to give some idea of the intense brightness of the sun's disc.

**Definition.** The apparent intrinsic brightness of any object, or luminary, is the degree of illumination of its image or picture at the bottom of the eye. It is this illumination only by which we judge of brightness. A luminary may in reality be ever so much brighter than another; but if by any cause the illumination of its image in the eye be enfeebled, it will appear no brighter than in proportion to its diminished intensity. Thus we can gaze steadily at the sun through a dark glass, or the vapours of the horizon.

**Definition.** The absolute light of a luminary is the sum of the areas of its elementary portions, each multiplied by its own intrinsic brightness; or, if every part of the surface be equally bright, simply the area multiplied by the intrinsic brightness. It is, therefore, the same quantity as that above represented by $L$.

**Definition.** The apparent light of an object is the total quantity of light which enters our eyes from it, however distributed on the retina.

In common language, when we speak of the brightness of an object of considerable size, we often mean its apparent intrinsic brightness. When, however, the object has no sensible size, as a star, we always mean its apparent light, (or, as it might be termed, its apparent absolute brightness,) because, as we cannot distinguish such an object into parts, we can only be affected by its total light indiscriminately. The same holds good with all small objects which require attention to distinguish them into parts. Optical writers have occasionally fallen into much confusion for want of attending to these distinctions.

As we recede from a luminary, its apparent light diminishes, from two causes; first, our eyes, being of a given size, present a given area to its light, and therefore receive from it a quantity of light inversely as the square of the distance; secondly, in passing through the air, a portion of the light is stopped, and lost from its want of perfect transparency. This, however, we will not now consider. In virtue of the first cause only, then, the apparent light of a luminary is inversely as the square of its distance, and directly as its absolute light.

The apparent intrinsic brightness is equal to the apparent light divided by the area of the picture on the retina of our eye. But this area is as the apparent superficial magnitude of the luminary, that is, as its real area $A$ divided by the square of its distance $D$, or as $\frac{A}{D^2}$. Moreover, the apparent light, as we have just seen, is as

$$\frac{A I}{D^8}, \quad \text{or simply to} \quad \frac{I}{D^8}, \quad \text{or simply to} \quad I, \quad \text{and is independent on} \quad A \quad \text{or} \quad D.$$  

The apparent intrinsic brightness is, therefore, the same at all distances, and is simply proportional to the real intrinsic brightness of the object. This conclusion is usually announced by optical writers by saying, that objects appear equally bright at all distances, which must be understood only of apparent intrinsic brightness, and the truth of which supposes also that no loss of light takes place in the media traversed.

The angle of emanation of a ray of light from a luminous surface is the inclination of the ray to the surface at the point from which it emanates.

A question has been agitated among optical philosophers, whether the intensity of the light of luminous bodies be the same in all directions; or whether, on the other hand, it be not dependent on the angle of emanation. Euler, in his Réflexions sur les divers degrés de la lumière du Soleil, Sc. Berlin, Mém. 1750, p. 280, has adopted
the former principle. Lambert, on the other hand, *Photometria*, p. 41, contends that the intensity of the light, or density of the rays, issuing from a luminous surface in any direction is proportional to the sine of the angle of emanation. If we knew the intimate nature of light, and the real mechanism by which bodies emit and reflect it, it might be possible to decide this question *a priori*. If, for instance, we were assured that light emanated strictly and solely from the molecules situated on the external surface of bodies, and that the emanation from each physical point of the surface were totally uninfluenced by the rest of the molecules of which the body consists, and dispersed itself equally in all directions, then, since every point of a plane surface is visible to an eye wherever situated above it, and each is supposed to send the same number of rays to the eye in an oblique as in a perpendicular situation, the total light received from a given area of the surface in the eye ought to be the same at all angles of emanation. But as the apparent magnitude of this area is as the sine of its inclination to the line of sight, i.e. of its angle of emanation, this light is distributed over a less apparent area; and therefore its intensity, or the apparent brightness of the surface, should be increased in the inverse ratio of the sine of the angle of emanation. On the other hand, if, as there is every reason to suppose, light emanates not strictly from the surfaces of bodies, but from sensible depths within their substance; if the surfaces themselves be not true mathematical planes, but consist of a series of physical points retained in their places by attractive and repulsive forces, and if the intensity of emanation of each of these points depend in any way on its relation to the points adjacent, there is no reason, *a priori*, to suppose the equal emanation of light in all directions; and to find what its law really is, we must have recourse to direct observation.

Astronomy teaches us that the sun is a sphere. Hence the several parts of its visible disc appear to us under every possible angle of inclination. Now if we examine the surface of the sun with a telescope, the circumference certainly does not appear brighter than the centre. But if the hypothesis of equal emanation were correct, the brightness ought to increase from the centre outwards, and should become infinite at the edges, so that the disc ought to appear surrounded by an annulus of infinitely greater splendour than the central parts. To this it may, however, be justly objected, that as the surface of the sun is obviously though generally spherical, yet full of local irregularities, every minute portion of it may be regarded as presenting every possible variety of inclination to our eye; and the brightness of every part being thus an average of all the gradations of which it is susceptible, should be alike throughout.

Bouguer, in his *Traité d'Optique*, Paris, 1760, p. 90, states himself to have found, by direct comparison, that the central portions of the disc of the sun are really much more luminous than the borders. A result so extraordinary, however, and so apparently incompatible with all we know of the constitution of the sun and the mode of emission of light from its surface, would require to be verified by very careful and delicate reexamination. If found correct, the only way of accounting for it would be to suppose a dense and imperfectly transparent atmosphere of great extent floating above the luminous clouds which form its visible surface. This is certainly possible, but our ignorance on the subject renders it unphilosophical to resort to a body so little within our reach for the establishment of any fundamental law of emanation. The objection above advanced, it will be observed, applies with nearly the same force to all surfaces. If we examine a piece of white paper with a magnifier, we shall find its texture to be in the last degree rough and coarse, presenting no approach to a plane; and so of all surfaces rough enough to reflect light in all directions.

However, as it is only with such luminous surfaces as occur in nature that we have any concern, we must take their properties as we find them; and, waiving all consideration of what would be the law of emanation from a mathematical surface, it may be stated as a result of observation, that luminous surfaces appear equally bright at all angles of inclination to the line of sight. This may be tried with a surface of red-hot iron; its apparent intrinsic brightness is not sensibly increased by inclining it obliquely to the eye.

If we take a smooth square bar of iron, or better, of silver, or a polished cylinder of either metal, heated to redness, into a dark room, the cylinder will appear equally bright in the middle of its convexity next the eye, and at the edges, and cannot be distinguished at all from a flat bar; and the square bar, when so presented as to have two of its sides at very different angles to the line of sight, will still appear of perfectly equal brightness, nor can the angle separating the adjacent sides be at all discerned; and if the whole bar be turned round on its axis, the motion can only be recognised by an alternating increase and decrease of its apparent brightness, according as it is seen alternately diagonally and laterally, its appearance being always that of a flat plate perpendicularly exposed to the eye. These and similar experiments with surfaces artificially illuminated, which the reader will have no difficulty in imagining and making, as well as those recorded by Mr. Ritchie in the *Edinburgh Philosophical Journal*, are sufficient to establish the principle announced in Article 42, to which (for the reasons already mentioned) the observation of Bouguer on the unequal brightness of the sun's disc offers no conclusive objection.

Hence it follows, that the surfaces of luminous bodies, at least their ultimate molecules, do not emit light with equal copiousness in all directions; but that, on the contrary, the copiousness of emission, in any direction, is as the sine of the angle of emanation from the surface.

**Problem.**

To determine the intensity of illumination of a small plane surface any how exposed to the rays from a luminary of any given size, figure, and distance; the luminary being supposed uniformly bright in every part. Conceive the surface of the luminary divided into infinitesimal elementary portions, of which let each be regarded as an oblique section of a pyramid, having for its vertex the centre of the infinitely small illuminated
Let \( P Q \) be any such portion, and let the pyramid \( B P \) be continued till it meets the surface of the heavens in \( p \), there projecting the surface \( P Q \) into the area \( p q \), and let the whole luminary \( C D E F \) be in like manner projected into the disc \( c d e f \). Let \( \pi Q \) be a section of the pyramid \( P Q \), perpendicular to its axis. Then, first, the plane \( B \) will be illuminated by the element \( P Q \), just as it would be by a surface \( \pi Q \) equally bright, in virtue of the principle just established. Hence \( P Q \) is equivalent to an equally bright surface \( \pi Q \). Again, since the apparent magnitude of \( \pi Q \) seen from \( B \) is the same with that of \( p q \), the area \( \pi Q \) is equivalent to an equally bright area \( p q \) placed at \( p q \). (Art. 29, 30, 31, Cor. 1, 2.) \( P Q \) is, therefore, equivalent to \( p q \). And since the same holds good of every other elementary portion of the surface, and the total light received by \( B \) is the sum of the lights it receives from all the elements of the luminary, the whole surface \( C D E F \) must be equivalent to its projection \( c d e f \).

Hence the illumination of \( B \) depends, not at all on the real, but only on the apparent figure and magnitude of the luminary; and whatever the luminary be, we may always substitute for it a portion of the visible heavens, supposed of equal intrinsic brightness, and bounded by the same outline.

Thus, instead of the sun, we may suppose a small circle equal in apparent diameter to the sun, and equally bright; instead of a luminous rectangle perpendicular to the illuminated plane \( B \), and of infinite height, as \( A G H I \), fig. 3, we may substitute the spherical sector \( Z A G \), bounded by the two vertical circles \( Z A \), \( Z G \), and so on.

Let then \( pq \), any elementary rectangle infinitely small in both dimensions of the spherical surface, be represented by \( d^2 A \), so that \( \int \int d^2 A \) shall represent the surface \( c d e f \) itself; then if we put \( z = \) the zenith distance \( Z p \) of this portion, its illuminating power on \( A \) will be \( d^2 A \cdot \cos z \), and the total illuminating power of the whole surface \( A \) will be

\[
L = \int \int d^2 A \cdot \cos z.
\]

**Example 1.** To find the illuminating power of the sector \( Z A G \) confined between any two vertical circles and the horizon. (fig. 3.) Here, putting \( \theta \) for the azimuth of the element \( d^2 A \), if we consider it as terminated by two contiguous verticals and two contiguous parallels of altitude, we have \( d^2 A = dz \times d\theta \cdot \sin z \). Hence we have

\[
L = \int \int dz \sin z \cdot \cos z = \frac{1}{2} \int \int d\theta dz \cdot \sin 2z = \frac{1}{2} \int (\theta + C) dz \cdot \sin 2z;
\]
and extending the integral from \( \theta = 0 \) to \( \theta = A G \), the amplitude of the sector, (which we will call \( a \)) we get

\[
L = -\frac{a}{2} \int dz \cdot \sin 2z = -\frac{a}{2} (C - \frac{1}{2} \cos 2z)
\]

which extended from \( Z = 0 \) to \( z = 90^\circ \) becomes simply \( L = \frac{a}{2} \).

**Corol. 1.** This is a measure of the illuminating power of the sector, on the same scale that that of an infinitely small area \( A \) placed at the zenith would be represented by \( A \) itself. Because in this case

\[
\cos z = 0, \quad \text{and} \quad \int \int d^2 A \cdot \cos z = A.
\]

**Corol. 2.** On the same scale the illuminating power of the whole hemisphere is \( \pi \) where \( \pi = 3.14159535 \)

**Example 2.** Required the illuminating power of a circular portion of the heavens whose centre is the zenith. Calling \( z \) the zenith distance of any element, and \( \theta \) its azimuth, we shall have, as before,

\[
d^2 A = d\theta dz \cdot \sin z, \quad \text{and therefore} \quad L = \int \int d\theta dz \cdot \sin z \cdot \cos z = \int \int d\theta \cdot \frac{dz \cdot \sin 2z}{2} = \pi \int dz \cdot \sin 2z
\]
and the integral from \( \theta = 0 \) to \( \theta = 2\pi \). That is \( L = \pi \cdot (\text{const} - \frac{1}{2} \cos 2z) \) which being made to vanish when \( z = 0 \) becomes

\[
L = \frac{\pi}{2} (1 - \cos 2z) = \pi \cdot (\sin z)^2
\]

**Corol. 3.** The illuminating power of a circular luminary, whose centre is in the zenith, is as the square of the sines of its apparent semidiameter.

**Example 3.** Required the illuminating power of any circular portion of the heavens whatever.

Let \( T K L M \) be the illuminating circle; conceive it composed of annuli concentric with itself, and of one of them, \( XYZ \), (fig. 4.) let \( X \) be an infinitesimal parallelogram terminated by contiguous radii \( S X \) and \( S x \), \( S \) being the centre.

\[
\text{Area } d^3 A = Xx = dx \times d\phi \cdot \sin x
\]
\[
\Rightarrow \quad L = \int \int d\phi dx \cdot \sin x \cdot \cos z
\]

but, by spherical trigonometry,

\[
\cos z = \cos a \cdot \cos x + \sin a \cdot \sin x \cdot \cos \phi,
\]
L I G H T.

Therefore

\[ L = \int \int d z \cdot d \phi \cdot \sin z \left\{ \cos \alpha \cdot \cos \phi + \sin \alpha \cdot \sin z \cdot \cos \phi \right\} \]

The first integration performed relative to \( \phi \), and extended from \( \phi = 0 \) to \( \phi = 360^\circ \), or \( 2 \pi \), gives

\[ L = \int d x \cdot \sin x \cdot 2 \pi \cdot \cos \alpha \cdot \cos z. \]

After which integrating, with respect to \( x \), and extending the integral from \( x = 0 \) to \( x = \pi = r \), we find

\[ L = \frac{\pi \cdot \cos \alpha}{2} \left( 1 - \cos 2 \pi \right) = \pi \cdot \cos \alpha \cdot \left( \sin \pi \right)^2. \]

This result is particularly elegant and remarkable. It shows, that to obtain the illuminating effect of a circular luminary (of any apparent diameter) at any altitude, on a horizontal plane, we have only to reduce its illuminating effect when in the zenith, in the ratio of radius to the cosine of the zenith distance, or sine of the altitude. For other examples, the reader may consult Lambert's Photometria, cap. ii. from which this is taken.

54. If the illuminating surface be not equally intrinsically bright in every part, if we call \( I \) the intrinsic brightness of the element \( d^2 A \), we shall have

\[ L = \int \int I \cdot d^2 A \cdot \cos z \]

for the general formula expressing the illuminating power of the surface \( A \). The moon, Venus and Mercury in their phases, the sky during twilight, a white sphere illuminated by the sun, &c. afford examples of this when themselves regarded as luminaries.

### Problem

55. To compare the illumination of a horizontal plane by the sun in the zenith with the illumination it would have were the whole surface of the heavens of equal brightness with the sun.

By Art. 53 we have \( L = \pi \cdot \cos \alpha \cdot \left( \sin \pi \right)^2 \). If, therefore, we call \( L \) and \( L' \) the two illuminations in question, we shall have

\[ L : L' : : \pi \cdot \cos \phi \cdot \left( \sin \pi \right)'s \text{ semidiam.} : \pi \cdot \cos \phi \cdot \left( \sin 90^\circ \right)'s \]

\[ :: \left( \sin 16^\circ \right)'s : 1 : 1 : 46166. \]

56. The illumination of a plane in contact with the sun's surface is the same as that of a plane on the earth's surface illuminated by a whole hemisphere of equal brightness with the sun in the zenith. Hence we see that the illumination of such a plane as the sun's surface would be nearly 50,000 times greater than that of the earth's surface at noon under the equator. Such would be the effect (in point of light alone) of bringing the earth's surface in contact with the sun's!

57. For measuring the intensity of any given light, various instruments called Photometers have been contrived, many of which have little to recommend them on the score of exactness, and some are essentially defective in principle, being adapted to measure—not the illuminating—but the heating power of the rays of light; and, therefore, must be regarded as undeserving the name of photometers.

58. We know of no instrument, no contrivance, as yet, by which light alone (as such) can be made to produce mechanical motion, so as to mark a point upon a scale, or in any way to give a direct reading off of its intensity, or quantity, at any moment. This obliges us to refer all our estimations of the degrees of brightness at once to our organs of vision, and to judge of their amount by the impression they produce immediately on our sense of sight. But the eye, though sensible to an astonishing range of different degrees of illumination, is (partly on that very account) but little capable of judging of their relative strength, or even of recognising their identity when presented at intervals of time, especially at distant intervals. In this manner the judgment of the eye is as little to be depended on for a measure of light, as that of the hand would be for the weight of a body casually presented. This uncertainty, too, is increased by the nature of the organ itself, which is in a constant state of fluctuation; the opening of the pupil, which admits the light, being continually expanding and contracting by the stimulus of the light itself, and the sensibility of the nerves which feel the impression varying at every instant. Let any one call to mind the blinding and overpowering effect of a flash of lightning in a dark night, compared with the sensation an equally vivid flash produces in full daylight. In the one case the eye is painfully affected, and the violent agitation into which the nerves of the retina are thrown is sensible for many seconds afterwards, in a series of imaginary alternations of light and darkness. By day no such effect is produced, and we trace the course of the flash, and the zig-zags of its motion with perfect distinctness and tranquillity, and without any of those ideas of overpowering intensity which previous and subsequent total darkness attach to it.

59. But yet more. When two unequally illuminated objects (surfaces of white paper, for instance) are presented at once to the sight, though we pronounce immediately on the existence of a difference, and see that one is brighter than the other, we are quite unable to say what is the proportion between them. Illuminate half a sheet of paper by the light of one candle, and the other half by that of several; the difference will be evident. But if ten different persons are desired, from their appearance only, to guess at the number of candles shining on each, the probability is that no two will agree. Nay, even the same person at different times will form different judgments. This throws additional difficulty in the way of photometrical estimations, and would seem to render this one of the most delicate and difficult departments of optics.
However, the eye, under favourable circumstances, is a tolerably exact judge of the equality of two degrees of illumination seen at once; and availing ourselves of this, we may by proper management obtain correct information as to the relative intensities of all lights. What these favourable circumstances are, we come now to consider.

1st. The degrees of illumination compared must be of moderate intensity. If so bright as to dazzle, or so faint as to strain the eye, no correct judgment can be formed.

Hence, it is rarely advisable to compare two luminaries directly with each other. It is generally better to let them shine on a smooth white surface, and judge of the degree in which they illuminate it; for it is an obvious axiom, That two luminaries are equal in absolute light when, being placed at equal distances from, and in similar situations with respect to, a given smooth white surface, or two equal and precisely similar white surfaces, they illuminate it or them equally.

2nd. The luminaries, or illuminated surfaces compared, must be of equal apparent magnitude, and similar figure, and of such small dimensions as to allow of the illumination in every part of each being regarded as the same.

3rd. They must be brought close together, in apparent contact; the boundary of one cutting upon that of the other by a well-defined straight line.

4th. They should be viewed at once by the same eye, and not one by one eye, and the other by the other.

5th. All other light but that of the two objects whose illumination is compared should be most carefully excluded.

6th. The lights which illuminate both surfaces must be of the same colour. Between very differently coloured illuminations no exact equalization can ever be obtained, and in proportion as they differ our judgment is uncertain.

When all these conditions obtain, we can pronounce very certainly on the equality or inequality of two illuminations. When the limit between them cannot be perceived, on passing the eye backwards and forwards across it, we may be sure that their lights are equal.

Bouguer, in his Traité d'Optique, 1760, p. 35, has applied these principles to the measure or rather the comparison of different degrees of illumination. Two surfaces of white paper, of exactly equal size and reflective power, (cut from the same piece in contact,) are illuminated, the one by the light whose illuminating power it is to be measured, the other by a light whose intensity can be varied at pleasure by an increase or decrease of distance, and can therefore be exactly estimated. The variable light is to be removed, or approached, till the two surfaces are judged to be equally bright, when, the distances of the luminaries being measured, or otherwise allowed for, the measure required is ascertained.

Mr. Ritchie has lately made a very elegant and simple application of this principle. His photometer consists of a rectangular box, about an inch and a half or two inches square, open at both ends, of which ABCD (fig. 5) is a section. It is blackened within, to absorb extraneous light. Within, inclined at angles of 45° to its axis, are placed two rectangular pieces of plane looking-glass FC, FD, cut from one and the same rectangular strip, of twice the length of either, to ensure the exact equality of their reflecting powers, and fastened so as to meet at F, in the middle of a narrow slit EFG about an inch long, and an eighth of an inch broad, which is covered with a slip of fine tissue or oiled paper. The rectangular slit should have a slip of blackened card at F, to prevent the lights reflected from the looking-glasses mingling with each other.

If we would compare the illuminating powers of two sources of light, (two flames, for instance) P and Q. They must be placed at such a distance from each other, and from the instrument between them, that the light from every part of each shall fall on the reflector next it, and be reflected to the corresponding portion of the paper E F or F G. The instrument is then to be moved nearer to the one or the other, till the paper on either side of the division F appears equally illuminated. To judge of this, it should be viewed through a prismatical blackened slit, within, and then be placed on the upper part A B of the photometer; the other applied quite close to the eye. When the lights are thus exactly equalized, it is clear that the total illuminating powers of the luminaries are directly as the squares of their distances from the middle of the instrument.

By means of this instrument we are furnished with an easy experimental proof of the decrease of light as the inverse squares of the distances. For if we place four candles at P, and one at Q, (as nearly equal as possible, and burning with equal flames,) it is found that the portions EF, GF of the paper will be equally illuminated when the distances PF, QF are as 2 : 1, and so for any number of candles at each side.

To render the comparison of the lights more exact, the equalization of the lights should be performed several times, turning the instrument end for end each time. The mean of the several determinations will then be very near the truth.

In some cases the looking-glasses are better dispensed with, and a slip of paper pasted over them, so as to present two oblique surfaces of white paper inclined at equal angles to the incident light. In this case the paper stretched over the slit E F G is taken away, and the white surfaces below examined and compared. One advantage of this disposition is the avoiding of a black interval between the two halves of the slit, which renders the exact comparison of their illuminations somewhat precarious.

If the lights compared be of different colours (as daylight, or moonlight, and candlelight,) their precise equalization is impracticable, (art. 67.) The best way of employing the instrument, in this case, is to move it till one of the sides of the slit (in spite of the difference of colours) is judged to be decidedly the brighter, and then to move it the other way, till the other becomes decidedly the brighter. The position half way between these points is to be taken as the true point of equal illumination.

If we would compare the degrees of illumination, or the intrinsic brightnesses of two surfaces, a given portion of each must be insulated for examination; this may be best done by the adaptation of two blackened tubes to
Comparison of the luminaries are as the squares of their distances directly, and the sines of the respective angles of inclination of their rays to the screen in inversely.

It may happen that the lights to be compared are not movable, or not conveniently so. In this case the equalization of the shadows may be performed by inclining the screen at different angles to the directions in which it receives the light of each, and noting the angles of inclination of the rays. In this case the illuminating powers of the luminaries are as the squares of their distances directly, and the sines of the respective angles of inclination of their rays to the screen inversely.

When a ray of light proceeds in empty space, or in a perfectly homogeneous medium, its course, as we have seen, is rectilinear, and its velocity uniform; but when it encounters an obstacle, or a different medium, it undergoes changes or modifications which may be stated as follows:

One of these parts is regularly reflected, and pursues, after reflexion, a course wholly exterior to the new medium, or obstacle. A second and a third portion are regularly refracted, that is, they enter the medium, and there pursue their course according to the laws of refraction. In many media these portions follow the same course precisely, and perhaps are no way distinguishable from each other. In such media (comprehending most uncrystallized substances and liquids) the refraction is said to be single. In numerous others (for instance in most crystallized media) they follow different courses, and also retain different physical characters. In these the refraction is said to be double.

A fourth portion is scattered in all directions, one part being intromitted into the medium, and distributed over the hemisphere interior to it, while the other is in like manner scattered over the exterior hemisphere. These two portions are those which render visible the surfaces of bodies to eyes situated any how with respect to them, and are therefore of the utmost importance to vision.

Of those portions which enter the medium, a part more or less considerable is absorbed, stifled, or lost, without any further change of direction; and that not at once, but progressively, as they penetrate deeper and deeper into its substance. In perfectly opaque media, such as the metals, this absorption is total, and takes place within a space less than we can appreciate; yet even here we have good reasons for believing that it does not take place per saltum. In crystallized bodies, those at least which are coloured, this absorption takes place differently on the two portions into which the regularly refracted ray is divided, according to laws to be explained when we come to treat of the absorption of light.

The regularly refracted portions of a ray of white or solar light are (except in peculiar circumstances) separated into a multitude of rays of different colours, and otherwise differing in their physical properties, each of which rays pursues its course afterwards, independently of all the rest, according to the laws of regular refraction or dispersion. The laws of this separation, or dispersion, of the coloured rays, and their physical and sensible properties, form the subject of Chromatics.

All those portions which are either regularly reflected, or regularly refracted, undergo, more or less, a modification termed polarization, in virtue of which they present, on their encountering another medium, different phenomena of reflexion and refraction from those presented by unpolarized light. Generally speaking, polarized light obeys the same laws of reflexion and refraction as unpolarized, as to the directions which the several portions, into which it is divided on encountering a new medium, take; but differs from it in the relative intensities of those portions, which vary according to the situation in which the surface of the medium and certain imaginary lines, or axes within it, are presented to the polarized ray.

The rays of light under certain circumstances exercise a mutual influence on each other, increasing, diminishing, or modifying each other's effects according to peculiar laws. This mutual influence is called the interference of the rays of light. We shall proceed to treat of these several modifications in order; and first of the regular reflexion of light.
§ 3. Of the regular Reflexion of unpolarized Light from Plane Surfaces.

88. When a ray of light is incident on a smooth-polished surface, a portion of it is regularly reflected, and pursues its course after reflexion in a right line wholly exterior to the reflecting medium. The direction and intensity of this portion are the objects of inquiry in this section; the physical properties acquired by the ray in the act of reflexion being reserved for examination at a more advanced period. And first, with regard to the direction of the reflected ray. This is determined by the following laws:

Laws of Reflexion.

Law 1. When the reflecting surface is a plane. At the point on which the ray is incident raise a perpendicular. The reflected ray will lie in the same plane with this perpendicular, and with the incident ray. It will lie on the opposite side of the perpendicular, and will make an angle with it equal to that made by the incident ray.

90. The plane in which the perpendicular to any surface at the point of incidence, and the incident ray, both lie, is called the plane of incidence.

91. The angle included between the incident ray and the perpendicular is called the angle of incidence.

92. The plane in which the reflected ray and perpendicular both lie is called the plane of reflexion; and the angle included between the perpendicular and reflected ray is, in like manner, termed the angle of reflexion.

93. Adopting these definitions, the law of reflexion from a plane surface may be announced by saying, that the plane of reflexion is the same with that of incidence, and the angle of reflexion equal to that of incidence, but situated on the contrary side of the perpendicular.

Law 2. When the surface is a curved one, the course of a ray reflected from any point is the same as if it were reflected at the same point from a plane, a tangent to the curve surface at that point; i.e. if a perpendicular be raised to the curve surface at the point of incidence, the reflected ray will lie in the plane of incidence, and the angle of reflexion will equal that of incidence.

The demonstration of these laws is a matter of experiment. If we admit a small sunbeam through a hole in the shutter of a darkened chamber, and receive it on a polished surface of glass, or metal, we may easily with proper instruments measure the inclinations of the incident and reflected rays to the surface, which will be found equal. But this method is rude and coarse. A much more delicate verification of this law is afforded by astronomical observations. It is the practice of astronomers to observe the altitudes of the stars above the horizon by direct vision; and, at the same instant, the apparent depression below the horizon of their images reflected at the surface of Mercury, (which is necessarily exactly horizontal,) and the depression so observed is always found precisely equal to the altitude, whatever the latter may be, whether great or small. Now as these observations, when made with large instruments, are susceptible of almost mathematical accuracy, we may regard the law of reflexion, or plane surfaces, as the best established in nature.

Reflexion at a curved surface may be considered as taking place at that infinitely small portion of the surface which is common to it, and to its tangent plane at the point of incidence; so that if a perpendicular to the surface be erected at the point of incidence, the incident and reflected rays will make equal angles with it on opposite sides.

Proposition. To find the direction of a ray of light after reflexion at any number of plane surfaces, given in position.

Construction. Since the direction of the ray after reflexion is the same whether it be reflected at the given surfaces, or at surfaces parallel to them, conceive surfaces parallel to the given ones to pass through any point C, (fig. 9,) and from C draw the straight lines CP, CP', CP'', &c. respectively perpendicular to these respective surfaces, and lying wholly exterior to the reflecting media. Draw SC parallel to the ray when incident on the first surface, and in the plane SCP, and on the opposite side of CP, from the incident ray SC make the angle PSC = PCS, then will C represent the ray at the moment of its reflexion from the second surface, whose normal is CP'. Again, make the angle P'C'C'' in the plane S'CP'', but on the other side of CP', equal to the angle S'CP', then will C represent the ray at the moment of its reflexion from the second surface, and, producing SC to S', S''C will represent it at the moment of its incidence on the third surface, whose normal is CP''. Similarly in the plane S''C'P''; but on the other side of C'P'' make the angle P''C'C''' = P'CP S'', and C will be the direction of the ray at the moment of its quitting the third surface, and so on.

Analysis. About C as a centre conceive a spherical surface described, (fig. 10,) then will the planes PS intersect it in a great circle PSS', p, and the plane in which CP, CP lie, or the plane at right angles to the two first reflecting planes in another great circle P'P''p, and the planes S'C' and S'C'' in other great circles S'P'p' and S k'.

Since CP and CP' are given directions, the angle PCP', or the arc P' (which is equal to the inclination of the two first surfaces to each other) is given. Call this I. Again, since the direction SC of the incident ray is given, the angle of incidence, or the first surface PSC (a) and the angle SSP', or the inclination of the plane of the first reflexion to the plane P' perpendicular to both surfaces (b) are given. Hence in
the spherical triangle $PP'S'$ we have $PP' = I$; $PS' = 180° - a$; and the angle $PP'S'$ is $\gamma$; consequently $S'P$, and therefore $2S'P' = S'S''$ and the angle $S'S''$ are known, as also the angle $PP'S'$, and therefore its supplement $P'P''$, which is the angle made by the second reflexion with the plane $PP'$. Again, in the spherical triangle $SS''$ we have given $SS' = 180° - 2a$; $S'S'' = 2S'P'$ and the included angle $SS'P''$, whence the third side $S''$ may be found, which is the angle between the incident and twice reflected rays.

Similarly, if a third reflexion be supposed, we have given $P'S'' = 180° - S'P'; PP'' = I'$, and the angle $S''P'P' = S'P'P'' = PP''P' - PP'S'$, whence we may compute $S''P'$ and proceed as before, and so on to any extent.

Confining ourselves however to the case of two reflexions we have, by spherical trigonometry, putting $P'S' = \alpha'$ = the angle of incidence on the second reflecting surface, $P'S'P' = \theta$; $P'S'' = \phi$, and $180° - S' = D$, the deviation of the ray after the second reflexion, the following equations:

\[
\begin{align*}
- \cos \alpha' &= \cos \alpha \cdot \cos \theta - \sin \alpha \cdot \sin \theta \cdot \cos \psi \\
\sin \theta &= \frac{\sin \alpha}{\sin \alpha'} \cdot \sin \psi \\
\sin \phi &= \frac{\sin \alpha}{\sin \alpha'} \cdot \sin \psi \\
\cos \psi &= \cos 2\alpha - \cos 2\alpha' - \sin 2\alpha \cdot \sin 2\alpha' \cdot \cos \theta
\end{align*}
\]

(A)

From these equations, any three of the seven quantities $\alpha, \alpha', \theta, \phi, \psi, D$ being given, the other four may be found. It will be observed, that $\phi$ is the angle between the plane of the second reflexion and the principal section of the two reflecting planes, and $\theta$ the angle between the planes of the first and second reflexion. If $\phi$ and $D$ only be sought, $\theta$ must be regarded as merely an auxiliary angle; but this may not be the case, and cases may occur in which $\theta$ alone may be sought, or in which it enters as a given quantity, &c. In short, the foregoing equations contain in themselves all the conditions which can arise in any proposed case of two reflexions.

Corol. If $\psi = 0$, or if the incident ray coincide with the principal section $PP$, i.e. if the two reflexions both take place in the plane perpendicular to the reflecting surfaces, these formulæ take a very simple form, for we then have

\[
\theta = 0; \quad \phi = 180°; \quad \cos \alpha' = - \cos (\alpha + 1)
\]

that is $(\alpha + \alpha') = 180° - I$; and consequently \(\cos (2 \alpha + 2 \alpha') = \cos (360° - 2 I) = \cos 2I, or 2 \alpha + 2 \alpha' = 2I\). But since $\theta = 0$, we have by the last of the equations (A) $\cos D = \cos 2 \alpha + 2 \alpha';$ consequently $D = 2 \alpha + 2 \alpha' = 2I$. That is to say, the deviation in this case, after two reflexions, is equal to twice the inclination of the reflecting planes, whatever be the original direction of the ray. This elegant property is the foundation of the common sextant and of the reflecting circle, and is commonly regarded as having been first applied to the measurement of angles by Hadley, though Newton appears also to have proposed it for the same object. See the explanation of these instruments.

In other cases, however, $D$, the deviation, is essentially a function of the angles expressing the position of the incident ray, and can only be obtained from the equations above stated.

**Proposition.** Given the angles of incidence on the two planes, and the angle made by the plane of the first reflexion with that of the second; required the positions of the incident and twice reflected rays, the deviation of the ray after both reflexions, and the angle included between the reflecting surfaces.

Retaining the same notation, we have given, $\alpha, \alpha', \theta$, required $I, D,$ and $\varphi, \psi$.

1st, $D$ is given at once, by the last of the general equations, (A.)

2ndly, To find the rest, put $x = \sin I$; $y = \sin \psi$; and $\alpha = \sin \alpha'$, $\sin \psi$; put also $\cos a = c$; $\sin a = s$;

\[
\cos \alpha' = d; \quad \sin \alpha' = \varphi. \quad \text{We have then } xy = \alpha, \text{ or } y = \frac{\alpha}{x}; \quad \text{and the first of the equations (A) then gives }
\]

\[-d = c \sqrt{1 - x^2 - s \sqrt{x^2 - a^2}}
\]

which, cleared of radicals and reduced, gives

\[
o = x^4 + x^2 \{2d^2 (c^2 - s^2) - 2c^2 - 2s^2 a^2\} + (d^2 - c^2)^2 + 2a^2 s^2 (d^2 + c^2) + a^4 x^4
\]

and this equation, which, though biquadratic, is of a quadratic form, contains the general solution of the problem.

Corol. 1. If $\theta = 90°$, or if the planes of the first and second reflexions be at right angles to each other, we have simply $\varphi = \sin I, \sin \psi = \sin \alpha', \text{ and } \alpha = \sin \alpha' = \alpha'$. In this case our final equation becomes

\[
o = x^4 - 2x^2 (1 - c^2 d^2) + (1 - c^2 d^2)^2
\]

which, being a complete square, gives

\[x^4 = 1 - c^2 d^2.
\]

Now $x = \sin I$, therefore $x^4 = 1 - \cos I^4$, consequently we have the following simple result,

\[
\cos I (c = c) = \cos \alpha \cdot \cos \alpha'.
\]
Or the cosine of the inclination of the planes to each other is equal to the product of the cosines of the angles of incidence on each. And, vice versa, if this relation holds good, the planes of the two reflexions will necessarily be at right angles to each other; for, this relation being supposed, we have of course \( x^2 = 1 - c'c'' \), and therefore \( 1 - c'c'' \) being put for \( x^2 \) in the general equation, the whole must vanish; now this substitution gives a biquadratic of a quadratic form for determining \( a \), which must evidently be satisfied by taking

\[
a = \sin a', \quad \text{and consequently} \quad \theta = 90^\circ.
\]

This elegant property will be useful when we come to treat of the polarization of light.

105. Corol. 2. In the same case if \( \theta = 90^\circ \), the deviation \( D \) is given by the equation

\[
\cos D = \cos 2a \cdot \cos 2a',
\]

or, the cosine of the deviation is equal to the product of the cosines of the doubles of the angles of incidence.

106. Problem. A ray of light is reflected from each of two planes in such a manner that all the angles of incidence and reflexion are equal. Given the inclination of the planes, and the angles of incidence; required, first, the deviation; secondly, the inclination of the planes of the first and second reflexion to each other, and the angles made by each of these planes with the principal section of the reflecting planes.

Preserving the same notation we have \( a = a' \), and therefore by the third of the equations (A), \( = \), so that these equations become

\[
\begin{align*}
\cos a (1 + \cos I) &= \sin a \cdot \sin I \cdot \cos \psi, \\
\sin a \cdot \sin \theta &= \sin I \cdot \sin \phi, \\
\cos D &= (\cos 2a)^2 - (\sin 2a)^2 \cdot \cos \theta.
\end{align*}
\]

107. The first of these gives (putting for \( 1 + \cos I \) its value \( 2 (\cos \frac{I}{2})^2 \) and for \( \sin I \) its equal \( 2 \cdot \sin \frac{I}{2} \cdot \cos \frac{I}{2} \))

\[
\cos \psi = \cotan a \cdot \cotan \frac{I}{2},
\]

whence \( \psi \) is immediately known. Hence \( \psi \) is had by the equation

\[
\sin \theta = \frac{\sin I}{\sin a} \cdot \sin \psi.
\]

Lastly, if we subtract each member of the third of the equations (a) from 1, divide both sides by 2, and reduce, we transform it into the following

\[
\sin D = \sin 2a \cdot \cos \frac{\theta}{2}.
\]

These equations afford ready and direct means of computing \( \psi \), \( \theta \), and \( D \) in succession, from the known values of \( a \) and \( I \); the formulae are adapted to logarithmic evaluation, and are in themselves not inelegant.

§ IV. Of Reflexion from Curved Surfaces.

108. The reflexion of a ray from a curved surface is performed as if it took place at a reflecting plane, a tangent to the point of incidence. The reflected ray will therefore lie in the plane which contains the incident ray and the normal or perpendicular at the point of incidence. The general expressions for the course of the ray after reflexion at surfaces of double curvature being considerably complex, and not likely to be of great service to us in the sequel, we shall confine ourselves to the particular case of a surface of revolution (comprehending the cases of a plane, and conoidal surfaces of all kinds) where the plane of incidence is supposed to pass through the axis of revolution.

Proposition. A ray being incident on any surface of revolution in a plane passing through the axis, to find the direction of the reflected ray.

Q P (fig. 11) being a section of the surface by the plane of incidence, Q N the axis, Q P the incident, and P r the reflected ray, which produced if necessary cuts the axis in q. Draw the tangent PT, the ordinate PM, and the normal PN, which produce to O, and put as follows,

\[
x = Q M; \quad y = M P; \quad p = \frac{dy}{dx}; \quad \theta = \text{the angle } MQ P,
\]

or the angle made by the incident ray with the axis; then, since the angle of reflexion is equal to that of incidence, we have

\[
\frac{\theta}{2} = \frac{\theta}{2} = \text{the angle } O P Q,
\]

and therefore \( \frac{\theta}{2} = \frac{\theta}{2} = \text{the angle } O P Q; \) consequently \( Q T = T q \). Now, \( Q q = Q M - M q = Q M - P M \cdot \tan M P q \).
But by the theory of curves we have \( \tan PTM = \frac{dy}{dx} = p \), consequently \( PTM = \arctan p = \tan^{-1} p \), denoting by \( \tan^{-1} \) the inverse function of that expressed by \( \tan \); and since \( PQM = \theta \), this expression becomes

\[
Qq = x - y . \cotan \left\{ 2 . \tan^{-1} p - \theta \right\}
\]

\[
= x - y . \cotan \left\{ 2 . \tan^{-1} \left( \frac{dy}{dx} \right) - \tan^{-1} \left( \frac{y}{x} \right) \right\} \tag{a}
\]

(Because \( \tan \theta = \frac{PM}{QM} = \frac{y}{x} \))

This then is the general expression for the distance between the points in which the incident and reflected rays cut the axis.

Now, by Trigonometry, we have \( A \) and \( B \) being any two quantities

\[
\cotan \left\{ 2 \tan^{-1} A - \tan^{-1} B \right\} = \cotan \left\{ \tan^{-1} \frac{2A}{1-A^2} - \tan^{-1} B \right\}
\]

\[
= \cotan . \tan^{-1} \left( \frac{2A - (1-A^2)B}{(1-A^2) + 2AB} \right)
\]

that is, since \( \cotan . \tan^{-1} \theta = \frac{1}{\theta} \), the cotangent and tangent being reciprocals of each other, simply

\[
\frac{1 - A^2 + 2AB}{2A - (1-A^2)B}
\]

Applying this to the present case, \( A = \frac{dy}{dx} = p \); \( B = \frac{y}{x} \), and therefore the expression above found for \( Qq \) becomes

\[
Qq = x - y . \cotan \left\{ 2 . \tan^{-1} p - \theta \right\}
\]

\[
= x - y . \cotan \left\{ 2 . \tan^{-1} \left( \frac{dy}{dx} \right) - \tan^{-1} \left( \frac{y}{x} \right) \right\}
\]

\[
\left\{ \frac{1 - A^2 + 2AB}{2A - (1-A^2)B} \right\} \tag{b}
\]

These expressions contain the whole theory of the foci and aberrations of reflecting surfaces.

Corol. 1. To find the angle made by the reflected ray with the axis, which we will call \( \theta' \). This is the angle \( PQM \), which is the complement of \( MPq \). Now we have found above

\[ Mq = 90° - 2 \tan^{-1} p + \theta. \]

Hence

\[ \theta' = 2 . \tan^{-1} p - \theta \]

But \( \tan \theta = \frac{y}{x} \), so that substituting we have

\[
\tan \theta' = 2px - (1-p^2)y ; \tag{c}
\]

\[
\frac{(x + py)(px - y)}{2px - (1-p^2)y} \tag{d}
\]

Corol. 2.

\[ A = a + 2 \frac{(x + py)(px - y)}{2px - (1-p^2)y}. \tag{d} \]

In all the foregoing formulæ we have supposed the origin of the \( x \) placed at \( Q \) the radiant point. If we would place it elsewhere, as at \( A \), we have only to write \( x - a \) for \( x \) throughout. The formulæ then become on this hypothesis,

\[
\left\{ \begin{array}{l}
\tan \theta = \frac{y}{x - a} \\
\tan \theta' = \frac{2p(x - a) - (1-p^2)y}{(1-p^2)(x - a) + 2py}
\end{array} \right. \tag{e}
\]

\[
A = a ; \quad Q = \frac{2(x - a + py)(px - pa - y)}{2p(x - a) - (1-p^2)y} \tag{f}
\]

\[
A = a' = \frac{2(x + py)(px - y) + \left\{ (1-p^4)y - 2px \right\} a}{2px - (1-p^2)y - 2pa} \tag{g}
\]

General expressions for the distance of the focus from the radiant point \( Qq \).

110. Angle made by the reflected ray and the axis.
If the incident ray be parallel to the axis, we have only to suppose the point Q infinitely distant; or placing, as in the last article, the origin of the x at a point A at a finite distance, to make a (= A Q) infinite. The above expressions then give

\[
Q q = q^2
\]

when the incident rays are parallel to the axis.

\[
\tan \theta' = \frac{2p}{1 - p^2}
\]

\[
A q = x - y \cdot \frac{1 - p^2}{2p}
\]

\[
(i)
\]

**Proposition.** To represent the incident and reflected rays by their equations.

The equation of any straight line is necessarily of the form \(Y = aX + \beta\). Suppose we take A for the common origin of the coordinates, and, retaining the foregoing notation, representing by \(x\) and \(y\) the coordinates of the point \(P\) in the curve, let \(X\) and \(Y\) represent those of any point in the incident ray; and, \(Q\) being the point in which that ray cuts the axis, and \(A Q = a\), it is evident, first, that when \(X = a\), \(Y = 0\); and secondly, since the ray passes through \(P\), when \(X = x\), \(Y = y\). Hence we have

\[
a = \frac{y}{x - a} \quad \beta = -\frac{ay}{x - a}; \quad (1)
\]

therefore, the equation of the incident ray is

\[
Y = \frac{y}{x - a} (X - a); \quad (2)
\]

or, which is the same in a different form,

\[
Y - y = \frac{y}{x - a} (X - x); \quad (3)
\]

or, since

\[
\tan \theta = \frac{PM}{MQ} = \frac{y}{x - a},
\]

\[
Y = (X - a) \cdot \tan \theta; \quad (4)
\]

or, again,

\[
Y - y = (X - x) \cdot \tan \theta. \quad (5)
\]

Similarly for the reflected ray, it is obvious that if we represent its equation by \(Y = a'X + \beta'\), we shall have

\[
a' = \frac{y}{x - a'} \quad \beta' = -\frac{a'y}{x - a'}; \quad (6)
\]

and consequently

\[
Y = \left(\frac{y}{x - a'}\right) (X - a') = (X - a') \cdot \tan \theta'; \quad (7)
\]

\[
Y - y = \frac{y}{x - a'} (X - x) = (X - x) \cdot \tan \theta'; \quad (8)
\]

will be the corresponding forms of the equation of the reflected ray, in which \(a'\) and \(\tan \theta'\) are given in terms of \(x, y, a\), and \(p = \frac{dy}{dx}\) by the equations (g) and (h) or (i).

If the whole figure (fig. 11) be turned about the axis \(A M\), and \(Q\) be supposed a radiant point, the rays in the whole conical surface generated by the revolution of \(Q P\) will be concentred after reflection in one and the same point \(q\), which will thus become infinitely more illuminated than by any single ray from an elementary molecule of the surface. The point \(P\) will generate an annulus, having \(MP\) for its radius; and \(q\) is called the focus of this annulus, and the distance \(A q\) the focal distance of the same annulus. This last expression is commonly understood to mean the distance of \(q\) from the vertex, or point where the curve meets the axis, but we shall use it at present in the more general sense.

Generally speaking, then, the focus varies as the point \(P\) in the reflecting annulus varies, unless in that particular case where, by the nature of the curve, the function expressing \(a'\) is constant. Let us examine this case.

**Proposition.** To find the curve which will have the same focus for every point in its surface of revolution, or on which rays diverging from or converging to any point \(Q\), being incident, shall all after reflexion converge to or diverge from one point \(q\).

The value of \(Q q\) assigned in Art. 109, Eq. (b) being made constant, affords the equation

\[
\frac{(x + p y) (p x - y)}{2px - (1 - p^2)y} = \text{constant} = c.
\]
Light. This equation, cleared of fractions, and putting $x$ for $x - c$, (which is merely shifting the origin of the coordinates to the distance $c$ from their former origin) becomes:

$$p \{ x^a - y^a - c^a \} = (1 - p^a) xy. \quad (a)$$

To integrate this equation, assume a new variable $z$, such that $p y = x z$, and (multiplying the original equation by $y$) we have:

$$p y (x^a - y^a - c^a) = x y^a - x \cdot p^a y^a,$$

that is:

$$x z (x^a - y^a - c^a) = x y^a - x^a x^a,$$

whence we find:

$$y^a = \frac{z x^a - x c^a + z^a x^a}{1 + z} = x y^a - c^a \cdot \frac{z}{1 + z}.$$

Differentiating this equation we get:

$$2 y d y \left(= 2 p y d x = \frac{2}{x} z d x \text{ because } p = \frac{d y}{d x} \right) = d \left( x^a z - \frac{c^a z}{1 + z} \right) = 2 x z d x + x^a d z - c^a d \left( \frac{z}{1 + z} \right)$$

that is:

$$x^a d z - c^a d \cdot \frac{z}{1 + z} = 0,$$

or:

$$\left\{ x^a - \frac{c^a}{(1 + z)^a} \right\} d z = 0. \quad (b)$$

This equation may obviously be satisfied in two ways; the first is, by putting the factor:

$$x^a - \frac{c^a}{(1 + z)^a} = 0, \text{ or } x = \frac{c}{1 + z}$$

which gives (restoring the value of $z, z = \frac{p y}{x}$) merely $x + p y = c$; and, eliminating $p$ between this and the original equation $(a)$ we find, on reduction,

$$y^a + (x - c)^a = 0.$$

This is, however, (as is clear from the way in which it has been obtained,) only a singular solution of the differential equation, (see Differential Calculus, singular solutions;) and as the value of $y$ which results from it is always imaginary, it affords no curve satisfying the conditions of the problem.

The other way in which the equation $(b)$ can be satisfied, is by putting $d z = 0$, or $z = $ constant. Let The curve is in all cases a conic section.

This constant be represented by $- h$; then, since $z = \frac{p y}{x}$, we have:

$$\frac{p y}{x} = \frac{y d y}{x d x} = - h,$$

which, integrated, gives:

$$y^a = h (a^a - x^a),$$

$a$ being another constant. This is the general equation to the conic sections, and it is obvious, from the properties of these curves, that they satisfy the conditions; because two lines drawn from their foci to any point in their periphery make equal angles with the tangent at that point, and, consequently, a ray proceeding from, or converging to, one focus, and reflected at the curve, must necessarily take a direction to or from the other. But, the foregoing analysis being direct, shows that they possess this property in common with no other curves.

Thus in the case of the ellipse, all rays, (fig. 12,) $S P$, $S P'$, &c. diverging from the focus $S$ will after reflection converge to the other focus $H$, the interior surface of the ellipse being polished; and all rays $Q P$, $Q P'$, &c. converging to $S$, will after reflection diverge from $H$.

In the hyperbola, (fig. 13,) rays $Q P$, $Q' P'$, &c. converging to one focus $S$, and incident on the polished convex surface of the curve, will after reflection converge to the other focus $H$; and if diverging from $S$, and reflected on the polished concave surface $P P'$, will after reflection diverge from $H$.

In the case of the parabola, rays parallel to the axis, incident on the interior or concave surface, will all be reflected to the focus $S$, fig. 14; and if reflected at the exterior or convex surfaces, will all after reflection diverge from $S$.

Rays converging to, or diverging from, the centre of a sphere will all after reflection diverge from, or converge to, the same centre.

Let us now apply our general formula $(b)$ (Art. 109) to some particular cases.
Light.

Proposition. Let the reflecting surface be a plane, or the curve PC a straight line. Required the focus of reflected rays.

Here we have \( x = \text{constant} = a \) \( \frac{dy}{dx} = \frac{Q}{y} \), and the general formula becomes simply

\[
Qy = a' = \frac{2axy}{y} = 2x = 2a.
\]

So that the focus of reflected rays is a point on the opposite side of the reflecting plane equally distant from it with the radiant point; and as this is independent of \( y \), or of the situation of the point \( P \), we see that all the rays after reflection diverge from this point, see fig. 15.

123. Proposition. To find the focus of any annulus of a spherical reflector.

Let \( r \) be the radius of the sphere, and, if we fix the origin of the coordinates at the radiant point, the equation of the generating circle will be

\[
r^2 = (x - a)^2 + y^2
\]

This, differentiated, gives

\[
p = \frac{dy}{dx} = -\frac{x - a}{y}; \quad 1 - p^2 = \frac{2y^2 - r^2}{y^2}
\]

Hence, substituting in the general expression \((b)\), we find for the focal distance the following value,

\[
Qq = \frac{2a\{r^2 + a(x - a)\}}{r^2 + 2a(x - a)}; \quad (a)
\]

which expresses in all cases the distance of the focus of reflected rays from the radiant point.

For optical purposes, however, it is more convenient to know its distance from the centre, or from the surface.

The distance from the centre (Eq. fig. 16.) is

\[
= Qq - QE = \frac{2a(a - x + r)}{2a + r} = a,
\]

or

\[
EQ = \frac{ar}{2a + r}; \quad (b)
\]

in which positive values of \( EQ \) lie to the right of \( E \), or the same way with those of \( x \) or of \( Qq \).

Corol. 1 If we would find the focus of the infinitely small annulus immediately adjoining to the vertex \( C \), or \( C' \) of the reflecting spherical surface, or, as it is termed in Optics, the focus of central rays, we must put in the case of the vertex \( C \) (when the reflexion takes place on a concave surface) \( x = a + r \), and in the other case, viz. that where the rays are reflected on the convex surface \( C' \), \( x = a - r \). The former gives

\[
EQ = \frac{ra}{2a + r}; \quad Cq = \frac{r(a + r)}{2a + r}; \quad (c)
\]

the latter gives the same results, writing only \(- r\) for \( r \).

124. If we bisect the radii \( CE \) and \( C'E \) in \( F \) and \( F' \), and suppose \( q \) and \( q' \) to be the foci of central rays reflected at \( C \) and at \( C' \), we shall have

\[
Fq = \frac{1}{2} r - \frac{ra}{2a + r} = \left(\frac{r}{2}\right)^2, \quad (d)
\]

which gives the following useful analogy,

\[
QF : FE : : EF : Fq. \quad (e)
\]

Similarly we have \( QF' : F'E : : EF' : F'q \); so that the same analogy applies to both cases, and may be regarded as the fundamental proposition in the theory of the foci for central rays. For it is obvious, that if \( PC \) were any other curve than a circle, the same must hold good, taking only \( E \) the centre of curvature at the vertex.

Corol. 2. If \( a \) be infinite, or the incident rays be parallel, we have \( Fq = 0 \), which shows that the focus of central parallel rays bisects the radius. This focus, for distinction's sake, is called the principal focus of the reflector.

125. Principal focus.

126. Corol. 3. Regarding only central rays: the conjugate foci move in opposite directions, and coincide at the centre and surface of the reflector.

For let \( a \) vary from \( \infty \) to \(- \infty \), then \( Fq \) will vary as follows: first, while \( a \) varies from \( \infty \) to \(- \frac{r}{2} \), \( F, q \) is
Light. 359

Light. 359

128.

Conjugate foci move in opposite directions.

When Q comes to E, \( a = 0 \), \( Fq = \frac{r}{2} \), or \( q \) is at \( E \) also.

When \( Q \) comes to \( C \), \( a = -r \), \( Fq = -\frac{r}{2} \), or \( q \) is at \( C \) also.

It appears by the value of \( E \), Equation (b), that a spherical reflector \( ACB \), fig. 17, whose chord (or aperture, as it is termed in Optics) is \( AB \), causes the ray reflected at its exterior annulus \( A \) to converge to, or Longitudinative. diverge from, a point \( q \), different from the focus of central rays. Let \( f \) be this latter focus, then we shall have

\[
Ef = \frac{ar}{2a + r}, \quad Cf = \frac{(a + r)r}{2a + r}; \quad fq = \frac{a r^2}{2a(x-a) + r^3} - \frac{ar}{2a + r}.
\]

This quantity \( fq \) is called the longitudinal aberration of the spherical reflector. If the rays fall on the convex portion, we need only write \(-r\) for \( r \).

Proposition. To express approximately the longitudinal aberration of a spherical reflector whose aperture is inconsiderable with respect to its focal length.

129.

Longitudinal aberration for small apertures.

130.

another expression.

131. Lateral aberration.

To express the lateral aberration, or the quantity by which the reflected ray \( Aqg \) deviates from the axis, at the focus of central rays, or the value of \( fg \), (fig. 17,) we have

\[
fg = fq \cdot \frac{AM}{Mq}; \text{ but } AM = y, \text{ and } Mq = EM - EQ = x - a - \frac{ar^2}{2a(x-a) + r^3} = \frac{2a(x-a)^3 + r^3(x-2a)}{2a(x-a) + r^3}; \text{ so that}
\]

\[
fg = \frac{2a^2 r}{2a + r} y \times \frac{a - x + r}{r^3(x + 2a) + 2a(x-a)^3}.
\]

When the aperture is very small, this becomes simply

\[
fg = \frac{a^2 y^2}{r^3 \cdot (r + a)(r + 2a)}.
\]

When \( a \) is infinite, or the incident rays are parallel, we have the following,

\[
\begin{align*}
fq &= \text{longitudinal aberration} = \frac{y^2}{4r} \quad (j) \\
fg &= \text{lateral aberration} = \frac{y^2}{2r^2} \quad (j)
\end{align*}
\]

If the rays fall on the convex side of the sphere we must make \( r \) negative, which only changes the signs of the aberrations.
§ V. Of Caustics by Reflexion, or Catacaustics.

134. If rays of light be incident on a medium of any other form than that of a conic section, having the radiant point in the focus, they will after reflexion no longer converge to or diverge from any one point, but will be dispersed according to a law depending on the nature of the reflecting curve; the inclination of each reflected ray to the axis varying according to the point of the curve from which it is reflected, and not being the same for any two consecutive rays. Of course each ray will intersect that immediately consecutive to it in some point or other, and the locus of these points of continual intersection will trace out a curve to which the reflected rays by all necessarily be tangents, and which is called a caustic. If these rays fall on another reflecting curve, they will be again dispersed, and another caustic will originate in the continual intersections of the consecutive rays of the former, and so on to infinity.

Let $QP, Q'P'$, (fig. 18.) be any two contiguous rays incident on consecutive points $P, P'$ of a reflecting curve $PP'$, and after reflexion let them pursue the courses $PR, P'R'$; and since they are not necessarily parallel, let $Y$ be their point of intersection, then will $Y$ be the point in the caustic $YY''$ corresponding to the point $P$ in the reflecting curve; and if we determine the points $YY', &c.$ from the consecutive points $P'P'', &c.$ in the same manner, the locus of these, or the curve $YY''$ will be the whole caustic.

135. Let $QP, Q'P'$, (fig. 18,) be any two contiguous rays incident on consecutive points $P, P'$ of a reflecting curve $PP'$, and after reflexion let them pursue the courses $PR, P'R'$; and since they are not necessarily parallel, let $Y$ be their point of intersection, then will $Y$ be the point in the caustic $YY''$ corresponding to the point $P$ in the reflecting curve; and if we determine the points $YY', &c.$ from the consecutive points $P'P'', &c.$ in the same manner, the locus of these, or the curve $YY''$ will be the whole caustic.

136. Since the reflected ray passes through $P$, whose coordinates are $x,y$, its equation, as we have already seen (Art. 114), is necessarily of the form

$$Y - y = P (X - x)$$

If we regard $x, y, P$ as variable, this will represent any one of the reflected rays $PR$, and the consecutive ray $P'R'$ will be represented by

$$Y - (y + d y) = (P + d P) (X - (x + d x))$$

Now since the point $Y$ in which these two rays intersect is common to both, the coordinates $X$ and $Y$ at this point are the same for both; and therefore at this point both these equations coexist, and thereby determine the values of $X$ and $Y$, or the situation of the point $Y$. Now the latter of these equations is nothing more than the former plus its differential, on the supposition of $X$ and $Y$ remaining constant. Therefore, we have to find $X$ and $Y$ from the two equations,

$$Y - y = P (X - x)$$

$$- d y = (X - x) d P - P d x,$$

which gives at once

$$X = x + \frac{P - p}{d P} d x \begin{cases} \\
Y = y + P . \frac{P - p}{d P} d x \end{cases}$$

In these equations we have only to substitute for $P$ its value $= \tan \theta'$, or $= 2 p (x - a) - (1 - p^2) y$; and after executing all the differentiations indicated, or implied, to eliminate $x$ and $y$ by the equations of the curve and the other conditions to which the quantity $a$ may be subjected, an equation between $X$ and $Y$ will result which will be the equation of the caustic.

137. Proposition. To determine the caustic when rays diverge from one fixed point in the axis of a given reflecting curve.

In this case $a$ is invariable, and the differentiation of $P$ must be performed on this hypothesis. It will, therefore, simplify the question if we put $a = \alpha$; or suppose the origin of the coordinates in the radiant point, in which case

$$P = \frac{2 p x - (1 - p^2) y}{2 p y + (1 - p^2) x}$$

$$\frac{d P}{d x} = (1 + p^2). \frac{(1 + p^2) (y - p x) + 2 q (x^2 + y^2)}{2 p y + (1 - p^2) x}$$

Where

$$q = \frac{d P}{d x}$$

$$P - p = \frac{(1 + p^2) (p x - y)}{2 p y + (1 - p^2) x}$$

$$\{2 p y + (1 - p^2) x\}^2$$
which substituted, we find

\[
X = 2 \cdot \frac{p (p x - y)^2 - q x (x^2 + y^2)}{(1 + p^2) (p x - y) - 2 q (x^2 + y^2)} \]

\[
Y = 2 \cdot \frac{(p x - y)^2 + q y (x^2 + y^2)}{-(1 + p^2) (p x - y) + 2 q (x^2 + y^2)} \]

Corol. 1. If the incident rays be parallel, or the radiant point at an infinite distance, we may fix the origin of the coordinates where we please; and since in this case the equation of any reflected ray is, by 113 equation Caustic for (i) and 114 equation (9),

\[
Y = \frac{p (p + y) + q (r + y)}{2 q (1 + p^2)} \]

we have

\[
P = \frac{2 p}{1 - p^2} ; \quad P - p = \frac{p (1 + p^2)}{1 - p^2} ; \quad \frac{d x}{d P} = \frac{(1 - p^2)^2}{2 q (1 + p^2)} \]

putting \( q \) for \( \frac{d p}{d x} \) or \( \frac{d^2 y}{d x^2} \).

These substitutions made, we get the following values for the coordinates of the caustic,

\[
X = x + \frac{p}{2 q} (1 - p^2) ; \quad Y = y + \frac{p^2}{q} \]

Corol. 2. In the general case, if we put \( f = \) the line \( P y \), or the distance between the point in the curve and the corresponding point in the caustic we have

\[
f = \sqrt{(X - x)^2 + (Y - y)^2} \]

Which, if we write for \( X - x \) and \( Y - y \), their values above found become

\[
f = \sqrt{1 + P^2} \cdot \frac{P - p}{d P} \cdot d x \]

or, writing for \( P \) its value, and executing the operations,

\[
f = \frac{1}{(y - px) (1 + p^2)} \sqrt{x^2 + y^2} + 2 q (x^2 + y^2) \cdot \sqrt{1 + P^2} \]

Corol. 3. In the case of parallel rays, when

\[
P = \frac{2 p}{1 - p^2} ; \quad \frac{d P}{d x} = \frac{2 q (1 + p^2)}{(1 - p^2)^2} - \frac{p (1 + p^2)}{1 - p^2} \]

we have

\[
f = \frac{p (1 + p^2)}{2 q} \]

Corol. 4. Call \( c \) the chord of the circle of curvature passing through the origin of the coordinates, or through the radiant point; then, by the theory of curves,

\[
c = \frac{2 (p x - y) (1 + p^2)}{q \sqrt{x^2 + y^2}} \]

so that

\[
q (x^2 + y^2) = \frac{2 (p x - y) (1 + p^2) \sqrt{x^2 + y^2}}{c} \]

and substituting this for \( q (x^2 + y^2) \), in the general expression for \( f \), we eliminate \( q \), and get

\[
f = \frac{c \sqrt{x^2 + y^2}}{4 \sqrt{x^2 + y^2} - c} = \frac{r c}{4 r - c} \]

putting

\[r = \sqrt{x^2 + y^2}.\]

Hence we have

\[
f - \frac{1}{4} c = \frac{(\frac{1}{4} c)^2}{r - \frac{1}{4} c} \]

which gives

\[
r - \frac{1}{4} c : \frac{1}{4} c : : \frac{1}{4} c : f - \frac{1}{4} c. \]

Hence the following general property. (Smith's Optics, ed. 1738, p. 160.)

Q and q being two conjugate foci of an elementary pencil of rays reflected at any curve surface at P, fig. 19. Fig. 19.

Let VPW be the circle of curvature; (if the curve be a circle, this will be the curve itself.) Let the chords vol. iv.
Light.

P V, P W in the direction of the incident and reflected rays be divided in F, f, so that PF and Pf shall each be one quarter of the whole chords, and the relation between Q and q will be expressed by the proportion

\[ \frac{QF}{FP} : \frac{PF}{f} = \frac{f}{q}. \]

General relation between conjugate points or foci of reflected rays. incident on any curve.

Corol. 5. Putting

\[ \frac{P - p}{dP} \quad \frac{dx}{M} = \frac{dX}{dP}; \]

\[ \frac{dY}{dx} = \frac{p + P \frac{dM}{dx} + M \frac{dP}{dx}}{P} \left(1 + \frac{dM}{dx}\right) \]

Hence it follows that

\[ P = \frac{dY}{dx}; \]

P therefore is to the caustic, for the coordinates X, Y, what p is to the reflecting curve for the corresponding point whose coordinates are x, y.

Corol. 6. If we put S for the length of the caustic

\[ = \text{the arc } A H K Y, \text{ we have } dS = \sqrt{dx^2 + dy^2} \]

or

\[ dS = dx \cdot \sqrt{1 + p^2} = (dx + dM) \sqrt{1 + p^2} \]

because

\[ df = dM \cdot \sqrt{1 + p^2} + M \frac{dp}{\sqrt{1 + p^2}}; \]

but

\[ M \frac{dp}{dx} = (P - p) \frac{dx}{dx} \]

so that we have

\[ dS = df + dx \left\{ \sqrt{1 + p^2} - \frac{(P - p)P}{\sqrt{1 + p^2}} \right\} \]

that is, substituting for P its value

\[ \frac{2px - (1 - p^2)y}{2py + (1 - p^2)x} \]

and integrating

\[ S = \text{constant} + f + \sqrt{x^2 + y^2}. \]

Hence it follows, that the caustic is always a rectifiable curve, and its

Length A K y = Q P + Py + constant

But

Arc A K F = Q C + CF + constant

consequently, subtracting

Arc F y = (Q C + CF) - (Q P + PY).

Hence it appears, that the caustic is necessarily a rectifiable curve when the reflecting curve is not itself transcendental.

If the rays P R, P R', P' R'', &c. after reflexion at the curve P P' P'' fall on another reflector R R' R'' and are reflected in the directions R S, R' S', R'' S'', &c. (fig. 20) their continual intersections will form another caustic Z Z' Z'', and so on ad infinitum, which may be determined by a similar analysis. In like manner, whatever be the law according to which the rays Q P, Q' P', &c. are dispersed, we may conceive each to be a tangent to a curve which may be regarded as the caustic of another reflecting curve, and so on. Let V V' V'' be this curve. Since P V Q is a tangent to it, if this curve and the curve P P' P'' be given, the point Q in the axis from which the incident ray Q P may be regarded as radiating, is determined in terms of the coordinates of P, and therefore the quantity a may be eliminated altogether. The manner of doing this is shown in the following

Proposition. To determine the relations between any two consecutive, or, as they may be termed, conjugate caustics V V' V'', Y Y' Y'', and the intermediate reflecting curve P P' P''.

Let V and Y be, as before, any two conjugate points in the caustics, P the reflecting point; then if we put

\[ \xi \quad \eta \quad f \quad g \]

for the coordinates of V

\[ x \quad y \quad f \quad g \]

of P

\[ X \quad Y \quad f \quad g \]

of Y
Since the line $PVQ$ is a tangent to the first curve at $V$, we must evidently have

$$y - \eta = \frac{d \eta}{d \xi} (x - \xi)$$

and this, combined with the equation between $\eta$ and $\xi$, which represents the curve $V'V''$ suffices to determine $\eta$ and $\xi$ in terms of $x, y$, or vice versa, $x$ and $y$ in terms of $\xi$ and $\eta$.

Again, we have also by Art. 114, equation (2)

$$y - \eta = \frac{y}{x - a} (x - \xi)$$

and consequently

$$x - a = y \cdot \frac{x - \xi}{y - \eta}; \quad a = \frac{\xi y - \eta x}{y - \eta}.$$

Thus $a$ is given in terms either of $x, y$, or of $\eta, \xi$, whichever we may prefer. It only remains to substitute this in the value of $P$.

$$P = \frac{2p(x - a) - (1 - p')y}{(1 - p')(x - a) + 2py}$$

which thus becomes

$$P = \frac{2p(x - \xi) - (1 - p')y}{(1 - p')(x - \xi) + 2p(y - \eta)}.$$

and this, being free of $a$, may be substituted in the equations (k) Art. 136, when $X$ and $Y$ will be at once obtained in terms of $x, y, \xi, \eta$, the coordinates of the reflecting curve and the preceding caustic.

We shall now proceed to illustrate the theory above delivered by an example or two. Required the caustic when the reflecting curve is a cycloid, and the incident rays are parallel to each other and to the axis of the cycloid.

The equation of the cycloid is

$$\frac{dy}{dx} = p = \frac{\sqrt{x}}{\sqrt{2 - x}}$$

taking unity for the radius of the generating circle.

From this we get

$$\frac{1}{q} (2 - x) \sqrt{2x - x^4}$$

and therefore

$$\frac{P}{q} = 2x - x^3;$$

consequently, by the equations (k) of Art. 136, we shall have

$$X = x + \frac{1 - p^2}{2} \cdot \frac{P}{q} = 2x - x^3$$

$$Y = y + \frac{P}{q} = y + x \sqrt{2x - x^4}$$

whence

$$\frac{dY}{dx} = p + \frac{\sqrt{x}}{\sqrt{2 - x}} (3 - 2x) = 2\sqrt{2} \sqrt{x - x^4} = 2 \sqrt{X}$$

Now we have also

$$\frac{dX}{dx} = 2(1 - x)$$

But since

$$X = 2x - x^3, \text{ we have } 1 - x = \sqrt{1 - X}, \text{ and therefore }$$

$$\frac{dX}{dx} = 2 \sqrt{1 - X}$$

So that we have, finally,

$$\frac{dY}{dX} = \sqrt{\frac{X}{1 - X}}$$

which shows that the caustic is itself a cycloid of half the linear dimensions of the reflecting curve.

To take one other example, let us suppose the reflecting curve a circle, and the radiant point infinitely distant. Here we have (placing the origin of the coordinates in the centre)
Light.

\[ x^2 + y^2 = r^2; \quad p = -\frac{x}{\sqrt{r^2 - x^2}}; \quad q = -\frac{r^2}{(r^2 - x^2)^{\frac{3}{2}}} \]

Caustic of a consequently, by the equations \((k)\) of Art. 136

\[
\begin{align*}
X &= x + \frac{p}{2q} \left(1 - p^2\right) = \frac{3r^2 - 2x^2}{2r^2} x \\
Y &= y + \frac{p^2}{q} = \frac{(r^2 - x^2)^{\frac{3}{2}}}{r^2} = \frac{y^2}{r^2}
\end{align*}
\]

Then since (supposing, for brevity, \(r = 1\), which will not affect the result)

\[
4X^2 = 9x^2 - 12x^2 + 4x^2
\]

\[
4Y^2 = 4 - 12x^2 + 12x^2 = 4
\]

Adding,

\[ 4(X^2 + Y^2) = 4 - 3x^2; \quad x^2 = \frac{4}{3} (1 - X^2 - Y^2) \]

So that we get, finally, substituting this value of \(x^2\) in that of \(Y\), and reducing,

\[ (4X^2 + 4Y^2 - 1)^2 = 27Y^4; \quad (v) \]

which is the equation of the caustic.

This equation belongs to an epicycloid generated by the revolution of a circle whose radius is \(\frac{1}{2}\) that of the reflecting circle on another concentric with the latter, and whose radius is \(\frac{1}{3}\) that of the reflecting circle.

Fig. 21 represents the caustic in this case; \(Q\) \(P\) being the incident ray, and \(P\) \(Y\) the reflected. It has a cusp at \(F\), which is the principal focus of rays reflected at the concave surface \(B\) \(C\) \(D\), and another at \(F'\), which is that of the rays reflected from the convex surface \(B\) \(A\) \(D\). In the latter case, it is not the rays themselves, but their prolongations backwards which touch the caustic.

**Corol.** When \(y\) is very small, or immediately adjacent to the cusp \(F\), the form of the caustic approaches indefinitely to that of a semicubical parabola. For, generally,

\[ X = \frac{1}{2} \sqrt{1 + 3Y^2} - 4Y^2, \]

and when \(Y\) is very small, neglecting \(Y^4\) in comparison with \(Y^4\)

\[ X = \frac{1}{2} + \frac{3}{4} Y^4, \quad \text{or} \quad Y^4 = \left(\frac{4}{3}\right)^2 \left(X - \frac{1}{2}\right)^2; \quad (w) \]

It is, as we have seen, only in certain very particular cases, when rays proceeding from one point and reflected at a curve proceed after reflexion all to or from one point. In general they are distributed in the manner described in Art. 145, 146, being all tangents to the caustic. The density of the rays therefore in any point of the caustic is infinitely greater than in the space surrounding it, and in the space between the caustic and the reflecting curve \((P\) \(C\) \(F\) \(Y\), fig. 18) is greater than in the space without the caustic \(Q\) \(Y\) \(F\). This is obvious, for in the latter space only the incident rays occur, while in the former are included all the reflected rays as well as the incident ones.

This may be easily shown experimentally, in a very satisfactory manner pointed out by Dr. Brewster, by bending a narrow strip of polished steel into any concave form, as in fig. 22, and placing it upright on a sheet of white paper. If in this state it be exposed to the rays of the sun, holding the plane of the paper so as to pass nearly but not quite through the sun, the caustic will be seen traced on the paper, and marked by a very bright well-defined line; the part within being brighter than that without, and the light graduating away from the caustic inwards by rapid gradations. If the form of the spring be varied, all the varieties of catacaustics, with their singular points, cusps, contrary flexures, &c. will be seen beautifully developed. The experiment is at once amusing and instructive.

The bright line seen on the surface of a drinking-glass full of milk, or, better still, of ink, standing in sunshine, is a familiar instance of the caustic of a circle just investigated.

If the figure 18 be turned round its axis, the reflecting curve will generate a surface of revolution, which, if supposed polished within or without, as the case may be, will become a mirror. The caustic will also generate a conoidal surface, to which all the rays reflected by the mirror will be tangents. No mirror, therefore, which is not formed by the revolution of a conic section having the radiant point in its focus, can converge all the reflected rays to one point or focus. There will, however, always be one point which receives the reflected rays in a more dense state than any other. This point is the cusp \(F\), as we shall presently see. The deviation of any reflected ray from this point is what is termed its aberration.

The concentration and dispersion of rays by reflecting and refracting surfaces forming the great business of practical optics, it will be necessary to enter at large into this subject; and, first, it will be proper to inquire how far any given reflector will enable us to concentrate the rays which fall on it. To this end let the following problem be proposed.

**Proposition.** A reflector of any figure, of a given diameter or aperture \(A\) \(B\), being proposed, to find the circle of least aberration, or the place where a screen must be placed to receive all the rays reflected from the surface, within the least possible circular space (since they cannot be all collected in one point) and the diameter of this circle.
A C B (fig. 23) being the mirror, Q the radiant point, G K f k g the caustic, f the cusp or focus for central rays, q the focus of the extreme rays A q, B q, produce these lines till they cut the caustic in Y y. It is clear, then, since all the rays reflected from the portion A C B of the reflector are tangents to points of the caustic between K, f and k, f, that they must all pass through the line Y y. Retaining the notation of the foregoing propositions, (i.e. supposing Q s = X; X y = Y.) Let us put Q L = X, L K = Y, Q D = Z; D A = y; and let \( \hat{P}, \hat{p} \) represent the values of P and p corresponding to the points K and A of the caustic and reflecting curves. The equation of the line A K Q y will then be

\[
Y - y = \hat{P} (X - \hat{x}); \quad (x)
\]

Y and X being the coordinates of any point in it. But at the point y, where it cuts the other branch of the caustic, these coordinates are common to the straight line, and to the caustic. At this point, therefore, the above equation, and those expressing the nature of the caustic, must subsist together. Now these are the equations (k) Art. 136, combined with the original equation of the reflecting curve. Eliminating, then, x and y, by the aid of two of them, and determining the values of X, Y from the rest, the problem is resolved.

Now the same equation which gives the value of y, or x y, must also give that of L K, because K is a point in both caustic and the line A K y, as well as y. But, moreover, since A K y is a tangent, the point K is a double point; therefore the final equation in Y must necessarily have two equal roots, besides the value of Y sought; and these being known, the other may be found from a depressed equation.

The method here followed is, apparently, different from that usually employed, which consists in making the value of y as determined by the intersection of the extreme reflected ray A K y, and any other reflected ray (from P) a maximum. But the difference is only apparent, for in the latter method we have to make Y as determined by the two equations (holding jointly)

\[
Y - y = \hat{P} (X - \hat{x}), \quad \text{and} \quad Y - y = P (X - x)
\]

a maximum, or d Y = 0. Now in this case the former equation gives d X = 0 also; and therefore, differentiating the latter, we have

\[
d y = (X - x) d P - P d x,
\]

whence

\[
X - x = \frac{P - p}{d P} d x
\]

and therefore

\[
Y - y = P - \frac{p}{d P} d x.
\]

Now these are nothing more than the equations of Art. 136, expressing the general properties of the caustic; so that this consideration of the maximum only leads by a more circuitous route to the same equations as the method above stated, and is in fact nothing more than a different mode of expressing the caustic.

Let us apply this reasoning to the case when the reflector is spherical. Resuming the equations and notation of Art. 148, and putting a for the extreme value of y, or the semi-aperture of the mirror, and b for the corresponding value of x, that of P will be

\[
\left( \frac{2 p}{1 - p^2} = \right) = \frac{2 a b}{b^2 - a^2} = \frac{2 a b}{1 - 2 a^2}.
\]

Hence the equation (m, 2) Art. 138, of the extreme reflected ray becomes

\[
Y = a = \frac{2 a b}{1 - 2 a^2} (X - b)
\]

whence we get

\[
2 X = \frac{1}{b} \left( 1 + \frac{1 - 2 a^2}{a}. Y \right)
\]

Assume \( z \), so that Y = a \( z^3 \), \( z \) being another unknown quantity, then we have

\[
4 X^3 = \frac{1}{1 - a^2} \left\{ 1 + \left( 1 - 2 a^2 \right) a^3 z^3 \right\}.
\]

Substituting this for \( 4 X^3 \), and for \( Y^3 \) its value \( a^2 z^3 \) in the equation of the caustic (c) Art. 148, extracting the cube root, and reducing, we get the following equation for finding \( z \),

\[
a^2 z^3 + \left( 2 - 4 a^2 \right) z^3 + \left( 3 a^2 - 3 \right) z^3 + 1 = 0.
\]

Now this, according to the remark in Art. 155, must have two equal roots, viz. when \( z = b \), or \( Y = a^3 \), that is, when \( z = 1 \). Hence this equation must necessarily be divisible by \( (z - 1)^4 \). Performing the division we find it is so, and the quotient gives

\[
a^2 z^4 + 2 a^4 z^3 + 3 a^4 z^2 + 2 z + 1 = 0; \quad (y)
\]

for determining the remaining values of \( z \).
Light

As this investigation is rigorous, nothing having been omitted or neglected as small, we have here the Part I.

Case when the aperture is moderate.

\[ x = -\frac{1}{2} - \frac{9}{32} a^4 - \frac{1395}{4096} a^6 - \text{&c.} \]

and of course since \[ Y = a^2 x^3, \]

\[ Y = -\frac{a^2}{8} - \frac{27}{128} a^4 - \frac{675}{2048} a^6 - \text{&c.} \]

The first term of this series is sufficient for most cases which occur in practice, and gives

or, supposing \( r \) the radius of curvature of the reflector,

\[ Y = -\frac{a^2}{8r^2} \]

The lateral aberration corresponding to the semi-aperture \( a \) is, by the equation (\( f \)), Art. 133, equal to \( \frac{a^2}{2r^2} \); consequently, in the case of small apertures, the radius of the least circle of aberration is equal to \( \frac{1}{2} \) of the lateral aberration (at the focus) of the exterior annulus.

Corol. The least circle of aberration is nearer the mirror than its principal focus, by \( \frac{3}{4} f g \) or \( \frac{3}{4} \), the longitudinal aberration = \( \frac{3}{16} \cdot \frac{a^2}{r} \).

To complete the theory of caustics, it only remains to examine the degree of concentration of the reflected rays at any assigned point. To this end, let \( S \) (Fig. 24) be any point, and through it let \( \text{P} \text{S} \text{Y} \text{q} \) be drawn touching the caustic in \( Y \). Then \( S \) may be regarded as lying in a conical surface generated by the revolution of the tangent \( \text{P} \text{Y} \text{s} \text{q} \) about the axis; and all the rays in the annulus, generated by the revolution of the element \( \text{P} \text{P}' \), will be contained in the hollow conoidals solid formed by the revolution of the figure \( \text{P} \text{P}' \text{Y} \text{q} \) about the same axis. Hence at \( S \) the rays will be concentrated: first, in a plane parallel to that of the paper, in the ratio of \( \text{P} \text{P}' \) to \( \text{S} \text{S}' \), or \( \text{P} \text{Y} \) to \( \text{S} \text{Y} \); and, secondly, in a plane perpendicular to that of the paper, in the ratio of the circumferences of the circles generated by the revolution of \( \text{P} \) and of \( S \), that is, in the ratio of these radii \( \text{P} \text{M} : \text{S} \text{T} \). On both accounts, therefore, the concentration at \( S \) will be represented by \( \frac{\text{P} \text{M}}{\text{S} \text{T}} \times \frac{\text{P} \text{Y}}{\text{S} \text{Y}} \), or \( \frac{\text{P} \text{q}}{\text{S} \text{q}} \times \frac{\text{P} \text{Y}}{\text{S} \text{Y}} \). If, therefore, we represent by 1 the density of the rays immediately on their reflexion at \( P \), their density at \( S \) corresponding, will be represented by \( \frac{\text{P} \text{Y} \cdot \text{P} \text{q}}{\text{S} \text{Y} \cdot \text{S} \text{q}} \), and this is true, whatever be the situation of \( S \).

1st case. KH V, N D W. no such tangent can be drawn to cut the reflector within its aperture \( \text{A} \text{B} \); therefore these spaces receive no rays at all, and the density = 0 in every point.

2nd case. Secondly, when \( S \) is situated anywhere within the spaces \( \text{A} \text{G} \text{B}, \text{V} \text{H} \text{F} \text{E}, \text{E} \text{F} \text{D} \text{W} \), only one such tangent can be drawn to cut the reflecting curve between \( \text{A} \) and \( \text{B} \). So that in these spaces the density is simply represented by

\[ D = \frac{\text{P} \text{Y} \cdot \text{P} \text{q}}{\text{S} \text{Y} \cdot \text{S} \text{q}} \]

3rd case. Thirdly, within the spaces \( \text{K} \text{G} \text{H} \) and \( \text{M} \text{G} \text{D} \), two tangents can be drawn from any point \( S \), both touching the branch \( \text{F} \text{k} \) on the same side of the axis as the point \( S \). If we suppose \( \text{P} \text{Y} \cdot \text{S} \text{q} \) and \( \text{P} \text{Y} \cdot \text{S} \text{q} \) to be these tangents, \( S \) will receive rays belonging to both these converging conoids, and the density will therefore be the sum of these belonging to either, or

\[ D = \frac{\text{P} \text{Y} \cdot \text{P} \text{q}}{\text{S} \text{Y} \cdot \text{S} \text{q}} + \frac{\text{P} \text{Y} \cdot \text{P} \text{q}}{\text{S} \text{Y} \cdot \text{S} \text{q}} \]

See fig. 25.

4th case. Fourthly and lastly, within the space \( \text{F} \text{H} \text{G} \text{D} \) there may be drawn three tangents \( \text{q} \text{S} \text{Y} \text{P} \text{r} \), \( \text{q} \text{s} \text{Y} \text{P} \text{r} \), \( \text{q} \text{S} \text{Y} \text{P} \text{r} \), all falling within \( \text{A} \text{B} \), the two first (fig. 26) touching the branch \( \text{F} \text{k} \) on the same side as \( S \), the
of the opposite side. The former belong to cones of rays converging to $q_1 q_2$, the latter to a cone converging to $q_2$, but intercepted by $S$ after meeting at $q$, and again diverging. Hence, in this case, the density will be expressed by

$$D = \frac{P_Y - P_q}{S Y_1 - S q_1} + \frac{P_Y - P_q}{S Y_2 - S q_2} + \frac{P_Y - P q_2}{S Y_3 - S q_3}.$$  

It would lead into too great complication to attempt developing the actual value of these fractions in terms of the coordinates of $S$, and we will therefore merely apply them to some remarkable positions of $S$.

Case 1. $S$ in the axis, beyond the principal focus, or between the mirror and its focus for extreme rays $G$. Here $Y$ coincides with $F$, and $q$ also does the same therefore in this case, $D = \frac{P F}{S}$, which shows that the density is inversely as the square of the distance of $S$ from the principal focus.

Case 2. $S$ in the axis between the principal focus and the focus for extreme rays $G$, (i.e. in the line $GF$). Here $S q_1 = 0$, $S Y = 0$, $S q_2 = 0$; so that here all the three several component portions of $D$ are infinite, and of course the density is infinitely greater than on the surface of the reflector.

Case 3. $S$ at $F$. Here not only $S q = 0$, but also $S Y$; therefore at $F$ the density is infinitely greater than in the last case, and is the greatest which exists anywhere.

Case 4. $S$ anywhere in the caustic. Here $S Y = 0$, therefore in this case also $D$ is infinite, or the density infinitely greater than at the surface of the reflector; and as $S$ approaches $F$, this is still further multiplied by the diminution of all the values of $S q$.

Case 5. $S$ anywhere in $HD$, the circle of least aberration. At the centre $z$ and the circumference $H$ the density is infinite. Between these two positions, finite, diminishing to a minimum, and again increasing according to a law too complicated to be here investigated. It will be observed, that the relations expressed in these articles (160—169) are general, and not restricted to the case where the reflecting surface is spherical.

In all the foregoing reasoning the point $S$ is supposed to receive the rays perpendicularly. The density of the rays therefore here intended must be understood to mean, The number of rays not incident on a given particular planesurface, but passing through a given infinitely small spherical portion of space, or received upon an infinitely small spherical body at $S$.

In cases, however, where the aperture is small, a screen perpendicular to the axis will receive the rays from every point very nearly at a perpendicular incidence; and hence the above expressions will in this case represent the intensity of illumination of the several points in such a surface, the screen being, however, supposed to stop none of the incident light.

§ VI. Of the Refraction of Homogeneous Light at Plane Surfaces.

When a ray of light is incident on the surface of any transparent uncrystallized medium, a portion of it is reflected; another portion is dispersed in all directions, and serves to render the surface visible; and the remainder enters the medium and pursues its course within it.

In the reflexion of light, the law of reflexion, as far as regards the direction of the reflected ray, is the same for all reflecting media; the angle of reflexion being equal to that of incidence for all. In refraction, however, the case is otherwise, and each different medium has its own peculiar law of action on light; some turning a ray incident at a given angle more out of its course than others. Whatever be the nature of the refracting medium, the following general laws are found to hold good, and suffice (when the medium is known) to determine the direction of the refracted ray.

1st. The incident ray, the perpendicular to the surface at the point of incidence, and the refracted ray, all lie in the same plane.

2nd. The incident and refracted rays lie on opposite sides of the perpendicular.

3rd. Whatever be the inclination of the incident ray to the refracting surface, the sine of the angle included between the incident ray and the perpendicular is to the sine of that included between the refracted ray and the perpendicular in a constant ratio.

These laws equally hold good for plane and for curved surfaces, and are found to be verified with perfect precision by the most delicate experiments, and all the phenomena of refracted light to take place in exact conformity with the results deduced from them by mathematical reasoning.
Let A C B (fig. 23) be the refracting surface, P C p the perpendicular to it at the point of incidence C, S C the incident, and C s the refracted ray. Then we shall have

$$\sin P C S : \sin p C s = \mu : 1,$$

\(\mu\) being a constant quantity; that is, constant for the same medium A B, though its value is different for different media.

178. It is usual, for brevity, to speak of the sine of incidence, and the sine of refraction, instead of the sines of the angle of incidence, and the angle of refraction.

179. The numerical value of the quantity \(\mu\), or of \(\frac{\sin \text{ of incidence}}{\sin \text{ of refraction}}\) in any medium, must be ascertained before the law of refraction in that medium can be regarded as perfectly known. This may be done experimentally by actually measuring the angle of refraction corresponding to any one given angle of incidence, for the value of the above fraction being thus determined for one incidence holds equally for every other, or by other more easy or more refined modes to be described hereafter. This quantity \(\mu\) is called the index of refraction of the medium A B.

180. The medium in which the ray proceeds previous to its incidence on A B is here regarded as a vacuum. If the medium A B be also a vacuum, it is clear that the ray will not change its course; so that the angle of incidence will equal that of refraction, and the value of \(\mu\) will be equal to 1. This is the lowest value of \(\mu\), as no medium has yet been discovered which refracts rays from the perpendicular when incident from a vacuum. The greatest value of \(\mu\) yet known is 3, when the refraction is made into chromate of lead; and between these limits almost every intermediate gradation has been found to belong to some one or other transparent body. Thus for air at its ordinary density \(\mu = 1.00028\), while for water it is 1.336, for ordinary crown glass 1.535, for flint glass 1.60, for oil of cassia 1.641, for diamond 2.487, and for the greatest refraction of chromate of lead 3.0.

181. It is a general law in Optics, that the visibility of two points from one another is mutual, whatever be the course pursued by the rays which proceed from one to the other. In other words, that if a ray of light proceeding from A arrives by any course at B, however often reflected, refracted, &c., a ray can also arrive at A from B by retracing precisely the same course in a contrary direction. It follows from this, that if the ray S C incident on the exterior surface of a medium A B, (fig. 23,) pursue after refraction the course C s, then will a ray s C, incident on the exterior surface of the medium, be refracted out of it in the direction C S, being bent from the perpendicular. Consequently, since in this case the angle of incidence is the same with the angle of refraction in the former case, and vice versa, we shall have here

$$\frac{\sin \text{ incidence}}{\sin \text{ refraction}} = \frac{1}{\mu}.$$
When the ray is incident on the exterior surface of the medium, a portion is reflected (R) and the remainder (r) refracted. The ratio of R to r is smallest at a perpendicular incidence, and increases regularly till the incidence becomes 90°; but even at extreme obliquities, and when the incident ray just grazes the surface, the reflexion is never total, or nearly total, a very considerable portion being always transmitted. On the other hand, when the ray is incident on the interior surface, the reflected portion (R) increases regularly, with a very moderate rate of increase, till the angle of incidence becomes equal to the critical angle, whose sine is \( \frac{1}{n} \); when it suddenly, and, as it were, *per saltum*, attains the whole amount of the incident light, and the refracted portion (r) becomes zero. This sudden change from the law of refraction to that of reflexion—this breach of continuity, as it were, is one of the most curious and interesting phenomena in Optics, and (as we shall see hereafter) is connected with the most important points in the theory of light.

The reflexion thus obtained, being total, far surpasses in brilliancy what can be obtained by any other means; from quicksilver, for instance, or from the most highly polished metals. It may be familiarly shown by filling a glass (a common drinking-glass) with water, and holding it above the level of the eye, (as in fig. 24, No. 2.) If we then look obliquely upwards in the direction E a c, we shall see the whole surface shining like polished silver, with a strong metallic reflexion; and any object, as a spoon, A C B, for instance, immersed in it will have its immersed part C B reflected on the surface as on a mirror, but with a brightness far superior to what any mirror would afford. This property of internal reflexion is employed to great advantage in the camera lucida, and might be turned to important uses in other optical instruments, especially in the Newtonian telescope, to obviate the loss of light in the second reflexion, of which more hereafter.
