Abstract

We construct robust empirical Bayes confidence intervals (EBCIs) in a normal means problem. The intervals are centered at the usual linear empirical Bayes estimator, but use a critical value accounting for shrinkage. Parametric EBCIs that assume a normal distribution for the means (Morris, 1983b) may substantially undercover when this assumption is violated. In contrast, our EBCIs control coverage regardless of the means distribution, while remaining close in length to the parametric EBCIs when the means are indeed Gaussian. If the means are treated as fixed, our EBCIs have an average coverage guarantee: the coverage probability is at least $1 - \alpha$ on average across the $n$ EBCIs for each of the means. Our empirical application considers the effects of U.S. neighborhoods on intergenerational mobility.

Keywords: average coverage, empirical Bayes, confidence interval, shrinkage

JEL codes: C11, C14, C18

*This paper is dedicated to the memory of Gary Chamberlain, who had a profound influence on our thinking about decision problems in econometrics, and empirical Bayes methods in particular. Luther Yap provided excellent research assistance. We received helpful comments from four anonymous referees, Otávio Bartalotti, Toru Kitagawa, Laura Liu, Ulrich Müller, Stefan Wager, Mark Watson, Martin Weidner, and numerous seminar participants. We are especially indebted to Bruce Hansen and Roger Koenker for inspiring our simulation study. Armstrong acknowledges support by the National Science Foundation Grant SES-2049765. Kolesár acknowledges support by the Sloan Research Fellowship and by the National Science Foundation Grant SES-22049356. 1 Introduction

Empirical researchers in economics are often interested in estimating effects for many individuals or units, such as estimating teacher quality for teachers in a given geographic area. In such problems, it has become common to shrink unbiased but noisy preliminary estimates of these effects toward baseline values, say the average fixed effect for teachers with the same experience. In addition to estimating teacher quality (Kane and Staiger, 2008; Jacob and Lefgren, 2008; Chetty et al., 2014), shrinkage techniques have been used recently in a wide range of applications including estimating school quality (Angrist et al., 2017), hospital quality (Hull, 2020), the effects of neighborhoods on intergenerational mobility (Chetty and Hendren, 2018), and patient risk scores across regional health care markets (Finkelstein et al., 2017).

The shrinkage estimators used in these applications can be motivated by an empirical Bayes (EB) approach. One imposes a working assumption that the individual effects are drawn from a normal distribution (or, more generally, a known family of distributions). The mean squared error (MSE) optimal point estimator then has the form of a Bayesian posterior mean, treating this distribution as a prior distribution. Rather than specifying the unknown parameters in the prior distribution ex ante, the EB estimator replaces them with consistent estimates, just as in random effects models. This approach is attractive because one does not need to assume that the effects are in fact normally distributed, or even take a “Bayesian” or “random effects” view: the EB estimators have lower MSE (averaged across units) than the unshrunk unbiased estimators, even when the individual effects are treated as nonrandom (James and Stein, 1961).

In spite of the popularity of EB methods, it is currently not known how to provide uncertainty assessments to accompany the point estimates without imposing strong parametric assumptions on the effect distribution. Indeed, Hansen (2016, p. 116) describes inference in shrinkage settings as an open problem in econometrics. The natural EB version of a confidence interval (CI) takes the form of a Bayesian credible interval, again using the postulated effect distribution as a prior (Morris, 1983b). If the distribution is correctly specified, this parametric empirical Bayes confidence interval (EBCI) will cover 95%, say, of the true effect parameters, under repeated sampling of the observed data and of the effect parameters. We refer to this notion of coverage as “EB coverage”, following the terminology in Morris (1983b, Eq. 3.6). Unfortunately, we show that, in the context of a normal means model, the parametric EBCI with nominal level 95% can have actual EB coverage as low as 74% for certain non-normal effect distributions. The potential undercoverage is increasing in the degree of shrinkage, and we derive a simple “rule of thumb” for gauging the potential coverage
To allow easy uncertainty assessment in EB applications that is reliable irrespective of the degree of shrinkage, we construct novel robust EBCIs that take a simple form and control EB coverage regardless of the true effect distribution. Our baseline model is an (approximate) normal means problem $Y_i \sim N(\theta_i, \sigma^2_i)$, $i = 1, \ldots, n$. In applications, $Y_i$ represents a preliminary asymptotically unbiased estimate of the effect $\theta_i$ for unit $i$. Like the parametric EBCI that assumes a normal distribution for $\theta_i$, the robust EBCI we propose is centered at the normality-based EB point estimate $\hat{\theta}_i$, but it uses a larger critical value to take into account the bias due to shrinkage. We provide software implementing our methods. EB coverage is controlled in the class of all distributions for $\theta_i$ that satisfy certain moment bounds, which we estimate consistently from the data (similarly to the parametric EBCI, which uses the second moment). We show that the baseline implementation of our robust EBCI is “adaptive” in the sense that its length is close to that of the parametric EBCI when the $\theta_i$’s are in fact normally distributed. Thus, little efficiency is lost from using the robust EBCI in place of the non-robust parametric one.

In addition to controlling EB coverage, we show that the robust $1 - \alpha$ EBCIs have a frequentist average coverage property: If the means $\theta_1, \ldots, \theta_n$ are treated as fixed, the coverage probability—averaged across the $n$ parameters $\theta_i$—is at least $1 - \alpha$. This average coverage property weakens the usual notion of coverage, which would be imposed separately for each $\theta_i$. As discussed in Remark 2.1 below, the average coverage criterion is motivated by the same idea as the usual EB point estimator (Efron, 2010): we seek CIs that are short and control coverage on average, without requiring good performance for every single unit $i$. Due to the weaker coverage requirement, our robust EBCIs are shorter than the usual CI centered at the unshrunk estimate $Y_i$, and often substantially so. Intuitively, the average coverage criterion only requires us to guard against the average coverage distortion induced by the biases of the individual shrinkage estimators $\hat{\theta}_i$, and the data is quite informative about whether most of these biases are large, even though individual biases are difficult to estimate. To complement the frequentist properties, our EBCIs can also be viewed as Bayesian credible sets that are robust to the prior on $\theta_i$, in terms of ex ante coverage.

Our underlying ideas extend to other linear and non-linear shrinkage settings with possibly non-Gaussian data. For example, our techniques allow for the construction of robust EBCIs that contain (nonlinear) soft thresholding estimators, as well as average coverage confidence bands for nonparametric regression functions.

We illustrate our results by computing EBCIs for the causal effects of growing up in different U.S. neighborhoods (specifically commuting zones) on intergenerational mobility. We follow Chetty and Hendren (2018), who apply EB shrinkage to initial fixed effects estimates.
Depending on the specification, we find that the robust EBCIs are on average 12–25% as long as the unshrunk CIs.

The average coverage criterion was originally introduced in the literature on nonparametric regression (Wahba, 1983; Nychka, 1988; Wasserman, 2006, Ch. 5.8). Cai et al. (2014) construct rate-optimal adaptive confidence bands that achieve average coverage. These procedures are challenging to implement in our EB setting, and do not have a clear finite-sample justification, unlike our procedure. Liu et al. (2019) construct forecast intervals in a dynamic panel data model that guarantee average coverage in a Bayesian sense (for a fixed prior). We give a detailed discussion of alternative approaches to inference in EB settings in Section 5.

The rest of this paper is organized as follows. Section 2 illustrates our methods in the context of a simple homoskedastic Gaussian model. Section 3 presents our recommended baseline procedure and discusses practical implementation issues. Section 4 presents our main results on the coverage and efficiency of the robust EBCI, and on the coverage distortions of the parametric EBCI; we also verify the finite-sample coverage accuracy of the robust EBCI through extensive simulations. Section 5 compares our EBCI with other inference approaches. Section 6 discusses extensions of the basic framework. Section 7 contains an empirical application to inference on neighborhood effects. Appendices A to C give details on finite-sample corrections, computational details, and formal asymptotic coverage results. The Online Supplement contains proofs as well as further technical results. Applied readers are encouraged to focus on Sections 2, 3 and 7.

2 Simple example

This section illustrates the construction of the robust EBCIs that we propose in a simplified setting with no covariates and with known, homoskedastic errors. Section 3 relaxes these restrictions, and discusses other empirically relevant extensions of the basic framework, as well as implementation issues.

We observe \( n \) estimates \( Y_i \) of elements of the parameter vector \( \theta = (\theta_1, \ldots, \theta_n)' \). Each estimate is normally distributed with common, known variance \( \sigma^2 \),

\[
Y_i \mid \theta \sim N(\theta_i, \sigma^2), \quad i = 1, \ldots, n. \tag{1}
\]

In many applications, the \( Y_i \)'s arise as preliminary least squares estimates of the parameters \( \theta_i \). For instance, they may correspond to fixed effect estimates of teacher or school value added, neighborhood effects, or firm and worker effects. In such cases, \( Y_i \) will only be approximately normal in large samples by the central limit theorem (CLT); we take this
explicitly into account in the theory in Appendix C.

A popular approach to estimation that substantially improves upon the raw estimator \( \hat{\theta}_i = Y_i \) under the compound MSE \( \sum_{i=1}^{n} E[(\hat{\theta}_i - \theta_i)^2] \) is based on empirical Bayes (EB) shrinkage. In particular, suppose that the \( \theta_i \)'s are themselves normally distributed, \( \theta_i \sim N(0, \mu_2) \).

\[
\text{(2)}
\theta_i \sim N(0, \mu_2).
\]

Our discussion below applies if Eq. (2) is viewed as a subjective Bayesian prior distribution for a single parameter \( \theta_i \), but for concreteness we will think of Eq. (2) as a “random effects” sampling distribution for the \( n \) mean parameters \( \theta_1, \ldots, \theta_n \). Under this normal sampling distribution, it is optimal to estimate \( \theta_i \) using the posterior mean \( \hat{\theta}_i = w_{EB} Y_i \), where

\[
w_{EB} = 1 - \frac{\sigma^2}{\sigma^2 + \mu_2}.
\]

To avoid having to specify the variance \( \mu_2 \), the EB approach treats it as an unknown parameter, and replaces the marginal precision of \( Y_i \), \( 1/(\sigma^2 + \mu_2) \), with a method of moments estimate \( n/(\sum_{i=1}^{n} Y_i^2) \), or the degrees-of-freedom adjusted estimate \( (n-2)/(\sum_{i=1}^{n} Y_i^2) \). The latter leads to \( w_{EB} = (1 - \sigma^2(n-2)/\sum_{i=1}^{n} Y_i^2) \), which is the classic estimator of James and Stein (1961).

One can also use Eq. (2) to construct CIs for the \( \theta_i \)'s. In particular, since the marginal distribution of \( w_{EB} Y_i - \theta_i \) is normal with mean zero and variance \( (1 - w_{EB})^2 \mu_2 + w_{EB}^2 \sigma^2 = w_{EB} \sigma^2 \), this leads to the \( 1 - \alpha \) CI

\[
w_{EB} Y_i \pm z_{1-\alpha/2} w_{EB}^{1/2} \sigma, \tag{3}
\]

where \( z_{\alpha} \) is the \( \alpha \) quantile of the standard normal distribution. Since the form of the interval is motivated by the parametric assumption (2), we refer to it as a parametric EBCI. With \( \mu_2 \) unknown, one can replace \( w_{EB} \) by \( \hat{w}_{EB} \). This is asymptotically equivalent to (3) as \( n \to \infty \).

The coverage of the parametric EBCI in (3) is \( 1 - \alpha \) under repeated sampling of \( (Y_i, \theta_i) \) according to Eqs. (1) and (2). To distinguish this notion of coverage from the case with fixed \( \theta \), we refer to coverage under repeated sampling of \( (Y_i, \theta_i) \) as “empirical Bayes coverage”. This follows the definition of an empirical Bayes confidence interval (EBCI) in Morris (1983b, Eq. 3.6) and Carlin and Louis (2000, Ch. 3.5). Unfortunately, this coverage property relies heavily on the parametric assumption (2). We show in Section 4.3 that the actual EB coverage of the nominal \( 1 - \alpha \) parametric EBCI can be as low as \( 1 - 1/\max\{z_{1-\alpha/2}, 1\} \) for certain non-normal distributions of \( \theta_i \) with variance \( \mu_2 \); for 95\% EBCIs, this evaluates to 74\%. This contrasts with existing results on estimation: although the empirical Bayes estimator is motivated by the parametric assumption (2), it performs well even if this assumption is

\[1\text{Alternatively, to account for estimation error in } \hat{w}_{EB}, \text{ Morris (1983b) suggests adjusting the variance estimate } \hat{w}_{EB} \sigma^2 \text{ to } \hat{w}_{EB} \sigma^2 + 2Y_i^2(1 - \hat{w}_{EB})^2/(n - 2). \text{ The adjustment does not matter asymptotically.} \]
dropped, with low MSE even if we treat \( \theta \) as fixed.

This paper constructs an EBCI with a similar robustness property: the interval will be close in length to the parametric EBCI when Eq. (2) holds, but its EB coverage is at least \( 1 - \alpha \) without any parametric assumptions on the distribution of \( \theta_i \). To describe the construction, suppose that all that is known is that \( \theta_i \) is sampled from a distribution with second moment given by \( \mu_2 \) (in practice, we can replace \( \mu_2 \) by the consistent estimate \( \frac{1}{n-1} \sum_{i=1}^{n} Y_i^2 - \sigma^2 \)).

Conditional on \( \theta_i \), the estimator \( w_{EB}Y_i \) has bias \( (w_{EB} - 1) \theta_i \) and variance \( w_{EB}^2 \sigma^2 \), so that the \( t \)-statistic \( \frac{w_{EB}Y_i - \theta_i}{w_{EB}\sigma} \) is normally distributed with mean \( b_i = (1 - 1/w_{EB})\theta_i/\sigma \) and variance 1. Therefore, if we use a critical value \( \chi \), the non-coverage of the CI \( w_{EB}Y_i \pm \chi w_{EB}\sigma \), conditional on \( \theta_i \), will be given by the probability

\[
  r(b_i, \chi) = P(|Z - b_i| \geq \chi | \theta_i) = \Phi(-\chi - b_i) + \Phi(-\chi + b_i),
\]

where \( Z \) denotes a standard normal random variable, and \( \Phi \) denotes the standard normal cdf.

Thus, by iterated expectations, under repeated sampling of \( \theta_i \), the non-coverage is bounded by

\[
  \rho(\sigma^2/\mu_2, \chi) = \sup_F E_F[r(b, \chi)] \quad \text{s.t.} \quad E_F[b^2] = \frac{(1 - 1/w_{EB})^2}{\sigma^2} \mu_2 = \frac{\sigma^2}{\mu_2},
\]

where \( E_F \) denotes expectation under \( b \sim F \). Although this is an infinite-dimensional optimization problem over the space of distributions, it turns out that it admits a simple closed-form solution, which we give in Proposition B.1 in Appendix B. Moreover, because the optimization is a linear program, it can be solved even in the more general settings of applied relevance that we consider in Section 3.

Set \( \chi = cva_{\alpha}(\sigma^2/\mu_2) \), where \( cva_{\alpha}(t) = \rho^{-1}(t, \alpha) \), and the inverse is with respect to the second argument. Then the resulting interval

\[
  w_{EB}Y_i \pm cva_{\alpha}(\sigma^2/\mu_2)w_{EB}\sigma
\]

will maintain coverage \( 1 - \alpha \) among all distributions of \( \theta_i \) with \( E[\theta_i^2] = \mu_2 \) (recall that we estimate \( \mu_2 \) consistently from the data). For this reason, we refer to it as a robust EBCI.

Figure 1 in Section 3.1 gives a plot of the critical values for \( \alpha = 0.05 \). We show in Section 4.2 below that by also imposing a constraint on the fourth moment of \( \theta_i \), in addition to the second moment constraint, one can construct a robust EBCI that “adapts” to the Gaussian case in the sense that its length will be close to that of the parametric EBCI in Eq. (3) if these moment constraints are compatible with a normal distribution.

Instead of considering EB coverage, one may alternatively wish to assess uncertainty associated with the estimates \( \hat{\theta}_i = w_{EB}Y_i \) when \( \theta \) is treated as fixed. In this case, the EBCI
in Eq. (6) has an average coverage guarantee that

\[
\frac{1}{n} \sum_{i=1}^{n} P(\theta_i \in [w_{EB} Y_i \pm cva(\sigma^2/\mu_2) w_{EB} \sigma] \mid \theta) \geq 1 - \alpha,
\]  

provided that the moment constraint can be interpreted as a constraint on the empirical second moment on the \( \theta_i \)'s, \( n^{-1} \sum_{i=1}^{n} \theta_i^2 = \mu_2 \). In other words, if we condition on \( \theta \), then the coverage is at least \( 1 - \alpha \) on average across the \( n \) EBCIs for \( \theta_1, \ldots, \theta_n \). To see this, note that the average non-coverage of the intervals is bounded by (5), except that the supremum is only taken over possible empirical distributions for \( \theta_1, \ldots, \theta_n \) satisfying the moment constraint. Since this supremum is necessarily smaller than \( \rho(\sigma^2/\mu_2, \chi) \), it follows that the average coverage is at least \( 1 - \alpha \).²

The usual CIs \( Y_i \pm z_{1-\alpha/2} \sigma \) also of course achieve average coverage \( 1 - \alpha \). The robust EBCI in Eq. (6) will, however, be shorter, especially when \( \mu_2 \) is small relative to \( \sigma^2 \)—see Figure 3 below: by weakening the requirement that each CI covers the true parameter \( 1 - \alpha \) percent of the time to the requirement that the coverage is \( 1 - \alpha \) on average across the CIs, we can substantially shorten the CI length. It may seem surprising at first that we can achieve this by centering the CI at the shrinkage estimates \( w_{EB} Y_i \). The intuition for this is that the shrinkage reduces the variability of the estimates. This comes at the expense of introducing bias in the estimates. However, we can on average control the resulting coverage loss by using the larger critical value \( cva(\sigma^2/\mu_2) \). Because under the average coverage criterion we only need to control the bias on average across \( i \), rather than for each individual \( \theta_i \), this increase in the critical value is smaller than the reduction in the standard error.

Remark 2.1 (Interpretation of average coverage). While the average coverage criterion is weaker than the classical requirement of guaranteed coverage for each parameter, we believe it is useful, particularly in the EB context, for three reasons. First, the EB point estimator achieves lower MSE on average across units at the expense of potentially worse performance for some individual units (see, for example, Efron, 2010, Ch. 1.3). Thus, researchers who use EB estimators instead of the unshrunk \( Y_i \)'s prioritize favorable group performance over protecting individual performance. It is natural to resolve the trade-off in the same way when it comes to uncertainty assessments. Our average coverage intervals do exactly this: they guarantee coverage and achieve short length on average across units at the expense of giving up on a coverage guarantee for every individual unit. See Section 5 for further

²This link between average risk of separable decision rules (here coverage of CIs, each of which depends only on \( Y_i \)) when the parameters \( \theta_1, \ldots, \theta_n \) are treated as fixed and the risk of a single decision rule when these parameters are random and identically distributed is a special case of what Jiang and Zhang (2009) call the fundamental theorem of compound decisions, which goes back to Robbins (1951).
Second, one motivation for the usual notion of coverage is that if one constructs many CIs, and there is not too much dependence between the data used to construct each interval, then by the law of large numbers, at least a $1 - \alpha$ fraction of them will contain the corresponding parameter. As we discuss further in Remark 4.1, average coverage intervals also have this interpretation.

Finally, under the classical requirement of guaranteed coverage for each $\theta_i$, it is not possible to substantially improve upon the usual CI centered at the unshrunk estimate $Y_i$, regardless of how one forms the CI. It is only by relaxing the coverage requirement that we can circumvent this impossibility result and obtain intervals that reflect the efficiency improvement from the empirical Bayes approach.

## 3 Practical implementation

We now describe how to compute a robust EBCI that allows for heteroskedasticity, shrinks towards more general regression estimates rather than towards zero, and exploits higher moments of the bias to yield a narrower interval. In Section 3.1, we describe the empirical Bayes model that motivates our baseline approach. Section 3.2 describes the practical implementation of our baseline approach.

### 3.1 Motivating model and robust EBCI

In applied settings, the unshrunk estimates $Y_i$ will typically have heteroskedastic variances. Furthermore, rather than shrinking towards zero, it is common to shrink toward an estimate of $\theta_i$ based on some covariates $X_i$, such as a regression estimate $X_i'\delta$. We now describe how to adapt the ideas in Section 2 to such settings.

Consider a generalization of the model in Eq. (1) that allows for heteroskedasticity and covariates,

$$Y_i \mid \theta_i, X_i, \sigma_i \sim N(\theta_i, \sigma_i^2), \quad i = 1, \ldots, n.$$  

The covariate vector $X_i$ may contain just the intercept, and it may also contain (functions of) $\sigma_i$. To construct an EB estimator of $\theta_i$, consider the working assumption that the sampling

---

3The results in Pratt (1961) imply that for CIs with coverage 95%, one cannot achieve expected length improvements greater than 15% relative to the usual unshrunk CIs, even if one happens to optimize length for the true parameter vector $(\theta_1, \ldots, \theta_n)$. See, for example, Corollary 3.3 in Armstrong and Kolesár (2018) and the discussion following it.
distribution of the \( \theta_i \)'s is conditionally normal:

\[
\theta_i \mid X_i, \sigma_i \sim N(\mu_{1,i}, \mu_2), \quad \text{where} \quad \mu_{1,i} = X_i'\delta.
\]  

(9)

The hierarchical model (8)–(9) leads to the Bayes estimate \( \hat{\theta}_i = \mu_{1,i} + w_{EB,i}(Y_i - \mu_{1,i}) \), where \( w_{EB,i} = \frac{\mu_2}{\mu_2^2 + \sigma_i^2} \). This estimate shrinks the unrestricted estimate \( Y_i \) of \( \theta_i \) toward \( \mu_{1,i} = X_i'\delta \). In contrast to (8), the normality assumption (9) typically cannot be justified simply by appealing to the CLT; the linearity of the conditional mean \( \mu_{1,i} = X_i'\delta \) may also be suspect.

Our robust EBCI will therefore be constructed so that it achieves valid EB coverage even if assumption (9) fails. To obtain a narrow robust EBCI, we augment the second moment restriction used to compute the critical value in Eq. (5) with restrictions on higher moments of the bias of \( \hat{\theta}_i \). In our baseline specification, we add a restriction on the fourth moment.

In particular, we replace assumption (9) with the much weaker requirement that the conditional second moment and kurtosis of \( \varepsilon_i = \theta_i - X_i'\delta \) do not depend on \((X_i, \sigma_i)\):

\[
E[(\theta_i - X_i'\delta)^2 \mid X_i, \sigma_i] = \mu_2, \quad E[(\theta_i - X_i'\delta)^4 \mid X_i, \sigma_i]/\mu_2^2 = \kappa,
\]  

(10)

where \( \delta \) is defined as the probability limit of the regression estimate \( \hat{\delta} \).

Appendix B shows that the infinite-dimensional linear program (11) can be reduced to two nested univariate optimizations. We also show that the least favorable distribution—the distribution \( F \) maximizing (11)—is a discrete distribution with up to 4 support points (see Remark B.1).

Define the critical value \( cv_{\alpha}(m_{2,i}, \kappa) = \rho^{-1}(m_{2,i}, \kappa, \alpha) \), where the inverse is in the last argument. Figure 1 plots this function for \( \alpha = 0.05 \) and selected values of \( \kappa \). This leads to

4Our framework can be modified to let \((X_i, \sigma_i)\) be fixed, in which case \( \delta \) depends on \( n \). See the discussion following Theorem 4.1 below.
Figure 1: Function $cva_\alpha(m_2, \kappa)$ for $\alpha = 0.05$ and selected values of $\kappa$. The function $cva_\alpha(m_2)$, defined in Section 2, that only imposes a constraint on the second moment, corresponds to $cva_\alpha(m_2, \infty)$. The function $cva_{P,\alpha}(m_2) = z_{1-\alpha/2}\sqrt{1+m_2}$ corresponds to the critical value under the assumption that $\theta_i$ is normally distributed.

the robust EBCI

$$\hat{\theta}_i \pm cva_\alpha(m_{2,i}, \kappa)w_{EB,i}\sigma_i,$$  \hspace{1cm} (12)

which, by construction, has coverage at least $1 - \alpha$ under repeated sampling of $(Y_i, \theta_i)$, conditional on $(X_i, \sigma_i)$, so long as Eq. (10) holds; it is not required that (9) holds. Note that both the critical value and the CI length are increasing in $\sigma_i$.

### 3.2 Baseline implementation

Our baseline implementation of the robust EBCI plugs in consistent estimates of the unknown quantities in Eq. (12), based on the data $\{Y_i, X_i, \hat{\sigma}_i\}_{i=1}^n$, where $\hat{\sigma}_i$ is a consistent estimate of $\sigma_i$ (such as the standard error of the preliminary estimate $Y_i$), and $X_i$ is a vector of covariates that are thought to help predict $\theta_i$.

1. Regress $Y_i$ on $X_i$ to obtain the fitted values $X_i\hat{\delta}$, with $\hat{\delta} = (\sum_{i=1}^n \omega_i X_i X_i')^{-1} \sum_{i=1}^n \omega_i X_i Y_i$ denoting the weighted least squares estimate with precision weights $\omega_i$. Two natural choices are setting $\omega_i = \hat{\sigma}_i^{-2}$, or setting $\omega_i = 1/n$ for unweighted estimates; see Appendix A.2 for further discussion. Let $\hat{\mu}_2 = \max \left\{ \frac{\sum_{i=1}^n \omega_i (\hat{\epsilon}_i^2 - \hat{\sigma}_i^2)}{\sum_{i=1}^n \omega_i}, \frac{2 \sum_{i=1}^n \omega_i \hat{\sigma}_i^4}{\sum_{i=1}^n \omega_i} \right\}$, and $\hat{\kappa} = \max \left\{ \frac{\sum_{i=1}^n \omega_i (\hat{\epsilon}_i^2 - 6\hat{\sigma}_i^4 + 3\hat{\sigma}_i^8)}{\hat{\mu}_2 \sum_{i=1}^n \omega_i}, 1 + \frac{32 \sum_{i=1}^n \omega_i \hat{\sigma}_i^8}{\hat{\mu}_2 \sum_{i=1}^n \omega_i \sum_{i=1}^n \omega_i \hat{\sigma}_i^4} \right\}$, where $\hat{\epsilon}_i = Y_i - X_i\hat{\delta}$.
2. Form the EB estimate

\[ \hat{\theta}_i = X'_i\hat{\delta} + \hat{w}_{EB,i}(Y_i - X'_i\hat{\delta}), \quad \text{where} \quad \hat{w}_{EB,i} = \frac{\hat{\mu}_2}{\hat{\mu}_2 + \hat{\sigma}_i^2}. \]

3. Compute the critical value \( cva_\alpha(\hat{\sigma}_i^2/\hat{\mu}_2, \hat{\kappa}) \) defined below Eq. (11).

4. Report the robust EBCI

\[ \hat{\theta}_i \pm cva_\alpha(\hat{\sigma}_i^2/\hat{\mu}_2, \hat{\kappa})\hat{w}_{EB,i}\hat{\sigma}_i. \] (13)

We provide a fast and stable software package that automates these steps.\(^5\) We discuss the assumptions needed for validity of the robust EBCI in Remarks 3.1 to 3.3 below.

**Remark 3.1** (Conditional EB coverage and moment independence). A potential concern about EB coverage in a heteroskedastic setting is that in order to reduce the length of the CI on average, one could choose to overcover parameters \( \theta_i \) with small \( \sigma_i \) and undercover parameters \( \theta_i \) with large \( \sigma_i \). Our robust EBCI ensures that this does not happen by requiring EB coverage to hold conditional on \( (X_i, \sigma_i) \). This also avoids analogous coverage concerns as a result of the value of \( X_i \).

The key to ensuring this property is assumption (10) that the conditional second moment and kurtosis of \( \varepsilon_i = \theta_i - X'_i\delta \) does not depend on \( (X_i, \sigma_i) \). Conditional moment independence assumptions of this form are common in the literature. For instance, it is imposed in the analysis of neighborhood effects in Chetty and Hendren (2018) (their approach requires independence of the second moment), which is the basis for our empirical application in Section 7. Nonetheless, such conditions may be strong in some settings, as argued by Xie et al. (2012) in the context of EB point estimation. In Remark 3.2 below, we drop condition (10) entirely by replacing \( \hat{\mu}_2 \) and \( \hat{\kappa} \) with nonparametric estimates of these conditional moments; alternatively, one could relax it by using a flexible parametric specification.\(^6\)

**Remark 3.2** (Nonparametric moment estimates). As a robustness check to guard against failure of the moment independence assumption (10), one may replace the critical value in Eq. (13) with \( cva_\alpha((1-1/\hat{w}_{EB,i})^2\hat{\mu}_{2i}/\hat{\sigma}_i^2, \hat{\kappa}_i) \), where \( \hat{\mu}_{2i} \) and \( \hat{\kappa}_i \) are consistent nonparametric estimates of \( \mu_{2i} = E[(\theta_i - X'_i\delta)^2 | X_i, \sigma_i] \) and \( \kappa_i = E[(\theta_i - X'_i\delta)^4 | X_i, \sigma_i]/\mu_{2i}^2 \). The resulting CI will be asymptotically equivalent to the CI in the baseline implementation if Eq. (13) holds, but it will achieve valid EB coverage even if this assumption fails. In our empirical

\(^5\)Matlab, Stata, and R packages are available at [https://github.com/kolesarm/ebci](https://github.com/kolesarm/ebci)

\(^6\)Another way to drop condition (10) is to base shrinkage on the \( t \)-statistics \( Y_i/\sigma_i \), applying the baseline implementation above with \( Y_i/\hat{\sigma}_i \) in place of \( Y_i \) and 1 in place of \( \hat{\sigma}_i \). Then the homoskedastic analysis in Section 2 applies, leading to valid EBCIs without any assumptions about independence of the moments. See Remark 3.8 and Appendix D.1 in Armstrong et al. (2020) for further discussion.
application, we use nearest-neighbor estimates, as described in Appendix A.1. As a simple diagnostic to gauge how the second moment of \( \theta_i - X_i' \delta \) varies with \((X_i, \sigma_i)\), one can report the \( R^2 \) gain in predicting \( \hat{\varepsilon}_i^2 - \hat{\sigma}_i^2 \) using \( \hat{\mu}_{2i} \) rather than the baseline estimate \( \hat{\mu}_2 \), as we illustrate in our empirical application.

**Remark 3.3** (Average coverage and non-independent sampling). We show in Section 4 that the robust EBCI satisfies an average coverage criterion of the form (7) when the parameters \( \theta = (\theta_1, \ldots, \theta_n) \) are considered fixed, in addition to achieving valid EB coverage when the \( \theta_i \)'s are viewed as random draws from some underlying distribution. To guarantee average coverage or EB coverage, we do not need to assume that the \( Y_i \)'s and \( \theta_i \)'s are drawn independently across \( i \). This is because the average coverage and EB coverage criteria only depend on the marginal distribution of \((Y_i, \theta_i)\), not the joint distribution. Indeed, in deriving the infeasible CI in Eq. (12), we made no assumptions about the dependence structure of \((Y_i, \theta_i)\) across \( i \). Consequently, to guarantee asymptotic coverage of the feasible interval in Eq. (13) as \( n \to \infty \), we only need to ensure that the estimates \( \hat{\mu}_2, \hat{\kappa}, \hat{\delta}, \hat{\sigma}_i \) are consistent for \( \mu_2, \kappa, \delta, \sigma_i \), which is the case under many forms of weak dependence or clustering. Furthermore, our baseline implementation above does not require the researcher to take an explicit stand on the dependence of the data; for example, in the case of clustering, the researcher does not need to take an explicit stand on how the clusters are defined.

**Remark 3.4** (Estimating moments of the distribution of \( \theta_i \)). The estimators \( \hat{\mu}_2 \) and \( \hat{\kappa} \) in step 1 of our baseline implementation above are based on the moment conditions \( E[(Y_i - X_i' \delta)^2 - \sigma_i^2 | X_i, \sigma_i] = \mu_2 \) and \( E[(Y_i - X_i' \delta)^4 + 3\sigma_i^4 - 6\sigma_i^2(Y_i - X_i' \delta)^2 | X_i, \sigma_i] = \kappa \mu_2^2 \), replacing population expectations by weighted sample averages. In addition, to avoid small-sample coverage issues when \( \mu_2 \) and \( \kappa \) are near their theoretical lower bounds of 0 and 1, respectively, these estimates incorporate truncation on \( \hat{\mu}_2 \) and \( \hat{\kappa} \), motivated by an approximation to a Bayesian estimate with flat prior on \( \mu_2 \) and \( \kappa \) as in Morris (1983a,b). We verify the small-sample coverage accuracy of the resulting EBCIs through extensive simulations in Section 4.4. Appendix A.1 discusses the choice of the moment estimates, as well as other ways of performing truncation.

**Remark 3.5** (Using higher moments and other forms of shrinkage). In addition to using the second and fourth moment of bias, one may augment (11) with restrictions on higher moments of the bias in order to further tighten the critical value. In Section 4.2, we show that using other moments in addition to the second and fourth moment does not substantially decrease the critical value in the case where \( \theta_i \) is normally distributed. Thus, the CI in our baseline implementation is robust to failure of the normality assumption (9), while being near-optimal when this assumption does hold. Section 4.2 also shows that further efficiency
gains are possible if one uses the linear estimator \( \tilde{\theta}_i = \mu_{1,i} + w_i(Y_i - \mu_{1,i}) \) with the shrinkage coefficient \( w_i \) chosen to optimize CI length, instead of using the MSE-optimal shrinkage \( w_{EB,i} \). For efficiency under a non-normal distribution of \( \theta_i \), one needs to consider non-linear shrinkage; we discuss this extension in Section 6.1.

4 Main results

This section provides formal statements of the coverage properties of the CIs presented in Sections 2 and 3. Furthermore, we show that the CIs presented in Sections 2 and 3 are highly efficient when the mean parameters are in fact normally distributed. Next, we calculate the maximal coverage distortion of the parametric EBCI, and derive a rule of thumb for gauging the potential coverage distortion. Finally, we present a comprehensive simulation study of the finite-sample performance of the robust EBCI. Applied readers interested primarily in implementation issues may skip ahead to the empirical application in Section 7.

4.1 Coverage under baseline implementation

In order to state the formal result, let us first carefully define the notions of coverage that we consider. Consider intervals \( CI_1, \ldots, CI_n \) for elements of the parameter vector \( \theta = (\theta_1, \ldots, \theta_n)' \). The probability measure \( P \) denotes the joint distribution of \( \theta \) and \( CI_1, \ldots, CI_n \). Following Morris (1983b, Eq. 3.6) and Carlin and Louis (2000, Ch. 3.5), we say that the interval \( CI_i \) is an (asymptotic) \( 1 - \alpha \) empirical Bayes confidence interval (EBCI) if

\[
\liminf_{n \to \infty} P(\theta_i \in CI_i) \geq 1 - \alpha. \tag{14}
\]

We say that the intervals \( CI_i \) are (asymptotic) \( 1 - \alpha \) average coverage intervals (ACIs) under the parameter sequence \( \theta_1, \ldots, \theta_n \) if

\[
\liminf_{n \to \infty} \frac{1}{n} \sum_{i=1}^{n} P(\theta_i \in CI_i \mid \theta) \geq 1 - \alpha. \tag{15}
\]

The average coverage property (15) is a property of the distribution of the data conditional on \( \theta \) and therefore does not require that we view the \( \theta_i \)'s as random (as in a Bayesian or “random effects” analysis). To maintain consistent notation, we nonetheless use the conditional notation \( P(\cdot \mid \theta) \) when considering average coverage. See Appendix C for a formulation with \( \theta \) treated as nonrandom.

Observe that under the exchangeability condition that \( P(\theta_i \in CI_i) = P(\theta_j \in CI_j) \) for all
\(i, j\), if the ACI property (15) holds almost surely, then the EBCI property (14) holds, since then
\[
P(\theta_i \in CI_i) = \frac{1}{n} \sum_{j=1}^{n} P(\theta_j \in CI_j) \geq 1 - \alpha + o(1) \quad \text{for all } i.
\]

We now provide coverage results for the baseline implementation described in Section 3.2. To keep the statements in the main text as simple as possible, we (i) maintain the assumption that the unshrunk estimates \(Y_i\) follow an exact normal distribution conditional on the parameter \(\theta_i\), (ii) state the results only for the homoskedastic case where the variance \(\sigma_i\) of the unshrunk estimate \(Y_i\) does not vary across \(i\), and (iii) consider only unconditional coverage statements of the form (14) and (15). In Appendix C, we allow the estimates \(Y_i\) to be only approximately normally distributed and allow \(\sigma_i\) to vary, and we verify that our assumptions hold in a linear fixed effects panel data model. We also formalize the statements about conditional coverage made in Remark 3.1.

**Theorem 4.1.** Suppose \(Y_i \mid \theta \sim N(\theta, \sigma^2)\). Let \(\mu_{j,n} = \frac{1}{n} \sum_{i=1}^{n} (\theta_i - X'_i \delta)^j\) and let \(\kappa_n = \mu_{4,n}/\mu_{2,n}^2\). Suppose the sequence \(\theta = \theta_1, \ldots, \theta_n\) and the conditional distribution \(P(\cdot \mid \theta)\) satisfy the following conditions with probability one:

1. \(\mu_{2,n} \to \mu_2\) and \(\mu_{4,n}/\mu_{2,n}^2 \to \kappa\) for some \(\mu_2 \in (0, \infty)\) and \(\kappa \in (1, \infty)\).
2. Conditional on \(\theta\), \((\hat{\delta}, \hat{\sigma}, \hat{\mu}_2, \hat{\kappa})\) converges in probability to \((\delta, \sigma, \mu_2, \kappa)\).

Then the CIs in Eq. (13) with \(\hat{\sigma} = \hat{\sigma}\) satisfy the ACI property (15) with probability one. Furthermore, if \(\theta_1, \ldots, \theta_n\) follow an exchangeable distribution and the estimators \(\hat{\delta}, \hat{\sigma}, \hat{\mu}_2\) and \(\hat{\kappa}\) are exchangeable functions of the data \((X'_1, Y_1)', \ldots, (X'_n, Y_n)',\) then these CIs satisfy the EB coverage property (14).

Theorem 4.1 follows immediately from Theorem C.2 in Appendix C. In order to cover both the EB coverage condition (14) and the average coverage condition (15), Theorem 4.1 considers a random sequence of parameters \(\theta_1, \ldots, \theta_n\), and shows average coverage conditional on these parameters. See Appendix C for a formulation with \(\theta\) treated as nonrandom.

The condition on the moments \(\mu_2\) and \(\kappa\) avoids degenerate cases such as when \(\mu_2 = 0\), in which case the EB point estimator \(\hat{\theta}_i\) shrinks each preliminary estimate \(Y_i\) all the way to \(X'_i \hat{\delta}\). Note also that the theorem does not require that \(\hat{\delta}\) be the ordinary least squares (OLS) estimate in a regression of \(Y_i\) onto \(X_i\), and that \(\delta\) be the population analog; one can define \(\delta\) in other ways, the theorem only requires that \(\hat{\delta}\) be a consistent estimate of it. The definition of \(\delta\) does, however, affect the plausibility of the moment independence assumption in Eq. (10) needed for conditional coverage results stated in Appendix C.\(^7\)

\(^7\)In addition, specification of \(\mu_{1i} = X'_i \delta\) affects the width of the resulting EBCIs through its effect on \(\mu_2\) and \(\kappa\).
**Remark 4.1.** As shown in Appendix C, if CIs satisfy the average coverage condition (15) given $\theta_1, \ldots, \theta_n$, they will typically also satisfy the stronger condition

$$\frac{1}{n} \sum_{i=1}^{n} I\{\theta_i \in CI_i\} \geq 1 - \alpha + o_P(\theta)(1),$$

where $o_P(\theta)(1)$ denotes a sequence that converges in probability to zero conditional on $\theta$ (Eq. (16) implies Eq. (15) since the left-hand side is uniformly bounded). That is, at least a fraction $1 - \alpha$ of the $n$ CIs contain their respective true parameters, asymptotically. This is analogous to the result that for estimation, the difference between the squared error $\frac{1}{n} \sum_{i=1}^{n} (\hat{\theta}_i - \theta_i)^2$ and the MSE $\frac{1}{n} \sum_{i=1}^{n} E[(\hat{\theta}_i - \theta_i)^2 | \theta]$ typically converges to zero.

### 4.2 Relative efficiency

The robust EBCI in Eq. (12), unlike the parametric EBCI $\hat{\theta}_i \pm z_{1-\alpha/2} \sigma_i \sqrt{w_{EB,i}}$, does not rely on the normality assumption in Eq. (9) for its validity. We now show that this robustness does not come at a high cost in terms of efficiency when in fact the normality assumption (9) holds: the inefficiency is small unless the signal-to-noise ratio $\mu_2/\sigma_i^2$ is very small.

There are two reasons for the inefficiency relative to this normal benchmark. First, the robust EBCI only makes use of the second and fourth moment of the conditional distribution of $\theta_i - X_i'\delta$, rather than its full distribution. Second, if we only have knowledge of these two moments, it is no longer optimal to center the EBCI at the estimator $\hat{\theta}_i$: one may need to consider other, perhaps non-linear, shrinkage estimators, as we do below in Section 6.1.

We decompose the sources of inefficiency by studying the relative length of the robust EBCI relative to the EBCI that picks the amount of shrinkage optimally. For the latter, we maintain assumption (10), and consider a more general class of estimators $\tilde{\theta}(w_i) = \mu_{1,i} + w_i(Y_i - \mu_{1,i})$: we impose the requirement that the shrinkage is linear for tractability, but allow the amount of shrinkage $w_i$ to be optimally determined. The normalized bias of $\tilde{\theta}(w_i)$ is given by $b_i = (1/w_i - 1)\varepsilon_i/\sigma_i$, which leads to the EBCI

$$\mu_{1,i} + w_i(Y_i - \mu_{1,i}) \pm \text{cva}_\alpha((1 - 1/w_i)^2 \mu_2/\sigma_i^2, \kappa)w_i\sigma_i.$$

The half-length of this EBCI, $\text{cva}_\alpha((1 - 1/w_i)^2 \mu_2/\sigma_i^2, \kappa)w_i\sigma_i$, can be numerically minimized as a function of $w_i$ to find the EBCI length-optimal shrinkage. Denote the minimizer by $w_{opt}(\mu_2/\sigma_i^2, \kappa, \alpha)$. Like $w_{EB,i}$, the optimal shrinkage depends on $\mu_2$ and $\sigma_i^2$ only through the signal-to-noise ratio $\mu_2/\sigma_i^2$. Numerically evaluating the minimizer shows that $w_{opt}(\cdot, \kappa, \alpha) \geq w_{EB,i}$ for $\kappa \geq 3$ and $\alpha \in \{0.05, 0.1\}$. The resulting EBCI is optimal among all fixed-length
Figure 2: Relative efficiency of robust EBCI (Rob) and optimal robust EBCI (Opt) relative to
the normal benchmark, for $\alpha = 0.05$. The figure plots ratios of Rob length, $2 \text{cva}_\alpha(\sigma_1^2/\mu_2, \kappa) \cdot \sigma_1 \mu_2/(\mu_2 + \sigma_1^2)$, and Opt length $2 \text{cva}_\alpha((1 - 1/w_{\text{opt}}(\mu_2/\sigma_1^2, \kappa, \alpha))^2 \mu_2/\sigma_1^2, \kappa) \cdot \sigma_1 w_{\text{opt}}(\mu_2/\sigma_1^2, \kappa, \alpha)$, relative to the parametric EBCI length $2z_{1-\alpha/2} \sqrt{\mu_2/(\mu_2 + \sigma_1^2)} \sigma_i$ as a function of the shrinkage factor $w_{EB,i} = \mu_2/(\mu_2 + \sigma_1^2)$, which maps the signal-to-noise ratio $\mu_2/\sigma_i$ to the interval $[0, 1]$.

EBCIs centered at linear estimators under (10), and we call it the optimal robust EBCI.

Figure 2 plots the ratio of lengths of the optimal robust EBCI and robust EBCI relative to
the parametric EBCI, for $\alpha = 0.05$. The figure shows that for efficiency relative to the normal benchmark, it is relatively more important to impose the fourth moment constraint than to use the optimal amount of shrinkage (and only impose the second moment constraint). It also shows that the efficiency loss of the robust EBCI is modest unless the signal-to-noise ratio is very small: if $w_{EB,i} \geq 0.1$ (which is equivalent to $\mu_2/\sigma_i \geq 1/9$), the efficiency loss is at most $11.4\%$ for $\alpha = 0.05$; up to half of the efficiency loss is due to not using the optimal shrinkage. For $\alpha = 0.1$ (not plotted), the results are very similar; in particular, if $w_{EB,i} \geq 0.1$, the efficiency loss is at most $12.9\%$.

When the signal-to-noise ratio is very small, so that $w_{EB,i} < 0.1$, the efficiency loss of the robust EBCI is higher (up to $39\%$ for $\alpha = 0.05$ or $0.1$). Using the optimal robust EBCI ensures that the efficiency loss is below $20\%$, irrespective of the signal-to-noise ratio. On the other hand, when the signal-to-noise ratio is small, any of these CIs will be significantly tighter than the unshrunk CI $Y_i \pm z_{1-\alpha/2}\sigma_i$. To illustrate this point, Figure 3 plots the efficiency of the robust EBCI that imposes the second moment constraint only, relative to this unshrunk CI. It can be seen from the figure that shrinkage methods allow us to tighten
\[ \alpha = 0.05 \]
\[ \alpha = 0.1 \]

Figure 3: Relative efficiency of robust EBCI \( \hat{\theta}_i \pm \text{cva}_\alpha (\sigma_i^2 / \mu_2, \kappa = \infty) \cdot \sigma \mu_2 / (\mu_2 + \sigma_i^2) \) relative to the unshrunk CI \( Y_i \pm z_{1-\alpha/2} \sigma_i \). The figure plots the ratio of the length of the robust EBCI relative to the unshrunk CI as a function of the shrinkage factor \( w_{EB,i} = \mu_2 / (\mu_2 + \sigma_i^2) \).

the CI by 44\% or more when \( \mu_2 / \sigma_i^2 \leq 0.1 \).

### 4.3 Undercoverage of parametric EBCI

The parametric EBCI \( \hat{\theta}_i \pm z_{1-\alpha/2} w_{EB,i}^{1/2} \sigma_i \) is an EB version of a Bayesian credible interval that treats (9) as a prior. We now assess its potential undercoverage when Eq. (9) is violated.

Given knowledge of only the second moment \( \mu_2 \) of \( \varepsilon_i = Y_i - X'_i \delta \), the maximal undercoverage of this interval is given by

\[ \rho(1/w_{EB,i} - 1, z_{1-\alpha/2}/\sqrt{w_{EB,i}}), \tag{17} \]

since \( w_{EB,i} = \mu_2 / (\mu_2 + \sigma_i^2) \). Here \( \rho \) is the non-coverage function defined in Eq. (5). Figure 4 plots the maximal non-coverage probability as a function of \( w_{EB,i} \), for significance levels \( \alpha = 0.05 \) and \( \alpha = 0.10 \). The figure suggests a simple “rule of thumb”: if \( w_{EB,i} \geq 0.3 \), the maximal coverage distortion is less than 5 percentage points for these values of \( \alpha \).

The following lemma confirms that the maximal non-coverage is decreasing in \( w_{EB,i} \), as suggested by the figure. It also gives an expression for the maximal non-coverage across all values of \( w_{EB,i} \) (which is achieved in the limit \( w_{EB,i} \to 0 \)).

**Lemma 4.1.** The non-coverage probability (17) of the parametric EBCI is weakly decreasing
as a function of \( w_{EB,i} \), with the supremum given by \( 1/ \max\{z_{1-\alpha}^2, 1\} \).

The maximal non-coverage probability \( 1/ \max\{z_{1-\alpha/2}^2, 1\} \) equals 0.260 for \( \alpha = 0.05 \) and 0.370 for \( \alpha = 0.10 \). For \( \alpha > 2\Phi(-1) \approx 0.317 \), the maximal non-coverage probability is 1.

If we additionally impose knowledge of the kurtosis of \( \varepsilon_i \), the maximal non-coverage of the parametric EBCI can be similarly computed using Eq. (11), as illustrated in the application in Section 7.

### 4.4 Monte Carlo simulations

Here we show through simulations that the robust EBCI achieves accurate average coverage in finite samples.

#### 4.4.1 Design

The data generating process (DGP) is a simple linear fixed effects panel data model. We first draw \( \theta_i, i = 1, \ldots, n \), i.i.d. from a random effects distribution specified below. Then we simulate panel data from the model

\[
W_{it} = \theta_i + U_{it}, \quad i = 1, \ldots, n, \quad t = 1, \ldots, T,
\]
where the errors $U_{it}$ are mean zero and i.i.d. across $(i,t)$ and independent of the $\theta_i$’s. The unshrunk estimator of $\theta_i$ is the sample average of $W_{it}$ for unit $i$, with standard error obtained from the usual unbiased variance estimator:

$$Y_i = \frac{1}{T} \sum_{t=1}^{T} W_{it}, \quad \hat{\sigma}_i = \sqrt{\frac{1}{T(T-1)} \sum_{t=1}^{T} (W_{it} - Y_i)^2}.$$  

We draw $U_{it}$ from one of two distributions: (1) a normal distribution and (2) a (shifted) chi-squared distribution with 3 degrees of freedom. In case (1), $Y_i$ is exactly normal conditional on $\theta_i$, but $\hat{\sigma}_i^2$ does not exactly equal $\text{var}(Y_i \mid \theta_i)$ for finite $T$. In case (2), $Y_i$ is non-normal and positively skewed (conditional on $\theta_i$) for finite $T$.

We consider six random effects distributions for $\theta_i$ (see Supplemental Appendix E.1 for detailed definitions): (i) normal (kurtosis $\kappa = 3$); (ii) scaled chi-squared with 1 degree of freedom ($\kappa = 15$); (iii) two-point distribution ($\kappa \approx 8.11$); (iv) three-point distribution ($\kappa = 2$); (v) the least favorable distribution for the robust EBCI that exploits only second moments ($\kappa$ depends on $\mu_2$, see Appendix B); and (vi) the least favorable distribution for the parametric EBCI.

Given $T$, we scale the $\theta_i$ distribution to match one of four signal-to-noise ratios $\mu_2/\text{var}(Y_i \mid \theta_i) \in \{0.1, 0.5, 1, 2\}$, for a total of $6 \times 4 = 24$ DGPs for each distribution of $U_{it}$. We shrink towards the grand mean ($X_i = 1$ for all $i$). We construct the robust EBCIs following the baseline implementation in Section 3.2 (with $\omega_i = 1/n$), as well as a version that does not impose constraints on the kurtosis.

As $T \to \infty$, we recover the idealized setting in Section 2, with $(Y_i - \theta_i)/\sqrt{\text{var}(Y_i \mid \theta_i)}$ converging in distribution to a standard normal (conditional on $\theta_i$), and $\hat{\sigma}_i^2/\text{var}(Y_i \mid \theta_i)$ converging in probability to 1, for each $i$.

### 4.4.2 Results

Table 1 shows that the 95% robust EBCIs achieve good average coverage when the panel errors $U_{it}$ are normally distributed. This is true for all DGPs, panel dimensions $n$ and $T$, and whether we exploit one or both of the (estimated) moments $\mu_2$ and $\kappa$. When the time dimension $T$ equals 10, the maximal coverage distortion across all DGPs and all cross-sectional dimensions $n \in \{100, 200, 500\}$ is 3.2 percentage points. For $T \geq 20$, the coverage distortion of the robust EBCIs is always below 2.1 percentage points.

Table 2 shows that coverage distortions are somewhat larger when the panel errors $U_{it}$ are chi-squared distributed and $T$ is small. The robust EBCIs undercover by up to 7.2 percentage points when $T = 10$ due to the pronounced non-normality of $Y_i$ given $\theta_i$. However, the

Notes: Normally distributed errors. Nominal average confidence level $1 - \alpha = 95\%$. All EBCI procedures use baseline estimate of $\hat{\mu}_2$ and (if applicable) $\hat{\kappa}$, except columns labeled “ora”, which use oracle values of $\mu_2$ and $\kappa$. Columns $T = \infty$ and “ora” use oracle standard errors $\sigma_i$. For each DGP, “average coverage” and “average length” refer to averages across units $i = 1, \ldots, n$ and across 2,000 Monte Carlo repetitions. Average CI length is measured relative to the robust EBCI that exploits the oracle values of $\mu_2$, $\kappa$, and $\sigma_i$ (but not of the grand mean $\delta = E[\theta]$).

| $n = 500$      | 1.05  | 1.09  | 1.11  | 1.16 | 0.99  | 1.00  | 1.00    | 1.00 | 0.79  | 0.82  | 0.83    | 0.86 |

Notes: Chi-squared distributed errors. See caption for Table 1. Results for $T = \infty$ are by definition the same as in Table 1.
distortion is at most 4.3 percentage points when \( T = 20 \), and at most 2.4 percentage points when \( T \geq 50 \). The coverage distortion due to non-normality when \( T \) is small is similar to the coverage distortion of the usual unshrunk CI (not reported).

Importantly, in all cases considered in Tables 1 and 2, the worst-case coverage distortion of the parametric EBCI substantially exceeds that of the corresponding robust EBCIs, sometimes by more than 10 percentage points. Nevertheless, the cost of robustness in terms of extra CI length is modest and consistent with the theoretical results in Section 4.2.

Both the estimation of the standard errors \( \sigma_i \) and the estimation of the moments \( \mu_2 \) and \( \kappa \) contribute to the finite-sample coverage distortions. The “ora” columns in Table 1 exploit the oracle (true) values of \( \mu_2, \kappa \), and \( \sigma_i = \sqrt{\text{var}(Y_i | \theta_i)} \), while the \( T = \infty \) columns use oracle standard errors but not oracle moments. By comparing these columns, we see that estimation of \( \mu_2 \) and \( \kappa \) is responsible for modest coverage distortions when \( n = 100 \) or 200. However, estimation of the standard errors \( \sigma_i \) also contributes to the distortions, as can be seen by comparing the \( T = 10 \) and \( T = \infty \) columns.

In Supplemental Appendix E.2 we show that the robust EBCI also has good coverage in a heteroskedastic design calibrated to the empirical application in Section 7 below.

5 Comparison with other approaches

Here we compare our EBCI procedure with other approaches to confidence interval construction in the normal means model. We also discuss other related inference problems.

5.1 Average coverage vs. alternative coverage concepts

The average coverage requirement in Eq. (15) is less stringent than the usual (pointwise) notion of frequentist coverage that \( P(\theta_i \in CI_i | \theta) \geq 1 - \alpha \) for all \( i \). An even stronger coverage requirement is that of simultaneous coverage: \( P(\forall i: \theta_i \in CI_i | \theta) \geq 1 - \alpha \). As discussed in Remark 2.1, under the pointwise coverage criterion, one cannot achieve substantial reductions in length relative to the unshrunk CI. Under the simultaneous coverage criterion, it is likewise impossible to substantially improve upon the usual sup-\( t \) confidence band based on the unshrunk estimates (Cai et al., 2014). Thus, undercoverage for some \( \theta_i \)’s must be tolerated if one wants to use shrinkage to improve CI length.

The fact that our EBCIs achieve improvements in average length at the expense of undercovering for certain units \( i \) is analogous to well-known properties of EB point estimators, as discussed in Remark 2.1. We now show that the units \( i \) for which our EBCI undercovers are quantitatively similar to the units for which the shrinkage estimator \( \hat{\theta}_i \) has higher MSE.
Figure 5: Value of $|\varepsilon_i|/\sqrt{\mu_2}$, as a function of $w_{EB,i}$, such that the MSE of the shrinkage point estimator equals that of the unshrunk estimator (MSE), and such that the coverage of the robust EBCI with $\kappa = \infty$ equals the nominal average coverage $1 - \alpha$ (coverage), for $\alpha = 0.05$.

than the unshrunk estimator $Y_i$. The pointwise coverage of our EBCI (conditional on $X_i$) is given by $1 - r(\sqrt{1/w_{EB,i} - 1} \cdot |\varepsilon_i|/\sqrt{\mu_2}, \text{cva}_\alpha(1/w_{EB,i} - 1, \kappa))$, with $r$ defined in Eq. (4), $w_{EB,i} = \mu_2/(\mu_2 + \sigma_i^2)$, and $\varepsilon_i = \theta_i - X'_i\delta$ is the “shrinkage error” defined in Section 3.1. Since $r$ is increasing in its first argument, for a fixed signal-to-noise ratio $\mu_2/\sigma_i^2$ (and hence fixed amount of shrinkage $w_{EB,i}$), the coverage is decreasing in the normalized shrinkage error $|\varepsilon_i|/\sqrt{\mu_2}$: the units $i$ for which our EBCI undercovers are those whose covariate-predicted value $X'_i\delta$ fails to approximate their true effect $\theta_i$ well. The MSE of the shrinkage estimator (for an individual unit $i$), normalized by the MSE $\sigma_i^2$ of the unshrunk estimator, equals $E[(\hat{\theta}_i - \theta_i)^2 | \theta_i, X_i]/\sigma_i^2 = w_{EB,i}^2 + (1 - w_{EB,i})w_{EB,i} |\varepsilon_i|/\sqrt{\mu_2}$; it is also increasing in $|\varepsilon_i|/\sqrt{\mu_2}$.

Figure 5 shows that the knife-edge value of $|\varepsilon_i|/\sqrt{\mu_2}$ for which the pointwise coverage of our EBCI equals $1 - \alpha$ is quantitatively close to the value of $|\varepsilon_i|/\sqrt{\mu_2}$ for which the MSE of the shrinkage estimator equals that of the unshrunk estimator. In other words, to the extent that one worries about undercoverage for certain types of $\theta_i$ values, one should simultaneously worry about the relative performance of the shrinkage point estimator for those same values.

We stress that the pointwise coverage depends on the unobservable shrinkage error $\varepsilon_i$, which cannot be gauged directly from the observables $(Y_i, X_i)$. If one wishes to avoid systematic differences in coverage across units $i$ with different genders, say (i.e., one is worried that
\( \varepsilon_i \) correlates with gender) one can simply add gender to the set of covariates \( X_i \): the baseline procedure in Section 3.2 ensures control of average coverage conditional on the covariates \( X_i \). In Section 6.2, we show how to adapt our EBCIs to settings where one focuses the analysis on a subset of units \( i \) based on the values of their unshrunk estimates \( Y_i \) (e.g., keeping only the largest estimates).

From a Bayesian point of view, our robust EBCI can be viewed as an uncertainty interval that is robust to the choice of prior distribution in the unconditional gamma-minimax sense: the coverage probability of this CI is at least \( 1 - \alpha \) when averaged over the distribution of the data and over the prior distribution for \( \theta_i \), for any prior distribution that satisfies the moment bounds. This follows directly from the derivations in Section 2, reinterpreting the random effects distribution for \( \theta_i \) as a prior distribution. In contrast, conditional gamma-minimax credible intervals, discussed recently by Giacomini et al. (2019, p. 6), are too stringent in our setting. This notion requires that the posterior credibility of the interval be at least \( 1 - \alpha \) regardless of the choice of prior, in any data sample, which would require reporting the entire parameter space (up to the moment bounds).

### 5.2 Finite-sample vs. asymptotic coverage

Our procedures are asymptotically valid as \( n \to \infty \), as proved in Section 4.1. These asymptotics do not capture the impact of estimation error in the “hyper-parameters” \( \hat{\sigma}_i, \hat{\delta}, \hat{\mu}_2, \) and \( \hat{\kappa} \), or the impact of lack of exact normality of the \( Y_i \)'s, on the finite-sample performance of the EBCIs. As detailed in Section 3.2 and Appendix A, we do apply a finite-sample adjustment to the moments \( \hat{\mu}_2 \) and \( \hat{\kappa} \), which is motivated by the same heuristic arguments that Morris (1983a,b) uses to motivate finite-sample adjustments to the parametric EBCI.\(^8\)

The promising simulation results in Section 4.4 notwithstanding, these adjustments do not ensure exact average coverage control in finite samples.\(^9\)

Our results are thus analogous to the results on coverage of Eicker-Huber-White CIs in cross-sectional OLS: asymptotic validity follows by consistency of the OLS variance estimate and asymptotic normality of the outcomes, while adjustments to account for finite-sample issues (such as the HC2 or HC3 variance estimators studied in MacKinnon and White, 1985) are justified heuristically. Deriving EBCIs with finite-sample coverage guarantees is an interesting problem that we leave for future research; the problem appears to be challenging.

\(^8\)An alternative approach would be to adapt the bootstrap adjustment proposed by Carlin and Louis (2000, Ch. 3.5.3) in the context of parametric EBCI construction (see also Efron, 2019). As with the Morris (1983a,b) adjustment, we are not aware of a formal result justifying it.

\(^9\)Alternatively, one could account for hyperparameter uncertainty by computing the critical value \( \sup_{\hat{\sigma}_i, \hat{\mu}_2, \hat{\kappa} \in \hat{C}_i} \text{cv}_\alpha(\hat{\sigma}_i^2/\hat{\mu}_2, \hat{\kappa}) \) over an initial confidence set \( \hat{C}_i \) for the hyper-parameters, coupled with a Bonferroni adjustment of the confidence level \( 1 - \alpha \). This approach appears to be highly conservative in practice.
even in the context of constructing parametric EBCIs.

5.3 Local vs. global optimality

Our EBCIs are designed to provide uncertainty assessments to accompany linear shrinkage estimates that, as the Introduction argues, have been popular in applied work. Our procedure’s global validity, as well as local near-optimality when the \( \theta_i \)’s are normal (cf. Section 4.2), is analogous to Eicker-Huber-White CIs for OLS estimators: these CIs are optimal under normal homoskedastic regression errors, but remain valid when this assumption is dropped.

Our EBCIs are, however, not globally efficient: when the \( \theta_i \)’s are not normally distributed, one may construct shorter CIs using non-linear shrinkage. In Section 6.1, we show how our method can be adapted to construct EBCIs that are locally near-optimal under non-normal baseline priors using non-linear shrinkage, such as soft thresholding. Since the distribution of \( \theta_i \) is nonparametrically identified under the normal sampling model (8), it is in principle possible to construct EBCIs that are globally efficient using nonparametric methods. In the context of the homoskedastic model with no covariates in Eq. (1), various approaches to nonparametric point estimation of the \( \theta_i \)’s have been proposed, including kernels (Brown and Greenshtein, 2009), splines (Efron, 2019), or nonparametric maximum likelihood (Kiefer and Wolfowitz, 1956; Jiang and Zhang, 2009; Koenker and Mizera, 2014). It is an interesting problem for future research to adapt these methods to EBCI construction, while ensuring asymptotic validity, good finite-sample performance, and allowing for covariates, heteroskedasticity, and possible dependence across \( i \).

5.4 Other inference problems

While we have sought to construct CIs for each of the \( n \) effects \( \theta_1, \ldots, \theta_n \), other papers have considered alternative inference problems in the normal means model. Efron (2015) develops a formula for the frequentist standard error of EB estimators, but this cannot be used to construct CIs without a corresponding estimate of the bias. Bonhomme and Weidner (2021) and Ignatiadis and Wager (2021) consider robust estimation and inference on functionals of the random effects distribution, rather than on the effects themselves. Finally, there is a substantial literature on shrinkage confidence balls, i.e., confidence sets of the form \( \{ \theta : \sum_{i=1}^n (\theta_i - \hat{\theta}_i)^2 \leq \hat{c} \} \) (see Casella and Hwang, 2012, for a review). While interesting from a theoretical perspective, these sets can be difficult to visualize and report in practice.\(^{10}\)

\(^{10}\)Confidence balls can be translated into intervals satisfying the average coverage criterion using Chebyshev’s inequality (see Wasserman, 2006, Ch. 5.8). However, the resulting intervals are very conservative compared to the ones we construct.
Finally, while we focus on CI length in our relative efficiency comparisons, our approach can be fruitfully applied when the goal of CI construction is to discern non-null effects, rather than to construct short CIs. In particular, suppose one forms a test of the null hypothesis $H_{0,i} : \theta_i = \theta_0$ for some null value $\theta_0$ by rejecting when $\theta_0 \notin CI_i$, where $CI_i$ is our robust EBCI given in (12). In Supplemental Appendix F, we show that the test based on our EBCI has higher average power than the usual $z$-test based on the unshrunk estimate when $X_i'\delta$ (the regression line towards which we shrink) is far enough from the null value $\theta_0$, and that these power gains can be substantial. Furthermore, such tests can be combined with corrections from the multiple testing literature to form procedures that asymptotically control the false discovery rate (FDR), a commonly used criterion for multiple testing.\footnote{In particular, Storey (2002) shows that the Benjamini and Hochberg (1995) procedure asymptotically controls the FDR so long as the $p$-values do not exhibit too much statistical dependence and the proportion of rejected null hypotheses does not converge too quickly to zero. While Storey (2002) assumes that the uncorrected tests control size in the classical sense, the argument goes through essentially unchanged so long as the tests invert CIs that satisfy (16), which holds so long as the CIs do not exhibit too much statistical dependence, as discussed in Remark 4.1. We note, however, that this does not hold for modifications of the Benjamini and Hochberg (1995) procedure that use initial estimates of the proportion of true null hypotheses.}

6 Extensions

We now discuss two extensions of our method: adapting our intervals to general, possibly non-linear shrinkage, and constructing intervals that achieve coverage conditional on $Y_i$ falling into a pre-specified interval.

6.1 General shrinkage

Our method can be generalized to cover general, possibly non-linear shrinkage based on possibly non-Gaussian data. Let $S(y; \chi, \tilde{X}_i) \subseteq \mathbb{R}$ be a family of candidate confidence sets for a parameter $\theta_i$, which depends on the data $Y_i = y$, a tuning parameter $\chi \in \mathbb{R}$ to be selected below, and covariates $\tilde{X}_i$ (that include any known nuisance parameters) that we treat as fixed. We assume that $S$ is increasing in $\chi$, in the sense of set containment, and that the non-coverage probability conditional on $\theta$ satisfies

$$P(\theta_i \notin S(Y_i; \chi, \tilde{X}_i) \mid \theta, \tilde{X}^{(n)}) = \tilde{r}(a_i, \chi),$$

where $a_i$ is some function of $\theta_i$, $\tilde{X}^{(n)} = (\tilde{X}_1, \ldots, \tilde{X}_n)$, and $\tilde{r}$ is a known function (perhaps computed numerically or through simulation). Similarly to linear shrinkage in the normal means model, Eq. (18) may only hold approximately if the set $S$ depends on estimated
parameters (such as standard error estimates or tuning parameters), or if we use a large-sample approximation to the distribution of $Y_i$. We assume that $a_i$ satisfies the moment constraints $E_F[g(a_i) | \tilde{X}^{(n)}] = m$, where $g$ is a $p$-vector of moment functions,\footnote{The moment functions $g$ need not be simple moments, and could incorporate constraints used for selection of hyper-parameters, such as constraints on the marginal data distribution or, if an unbiased risk criterion is used, the constraint that the derivative of the risk equals zero at the selected prior hyper-parameters.} and the expectation is over the conditional distribution $F$ of $a_i$ conditional on $\tilde{X}^{(n)}$. To guarantee EB coverage, we compute the maximal non-coverage

$$\rho_g(m, \chi) = \sup_{F} E_F[\tilde{r}(a, \chi)], \quad E_F[g(a)] = m,$$

(19)

analogously to Eq. (11). This is a linear program, which can be computed numerically to a high degree of precision even with several constraints; see Appendix B for details. Given an estimate $\hat{m}$ of the moment vector $m$, we form a robust EBCI as

$$S(Y_i; \hat{\chi}, \tilde{X}_i), \quad \text{where} \quad \hat{\chi} = \inf\{\chi : \rho_g(\hat{m}, \chi) \leq \alpha\}.\quad (20)$$

**Example 6.1** (Linear shrinkage in the normal model). The setting in Section 3.1 obtains if we set $\tilde{X}_i = (X_i, \sigma_i)$ and $S(y; \chi, \tilde{X}_i) = \{(1 - w_{EB,i})X'_i\delta + w_{EB,i}Y_i \pm \chi w_{EB,i}\sigma_i\}$. Here $a_i$ is given by the normalized bias $b_i = (1/w_{EB,i} - 1)(\theta_i - X'_i\delta)/\sigma_i$, and the function $\tilde{r}$ is given by the function $r(b, \chi)$ defined in (4). Our baseline implementation uses constraints on the second and fourth moments, $g(a_i) = (a_i^2, a_i^4)$.

**Example 6.2** (Nonlinear soft thresholding). Consider for simplicity the homoskedastic normal model $Y_i | \theta_i \sim N(\theta_i, \sigma^2)$ without covariates. A popular alternative to linear estimators is the soft thresholding estimator $\hat{\theta}_{ST,i} = \text{sign}(Y_i) \max\{|Y_i| - \sqrt{2/\mu_2}, 0\}$ (e.g. Abadie and Kasy, 2019). It equals the posterior mode corresponding to a baseline Laplace prior with second moment $\mu_2$, which has density $\pi_0(\theta) = \frac{1}{\sqrt{2\mu_2}} \exp(-|\theta|\sqrt{2/\mu_2})$ (Johnstone, 2019, Example 2.5). To construct a robust EBCI that always contains the soft thresholding estimator, we calibrate the corresponding highest posterior density set:

$$S(Y_i; \chi) = \left\{ t \in \mathbb{R} : \log \frac{\sigma^{-1}\phi((Y_i - t)/\sigma)\pi_0(t)}{\int_{-\infty}^{\infty} \sigma^{-1}\phi((Y_i - \theta)/\sigma)\pi_0(\theta) d\theta} + \chi \geq 0 \right\},$$

(21)

where $\phi$ is the standard normal density. This set is available in closed form and takes the form of an interval (see Supplemental Appendix G.1). Here $a_i = \theta_i$, and the function $\tilde{r}(a, \chi)$ in (18) can be computed via numerical integration.

In Supplemental Appendix G.1, we show that the resulting robust EBCI that imposes
the constraint $E[\theta_i^2] = \mu_2$ not only has robust EB coverage (by definition), it also achieves substantial expected length improvements when the $\theta_i$’s are in fact Laplace distributed. For $\alpha = 0.05$ and $\mu_2/\sigma^2 \leq 0.2$, the expected length under the Laplace distribution of the soft thresholding EBCI is at least 49% smaller than the length of the unshrunk CI. This exceeds the length reduction achieved by the linear robust EBCI shown in Figure 3.

Example 6.3 (Poisson shrinkage). Supplemental Appendix G.2 constructs a robust EBCI for the rate parameter $\theta_i$ in a Poisson model $Y_i \mid \theta_i \sim \text{Poisson}(\theta_i)$. This example demonstrates that our general approach does not require normality of the data.

Example 6.4 (Linear estimators in other settings). While our focus has been on EB shrinkage, our approach applies to other settings in which an estimator $\hat{\theta}_i$ is approximately normally distributed with non-negligible bias. In particular, suppose $(\hat{\theta}_i - \theta_i)/\text{se}_i$ is distributed $N(a_i, 1)$, where $\text{se}_i$ is the standard deviation of the estimate $\hat{\theta}_i$, which for simplicity we take to be known. This holds whenever $\hat{\theta}_i$ is a linear function of jointly normal observations $W_1, \ldots, W_N$, i.e., $\hat{\theta}_i = \sum_{j=1}^N k_{ij}W_j$ for some deterministic weights $k_{ij}$. Examples include series, kernel, or local polynomial estimators in a nonparametric regression with fixed covariates and normal errors. We can construct a confidence interval for $\theta_i$ as $\hat{\theta}_i \pm \chi \cdot \text{se}_i$, in which case Eq. (18) holds with $\tilde{r} = r$ given in Eq. (4). It follows from Theorem C.1 in Appendix C that if the moment constraints $m$ on the normalized bias in Eq. (19) are replaced by consistent estimates, the resulting robust EBCI will satisfy the average coverage property (15) in large samples. We leave a full treatment of these applications for future research.

6.2 Coverage after selection

In some applications, researchers may be primarily interested in the $\theta_i$ parameters corresponding to those units $i$ whose initial $Y_i$ estimates fall in a given interval $[\iota_1, \iota_2]$, where $-\infty \leq \iota_1 < \iota_2 \leq \infty$. For example, in a teacher value added application, we may only be interested in the ability $\theta_i$ of those teachers $i$ whose fixed effect estimates $Y_i$ are positive, corresponding to setting $\iota_1 = 0$ and $\iota_2 = \infty$. Because of the selection on outcomes, naively applying our baseline EBCI procedure to the selected sample $\{i: Y_i \in [\iota_1, \iota_2]\}$ does not yield the desired average coverage across the selected units $i$ (the same issue arises with classical CIs; see Benjamini and Yekutieli, 2005; Lee et al., 2016; Andrews et al., 2021). We now show how to correct for the selection bias in the simple homoskedastic model $Y_i \mid \theta_i \sim N(\theta_i, \sigma^2)$ without covariates from Section 2 (reintroducing the extra model features in Section 3.1 only complicates notation).

We seek a critical value $\chi$ such that the average coverage of the CI $[\hat{\theta}_i \pm \chi w_{EB}\sigma]$ is at
least $1 - \alpha$ conditional on the sample selection, i.e.,

$$P(\theta_i \in \hat{\theta}_i \pm \chi_{EB}\sigma \mid Y_i \in [t_1, t_2]) \geq 1 - \alpha$$

under repeated sampling of $(Y_i, \theta_i)$, regardless of the distribution for $\theta_i$. Straightforward calculations show that the conditional (on $\theta_i$ and on selection) non-coverage equals

$$\tilde{r}_{t_1, t_2}(\theta_i, \chi) = P(\theta_i \not\in \hat{\theta}_i \pm \chi_{EB}\sigma \mid Y_i \in [t_1, t_2], \theta_i)$$

$$= \min \left\{ 1 - \frac{\Phi(\min\{\chi - b_i, (t_2 - \theta_i)/\sigma\}) - \Phi(\max\{-\chi - b_i, (t_1 - \theta_i)/\sigma\})}{\Phi((t_2 - \theta_i)/\sigma) - \Phi((t_1 - \theta_i)/\sigma)}, 1 \right\},$$

where $b_i = (1 - 1/w_{EB})\theta_i/\sigma$ as in Section 2. Among all distributions for $\theta_i$ consistent with the conditional moment $\tilde{\mu}_{2,t_1,t_2} = E[\theta_i^2 \mid Y_i \in [t_1, t_2]]$, the worst-case non-coverage probability, conditional on selection, is given by

$$\tilde{\rho}_{t_1, t_2}(\tilde{\mu}_{2,t_1,t_2}, \chi) = \sup_F E_F[\tilde{r}_{t_1, t_2}(\theta_i, \chi)] \quad \text{s.t.} \quad E_F[\theta_i^2] = \tilde{\mu}_{2,t_1,t_2},$$

where $E_F$ denotes expectation under $\theta_i \sim F$. This is an infinite-dimensional linear program that can be solved numerically to a high degree of accuracy, cf. Appendix B. To achieve robust conditional coverage, we solve numerically for the $\chi$ such that $\tilde{\rho}_{t_1, t_2}(\tilde{\mu}_{2,t_1,t_2}, \chi) = \alpha$.

We can estimate the conditional second moment $\hat{\mu}_{2,t_1,t_2}$ as follows. Denote the log marginal density of $Y_i$ by $\ell(y) \equiv \log \int \phi(y - \theta) d\Gamma_0(\theta)$, where $\Gamma_0$ is the true distribution of $\theta_i$. Tweedie’s formulas (e.g. Efron, 2019, Eq. (26)) imply

$$\hat{\mu}_{2,t_1,t_2} = E[\theta_i^2 \mid Y_i \in [t_1, t_2]] = 1 + E[(Y_i + \hat{\ell}'(Y_i))^2 + \hat{\ell}''(Y_i) \mid Y_i \in [t_1, t_2]]. \quad (22)$$

Let $\hat{\ell}(y)$ be a kernel estimate of the log marginal density function of the data $Y_1, \ldots, Y_n$. Then the estimate

$$\hat{\mu}_{2,t_1,t_2} \equiv 1 + \frac{\sum_{i: Y_i \in [t_1, t_2]} \{(Y_i + \hat{\ell}'(Y_i))^2 + \hat{\ell}''(Y_i)\}}{\# \{i: Y_i \in [t_1, t_2] \}}$$

will be consistent as $n \to \infty$ for $\hat{\mu}_{2,t_1,t_2}$ in (22) under mild regularity conditions.

### 7 Empirical application

We illustrate our methods using the data and model in Chetty and Hendren (2018), who are interested in the effect of neighborhoods on intergenerational mobility.
7.1 Framework

We adopt the main specification of Chetty and Hendren (2018), which focuses on two definitions of a “neighborhood effect” $\theta_i$. The first defines it as the effect of spending an additional year of childhood in commuting zone (CZ) $i$ on children’s rank in the income distribution at age 26, for children with parents at the 25th percentile of the national income distribution. The second definition is analogous, but for children with parents at the 75th percentile. Using de-identified tax returns for all children born between 1980 and 1986 who move across CZs exactly once as children, Chetty and Hendren (2018) exploit variation in the age at which children move between CZs to obtain preliminary fixed effect estimates $Y_i$ of $\theta_i$.

Since these preliminary estimates are measured with noise, to predict $\theta_i$, Chetty and Hendren (2018) shrink $Y_i$ towards average outcomes of permanent residents of CZ $i$ (children with parents at the same percentile of the income distribution who spent all of their childhood in the CZ). To give a sense of the accuracy of these forecasts, Chetty and Hendren (2018) report estimates of their unconditional MSE (i.e. treating $\theta_i$ as random), under the implicit assumption that the moment independence assumption in Eq. (10) holds. Here we complement their analysis by constructing robust EBCIs associated with these forecasts.

Our sample consists of 595 U.S. CZs, with population over 25,000 in the 2000 census, which is the set of CZs for which Chetty and Hendren (2018) report baseline fixed effect estimates $Y_i$ of the effects $\theta_i$. These baseline estimates are normalized so that their population-weighted mean is zero. Thus, we may interpret the effects $\theta_i$ as being relative to an “average” CZ. We follow the baseline implementation from Section 3.2 with standard errors $\hat{\sigma}_i$ reported by Chetty and Hendren (2018), and covariates $X_i$ corresponding to a constant and the average outcomes for permanent residents. In line with the original analysis, we use precision weights $\omega_i = 1/\hat{\sigma}_i^2$ when constructing the estimates $\hat{\delta}, \hat{\mu}_2$ and $\hat{\kappa}$.

7.2 Results

Columns (1) and (2) in Table 3 summarize the main estimation and efficiency results. The shrinkage magnitude and relative efficiency results are similar for children with parents at the 25th and 75th percentiles of the income distribution. In both columns, the estimate of the kurtosis $\kappa$ is large enough so that it does not affect the critical values or the form of the optimal shrinkage: specifications that only impose constraints on the second moment yield identical results.\(^{13}\) In line with this finding, a density plot of the $t$-statistics (reported as Figure S2 in Armstrong et al. (2020)) exhibits a fat lower tail. As a robustness check,\(^{13}\) the truncation in the $\hat{\kappa}$ formula in our baseline algorithm in Section 3.2 binds in columns (1) and (2), although the non-truncated estimates 345.3 and 5024.9 are similarly large; using these non-truncated estimates yields identical results.

\(^{13}\)The truncation in the $\hat{\kappa}$ formula in our baseline algorithm in Section 3.2 binds in columns (1) and (2), although the non-truncated estimates 345.3 and 5024.9 are similarly large; using these non-truncated estimates yields identical results.

Notes: Columns (1) and (2) correspond to shrinking $Y_i$ as in the baseline implementation that imposes Eq. (10), so that $\mu_{2i} = E[(\theta_i - X_i\delta)^2 | X_i, \sigma_i]$ and $\kappa_i = E[(\theta_i - X_i\delta)^4 | X_i, \sigma_i]/\mu_{2i}^2$ do not vary with $i$. Columns (3) and (4) use nonparametric estimates of $\mu_{2i}$ and $\kappa_i$, using the nearest neighbor estimator described in Appendix A.1. The number of nearest neighbors $J = 422$ (Column (3)) and $J = 525$ (Column (4)) is selected using cross-validation. For all columns, $\hat{\delta} = (\hat{\delta}_{\text{intercept}}, \hat{\delta}_{\text{perm. resident}})$ is computed by regressing $Y_i$ onto a constant and outcomes for permanent residents. “Optimal Robust EBCI” refers to a robust EBCI based on length-optimal shrinkage $w_{opt,i}$, described in Section 4.2. “$E[\text{non-cov of parametric EBCI}_i]$: average of maximal non-coverage probability of parametric EBCI, given the estimated moments.
Figure 6: Neighborhood effects for New York and 90% robust EBCIs for children with parents at the $p = 25$ percentile of the national income distribution, plotted against mean outcomes of permanent residents. Gray lines correspond to CIs based on unshrunk estimates represented by circles, and black lines correspond to robust EBCIs based on EB estimates represented by squares that shrink towards a dotted regression line based on permanent residents’ outcomes. Baseline implementation as in Section 3.2.

Columns (3) and (4) report results based on nonparametric moment estimates (see Remark 3.2 and Appendix A.1): the results are very similar. Indeed, the $R^2$ gain in predicting $\hat{\varepsilon}_i^2 - \hat{\sigma}_i^2$ using $\hat{\mu}_i$ is less than 0.001 in both specifications, indicating that there is little evidence in the data against the moment independence assumption.

The baseline robust 90% EBCIs are 75.2–87.7% shorter than the usual unshrunk CIs $Y_i \pm z_{1-\alpha/2}\hat{\sigma}_i$. To interpret these gains in dollar terms, for children with parents at the 25th percentile of the income distribution, a percentile gain corresponds to an annual income gain of $818 (Chetty and Hendren, 2018, p. 1183). Thus, the average half-length of the baseline robust EBCIs in column (1) implies CIs of the form $\pm$160 on average, while the unshrunk CIs are of the form $\pm$643 on average. These large gains are a consequence of a low signal-to-noise ratio $\mu_2/\sigma_i^2$ in this application. Because the shrinkage magnitude is so large on average, the tail behavior of the bias matters, and since the kurtosis estimates suggest these tails are fat, it is important to use the robust critical value: the parametric EBCI exhibits average potential size distortions of 12.7–17.8 percentage points. Indeed, for over 90% of the CIs in the specifications in columns (1) and (2), the shrinkage coefficient $w_{EB,i}$ falls below the “rule of thumb” threshold of 0.3 derived in Section 4.3.
To visualize these results, Figure 6 plots the unshrunk 90% CIs based on the preliminary estimates, as well as robust EBCIs based on EB estimates for cities in the state of New York for children with parents at the 25th percentile. While the EBCIs for large CZs like New York City or Buffalo are similar to the unshrunk CIs, they are much tighter for smaller CZs like Plattsburgh or Watertown, with point estimates that shrink the preliminary estimates $Y_i$ most of the way toward the regression line $X_i'\delta$.

In summary, using shrinkage allows us to considerably tighten the CIs based on preliminary estimates. This is true even though the CIs only effectively use second moment constraints—imposing constraints on the kurtosis does not affect the critical values in this application.

Appendix A  Moment estimates

The EBCI in our baseline implementation has valid EB coverage asymptotically as $n \to \infty$, so long as the estimates $\hat{\mu}_2$ and $\hat{\kappa}$ are consistent. While the particular choice of the estimates $\hat{\mu}_2$ and $\hat{\kappa}$ does not affect the CI asymptotically, finite sample considerations can be important for small to moderate values of $n$. In particular, unrestricted moment-based estimates of $\mu_2$ and $\kappa$ may fall below their theoretical lower bounds of 0 and 1, in which case it is not clear how to define the EBCI.\(^{14}\) To address this issue, in analogy to finite-sample corrections to parametric EBCIs proposed in Morris (1983a,b), Appendix A.1 derives two finite-sample corrections to the unrestricted estimates that approximate a Bayesian estimate under a flat hyperprior on $(\mu_2, \kappa)$. We verify that these corrections give good coverage in an extensive set of Monte Carlo designs in Section 4.4. We also discuss implementation of nonparametric moment estimates. Appendix A.2 discusses the choice of weights $\omega_i$.

A.1 Finite $n$ corrections and nonparametric moment estimates

To derive our estimates of $\mu_2$ and $\kappa$, we first consider unrestricted estimation under the moment independence condition (10). For $\mu_2$, this condition implies the moment condition

$$E[(Y_i - X_i'\delta)^2 - \sigma_i^2 | X_i, \sigma_i] = \mu_2.$$

Replacing $Y_i - X_i'\delta$ with the residual $\hat{\varepsilon}_i = Y_i - X_i'\hat{\delta}$ yields the estimate

$$\hat{\mu}_{2,UC} = \frac{\sum_{i=1}^{n} \omega_i W_{2i}}{\sum_{i=1}^{n} \omega_i}, \quad W_{2i} = \hat{\varepsilon}_i^2 - \hat{\sigma}_i^2,$$

for any weights $\omega_i = \omega_i(X_i, \hat{\sigma}_i)$. Here, UC stands for “unconstrained,” since the estimate $\hat{\mu}_{2,UC}$ can be negative. To incorporate the constraint $\mu_2 > 0$, we use an approximation

\(^{14}\)Formally, our results are asymptotic and require $\mu_2 > 0$ and $\kappa > 1$, so that these issues do not occur when $n$ is large enough. We discuss the difficulty of providing finite-sample coverage guarantees in Section 5.
where we compute the posterior mean given $\hat{\mu}_2$. For simplicity, we compute the posterior mean given $\hat{\mu}_{2,UC}$, and we use a normal approximation to the likelihood. Since the posterior distribution only uses knowledge of $\hat{\mu}_{2,UC}$, we refer to this as a flat prior limited information Bayes (FPLIB) approach.

To derive this formula, first note that, if $\hat{m}$ is an estimate of a parameter $m$ with $\hat{m} \mid m \sim N(m, V)$, then under a flat prior for $m$ on $[0, \infty)$, the posterior mean of $m$ is given by

$$b(\hat{m}, V) = \hat{m} + \sqrt{V} \phi(\hat{m}/\sqrt{V})/\Phi(\hat{m}/\sqrt{V}),$$

where $\phi$ and $\Phi$ are the standard normal pdf and cdf respectively. Furthermore, if $\hat{m} = \sum_{i=1}^{n} \omega_i Z_i / \sum_{i=1}^{n} \omega_i$ where the $Z_i$'s are independent with mean $m$ conditional on the weights $\omega = (\omega_1, \ldots, \omega_n)'$, then an unbiased estimate of the variance of $\hat{m}$ given $\omega$ is given by

$$V(Z, \omega) = \frac{\sum_{i=1}^{n} \omega_i^2 (Z_i^2 - \hat{m}^2)}{(\sum_{i=1}^{n} \omega_i)^2 - \sum_{i=1}^{n} \omega_i^2}.$$ 

Conditioning on the $X_i$'s and $\sigma_i$'s (and ignoring sampling variation in $\hat{\delta}$ and the $\hat{\sigma}_i$'s), we can then apply this formula to $\hat{\mu}_{2,UC}$, with $Z_i = W_{2i}$, where $W_{2i}$ is given in (23). This gives the FPLIB estimate for $\mu_2$:

$$\hat{\mu}_{2,FPLIB} = b(\hat{\mu}_{2,UC}, V(W_2, \omega)).$$

To derive the FPLIB estimate for $\kappa$, we begin with an unconstrained estimate of $\mu_4 = E[(\theta_i - X_i' \delta)^4]$. The moment independence condition (10) delivers the moment condition $\mu_4 = E[(Y_i - X_i' \delta)^4 + 3 \sigma_i^4 - 6 \sigma_i^2 (Y_i - X_i' \delta)^2 \mid X_i, \sigma_i]$, which leads to the unconstrained estimate

$$\hat{\mu}_{4,UC} = \frac{\sum_{i=1}^{n} \omega_i W_{4i}}{\sum_{i=1}^{n} \omega_i}, \quad W_{4i} = \varepsilon_i^4 - 6 \hat{\sigma}_i^2 \varepsilon_i^2 + 3 \hat{\delta}_i^4.$$ 

To avoid issues with small values of estimates of $\mu_2$ in the denominator, we apply the FPLIB approach to an estimate of $\mu_4 - \mu_2^2$, using a flat prior on the parameter space $[0, \infty)$. Using the delta method leads to approximating the variance of $\hat{\mu}_{4,UC} - \hat{\mu}_{2,UC}^2$ with the variance of $\sum_{i=1}^{n} \omega_i (W_{4i} - 2\mu_2 W_{2i}) / \sum_{i=1}^{n} \omega_i$, so that the FPLIB estimate of $\mu_4 - \mu_2^2$ is $b(\hat{\mu}_{4,UC} - \hat{\mu}_{2,UC}^2, V(W_4 - 2\hat{\mu}_{2,FPLIB} W_2, \omega))$, and the FPLIB estimate of $\kappa$ is

$$\hat{\kappa}_{FPLIB} = 1 + \frac{b(\hat{\mu}_{4,UC} - \hat{\mu}_{2,UC}^2, V(W_4 - 2\hat{\mu}_{2,FPLIB} W_2, \omega))}{\hat{\mu}_{2,FPLIB}}.$$
As a further simplification, we derive approximations in which the posterior mean formula \( b(\hat{m}, V) \) is replaced by a simple truncation formula. We refer to this approach as posterior mean trimming (PMT). In particular, suppose we apply the formula \( b(\hat{m}, V) \) to an estimator \( \hat{m} \) such that \( \hat{m} \geq m_0 \) and \( V \geq V_0 \) by construction, where \( m_0 < 0 \). Then the posterior mean satisfies \( b(\hat{m}, V) \geq b(m_0, V_0) \) (Pinelis, 2002, Proposition 1.2). Thus, a simple approximation to the FPLIB estimator is to truncate \( \hat{m} \) from below at \( b(m_0, V_0) \). To obtain an even simpler formula, we use the approximation \( b(m_0, V_0) = -V_0/m_0 + O(V_0^{3/2}) \) (Pinelis, 2002, Proposition 1.3), which holds as \( V_0 \to 0 \) (or, equivalently, as \( n \to \infty \), provided the estimator \( \hat{m} \) is consistent). The variance of \( \hat{\mu}_{2,UC} \) conditional on \((X_i, \sigma_i)\) is bounded below by \( 2 \sum_{i=1}^{n} \omega_i^2 \sigma_i^4 / (\sum_{i=1}^{n} \omega_i)^2 \), and \( \hat{\mu}_{2,UC} \geq -\sum_{i=1}^{n} \omega_i \sigma_i^2 / \sum_{i=1}^{n} \omega_i \), so we can use \( V_0/m_0 = -\sum_{i=1}^{n} \omega_i \sigma_i^2 / \sum_{i=1}^{n} \omega_i \), which gives the PMT estimator

\[
\hat{\mu}_{2,PMT} = \max \left\{ \hat{\mu}_{2,UC}, \frac{2 \sum_{i=1}^{n} \omega_i^2 \sigma_i^4}{\sum_{i=1}^{n} \omega_i \sigma_i^2 \cdot \sum_{i=1}^{n} \omega_i} \right\}.
\]

For \( \kappa \), we simplify our approach to deriving a trimming rule by treating \( \mu_2 \) as known, and considering the variance of the infeasible estimate \( \hat{\kappa}_{UC}^* = \frac{\sum_{i=1}^{n} \omega_i (\omega_i^2 - 6 \omega_i^2 \mu_2 - 3 \sigma_i^4)}{\mu_2^2 \sum_{i=1}^{n} \omega_i} \). Using the above truncation formula for \( \hat{\kappa}_{UC}^* - 1 \) along with the fact that \( \hat{\kappa}_{UC}^* \geq \frac{\sum_{i=1}^{n} \omega_i (\omega_i^2 - 6 \omega_i^2 \mu_2 - 3 \sigma_i^4)}{\mu_2^2 \sum_{i=1}^{n} \omega_i} \) and the lower bound \( 8 \sum_{i=1}^{n} \omega_i^2 (2 \mu_2^2 \sigma_i^2 + 21 \mu_2^2 \sigma_i^4 + 48 \mu_2 \sigma_i^6 + 12 \sigma_i^8) / \mu_2^4 (\sum_{i=1}^{n} \omega_i)^2 \) on the variance yields \( V_0/m_0 = -\frac{32 \sum_{i=1}^{n} \omega_i^2 \sigma_i^8}{\mu_2^2 (\sum_{i=1}^{n} \omega_i) \sum_{i=1}^{n} \omega_i \sigma_i^4} + o(1/\mu_2) \). To simplify the trimming rule even further, we only use the leading term of \( V_0/m_0 \) as \( \mu_2 \to 0 \), \( V_0/m_0 = -\frac{32 \sum_{i=1}^{n} \omega_i^2 \sigma_i^8}{\mu_2^2 (\sum_{i=1}^{n} \omega_i) \sum_{i=1}^{n} \omega_i \sigma_i^4} + o(1/\mu_2) \). Plugging in \( \hat{\mu}_{2,PMT} \) in place of the unknown \( \mu_2 \) then gives the PMT estimator

\[
\hat{\kappa}_{PMT} = \max \left\{ \frac{\hat{\mu}_{4,UC}}{\hat{\mu}_{2,PMT}^2}, 1 + \frac{32 \sum_{i=1}^{n} \omega_i^2 \sigma_i^8}{\hat{\mu}_{2,PMT}^2 \sum_{i=1}^{n} \omega_i \cdot \sum_{i=1}^{n} \omega_i \sigma_i^4} \right\}.
\]

The estimators in step 1 of our baseline implementation in Section 3.2 correspond to \( \hat{\mu}_{2,PMT} \) and \( \hat{\kappa}_{PMT} \), due to their slightly simpler form relative to the FPLIB estimators. In unreported simulations based on the designs described in Section 4.4 and Supplemental Appendix E.2, we find that EBCIs based on FPLIB lead to even smaller finite-sample coverage distortions than those based on the baseline implementation that uses PMT, at the expense of slightly longer average length.

To implement the nonparametric estimates \( \hat{\kappa}_i \) and \( \hat{\mu}_2 \) in Remark 3.2, we use the nearest-neighbor estimator that for each \( i \) computes the PMT estimates \( \hat{\mu}_{2,PMT} \) and \( \hat{\kappa}_{PMT} \) described above, using only the \( J \) observations closest to \( i \), rather than the full sample of \( n \) observations. We define distance as a Euclidean distance on \((X_i, \sigma_i)\), after scaling elements of this vector by their standard deviations. Under regularity conditions, the resulting estimates will be
consistent for $\mu_{2i}$ and $\kappa_i$, so long as $J \to \infty$ and $J/n \to 0$. We select $J$ using leave-one-out cross-validation, using the squared prediction error in predicting $W_{2i}$ as the criterion. For simplicity, we use the same $J$ for estimating the kurtosis as that used for estimating the second moment.

A.2 Choice of weighting

Under condition (10), the weights $\omega_i$ used to estimate $\mu_2$ and $\kappa$ can be any function of $X_i, \sigma_i$. Furthermore, while $\hat{\delta}$ can be essentially arbitrary as long as it converges in probability to some $\delta$ such that Eq. (10) holds, that equation will often be motivated by the assumption that the conditional mean of $\theta_i$ is linear in $X_i$,

$$E[\theta_i - X'_i \delta \mid X_i, \sigma_i] = 0. \quad (24)$$

Under this condition, the weights $\omega_i$ used to estimate $\delta$ can also be any function of $X_i, \sigma_i$.

Thus, under conditions (10) and (24), the choice of weighting can be guided by efficiency considerations. In general, the optimal weights are different for each of the three estimates of $\delta, \mu_2$, and $\kappa$, and implementing them requires first stage estimates of the variances of $Y_i, W_{2i}$ and $W_{4i}$, conditional on $(X_i, \sigma_i)$ (with $W_{2i}$ and $W_{4i}$ defined in Appendix A.1). To avoid estimation of these variances, consider the limiting case where the signal-to-noise ratio goes to 0, i.e. $\mu_2/\min_i \sigma_i^2 \to 0$. The resulting weights will be near-optimal under a low signal-to-noise ratio, when precise estimation of these parameters is relatively more important for accurate coverage (under a high signal-to-noise ratio, shrinkage is limited, and estimation error in these parameters has little effect on coverage). Let us also ignore estimation error in $\delta$ for simplicity, and suppose that the $Y'_i$’s are independent conditional on $(\theta_i, X_i, \sigma_i)$. Then, as $\mu_2/\min_i \sigma_i^2 \to 0$, the weights $\hat{\sigma}_i^{-2}, \hat{\sigma}_i^{-4}$, and $\hat{\sigma}_i^{-8}$, for estimating $\delta, \mu_2$, and $\mu_4$, respectively, become optimal. For simplicity, the baseline implementation in Section 3.2 uses the same weights $\omega_i$ for each of the estimates; the choice $\omega_i = \hat{\sigma}_i^{-2}$ targets optimal estimation of $\delta$. However, one could relax this constraint, and use the weights $\hat{\sigma}_i^{-4}$, and $\hat{\sigma}_i^{-8}$ for estimating $\mu_2$ and $\mu_4$ instead. The choice $\omega_i = 1/n$ has the advantage of simplicity; one may also motivate it by robustness concerns when Eq. (10) fails, though our preferred robustness check is to use nonparametric moment estimates, as outlined in Remark 3.2.

Appendix B Computational details

To simplify the statement of the results below, let $r_0(b, \chi) = r(\sqrt{b}, \chi)$, and put $m_2 = \sigma^2/\mu_2$. The next proposition shows that, if only a second moment constraint is imposed, the maximal
then the solution is given by

$$\rho(m_2, \chi) = \begin{cases} r_0(0, \chi) + \frac{m_2^2}{t_0}(r_0(t_0, \chi) - r_0(0, \chi)) & \text{if } m_2 < t_0, \\ r_0(m_2, \chi) & \text{otherwise.} \end{cases}$$

Here $t_0 = 0$ if $\chi < \sqrt{3}$, otherwise $t_0$ is the unique solution to $r_0(t, \chi) + u \frac{\partial}{\partial u} r_0(u, \chi) = r_0(u, \chi)$.

The proof of Proposition B.1 shows that $\rho(m_2, \chi)$ corresponds to the least concave majorant of the function $r_0$.

The next result shows that, if in addition to a second moment constraint, we impose a constraint on the kurtosis, the maximal non-coverage probability can be computed as a solution to two nested univariate optimizations:

**Proposition B.2.** Suppose $\kappa > 1$ and $m_2 > 0$. Then the solution to the problem

$$\rho(m_2, \kappa, \chi) = \sup_{F} E_F[r(b, \chi)] \quad \text{s.t.} \quad E_F[b^2] = m_2, \ E_F[b^4] = \kappa m_2^2,$$

is given by $\rho(m_2, \kappa, \chi) = r_0(m_2, \chi)$ if $m_2 \geq t_0$, with $t_0$ defined in Proposition B.1. If $m_2 < t_0$, then the solution is given by

$$\inf_{0 < x_0 \leq t_0} \left\{ r_0(x_0, \chi) + (m_2 - x_0)r'_0(x_0, \chi) + ((x_0 - m_2)^2 + (\kappa - 1)m_2^2) \sup_{0 \leq x \leq t_0} \delta(x; x_0) \right\}, \quad (25)$$

where $r'_0(x_0, \chi) = \partial r_0(x_0, \chi) / \partial x_0$, $\delta(x; x_0) = \frac{r_0(x, \chi) - r_0(x_0, \chi) - (x - x_0)r'_0(x_0, \chi)}{(x - x_0)^2}$ if $x \neq x_0$, and $\delta(x_0; x_0) = \lim_{x \to x_0} \delta(x; x_0) = \frac{1}{2} \frac{\partial^2}{\partial x_0^2} r_0(x_0, \chi)$.

If $m_2 \geq t_0$, then imposing a constraint on the kurtosis does not help to reduce the maximal non-coverage probability, and $\rho(m_2, \kappa, \chi) = \rho(m_2, \chi)$.

**Remark B.1 (Least favorable distributions).** It follows from the proof of these propositions that distributions maximizing Eq. (5)—the least favorable distributions for the normalized bias $b$—have two support points if $m_2 \geq t_0$, namely $-\sqrt{m_2}$ and $\sqrt{m_2}$ (since the rejection probability $r(b, \chi)$ depends on $b$ only through its absolute value, any distribution with these two support points maximizes Eq. (5)). If $m_2 < t_0$, there are three support points, $b = 0$, with probability $1 - m_2/t_0$ and $b = \pm \sqrt{t_0}$ with total probability $m_2/t_0$ (again, only the sum of the probabilities is uniquely determined). If the kurtosis constraint is also imposed, then there are four support points, $\pm \sqrt{x_0}$ and $\pm \sqrt{t}$, where $x$ and $x_0$ optimize Eq. (25).
Finally, the characterization of the solution to the general program in Eq. (19) depends on the form of the constraint function $g$. To solve the program numerically, discretize the support of $F$ to turn the problem into a finite-dimensional linear program, which can be solved using a standard linear solver. In particular, we solve the problem

$$\rho_g(m, \chi) = \sup_{p_1, \ldots, p_K} \sum_{k=1}^{K} p_k r(x_k, \chi) \quad \text{s.t.} \quad \sum_{k=1}^{K} p_k g(x_k) = m, \quad \sum_{k=1}^{K} p_k = 1, \quad p_k \geq 0.$$ 

Here $x_1, \ldots, x_K$ denote the support points of $b$, with $p_k$ denoting the associated probabilities.

### Appendix C Coverage results

This Appendix provides coverage results that generalize Theorem 4.1. Appendix C.1 introduces the general setup. Appendix C.2 provides results for general shrinkage estimators that satisfy an approximate normality assumption. Appendix C.3 considers a generalization of our baseline specification in the EB setting, and states a generalization of Theorem 4.1.

#### C.1 General setup and notation

Let $\hat{\theta}_1, \ldots, \hat{\theta}_n$ be estimates of parameters $\theta_1, \ldots, \theta_n$, with standard errors $se_1, \ldots, se_n$. The standard errors may be random variables that depend on the data. We are interested in coverage properties of the intervals $CI_i = \{\hat{\theta}_i \pm se_i \cdot \chi_i\}$ for some $\chi_1, \ldots, \chi_n$, which may be chosen based on the data. In some cases, we will condition on a variable $\tilde{X}_i$ when defining EB coverage or average coverage. Let $\tilde{X}^{(n)} = (\tilde{X}_1, \ldots, \tilde{X}_n)'$ and let $\chi^{(n)} = (\chi_1, \ldots, \chi_n)'$.

As discussed in Section 4.1, the average coverage criterion does not require thinking of $\theta$ as random. To save on notation, we will state most of our average coverage results and conditions in terms of a general sequence of probability measures $\tilde{P} = \tilde{P}^{(n)}$ and triangular arrays $\theta$ and $\tilde{X}^{(n)}$. We will use $E_{\tilde{P}}$ to denote expectation under the measure $\tilde{P}$. We can then obtain EB coverage statements by considering a distribution $P$ for the data and $\theta$, $\tilde{X}^{(n)}$ and an additional variable $\nu$ such that these conditions hold for the measure $\tilde{P}(\cdot) = P(\cdot | \theta, \nu, \tilde{X}^{(n)})$ for $\theta, \nu, \tilde{X}^{(n)}$ in a probability one set. The variable $\nu$ is allowed to depend on $n$, and can include nuisance parameters as well as additional variables.

It will be useful to formulate a conditional version of the average coverage criterion (15), to complement the conditional version of EB coverage discussed in the main text. Due to discreteness of the empirical measure of the $\tilde{X}_i$’s, we consider coverage conditional on each set in some family $A$ of sets. To formalize this, let $\mathcal{I}_{X,n} = \{i \in \{1, \ldots, n\}: \tilde{X}_i \in \mathcal{X}\}$, and let
\( N_{X,n} = \# I_{X,n} \). The sample average non-coverage on the set \( X \) is then given by

\[
ANC_n(\chi; X) = \frac{1}{N_{X,n}} \sum_{i \in I_{X,n}} I\{\theta_i \notin \{\hat{\theta} \pm se_i \cdot \chi_i\}\} = \frac{1}{N_{X,n}} \sum_{i \in I_{X,n}} I\{|Z_i| > \chi_i\},
\]

where \( Z_i = (\hat{\theta}_i - \theta_i)/se_i \). We consider the following notions of average coverage control, conditional on the set \( X \in A \):

\[
ANC_n(\chi; X) \leq \alpha + o_\tilde{P}(1),
\]

and

\[
\lim sup_n E_{\tilde{P}}[ANC_n(\chi; X)] = \lim sup_n \frac{1}{N_{X,n}} \sum_{i \in I_{X,n}} \tilde{P}(|Z_i| > \chi_i) \leq \alpha. \tag{27}
\]

Note that (26) implies (27), since \( ANC_n(\chi; X) \) is uniformly bounded. Furthermore, if we integrate with respect to some distribution on \( \nu, \tilde{X}^{(n)} \) such that (27) holds with \( \tilde{P}(\cdot) = P(\cdot | \theta, \nu, \tilde{X}^{(n)}) \) almost surely, we get (again by uniform boundedness)

\[
\lim sup_n E[ANC_n(\chi; X) | \theta] \leq \alpha,
\]

which, in the case where \( X \) contains all \( \tilde{X}_i \)'s with probability one, is condition (15) from the main text.

Now consider EB coverage, as defined in Eq. (14) in the main text, but conditioning on \( \tilde{X}_i \). We consider EB coverage under a distribution \( P \) for the data, \( \tilde{X}^{(n)}, \theta \) and \( \nu \), where \( \nu \) includes additional nuisance parameters and covariates, and where the average coverage condition (27) holds with \( \tilde{P}(\cdot) = P(\cdot | \theta, \nu, \tilde{X}^{(n)}) \) playing the role of \( \tilde{P} \) with probability one. Consider the case where \( \tilde{X}_i \) is discretely distributed under \( P \). Suppose that the exchangeability condition

\[
P(\theta_i \in CI_i | \mathcal{I}_{\{\tilde{x}\},n}) = P(\theta_j \in CI_j | \mathcal{I}_{\{\tilde{x}\},n}) \text{ for all } i, j \in \mathcal{I}_{\{\tilde{x}\},n} \tag{28}
\]

holds with probability one. Then, for each \( j \),

\[
P(\theta_j \in CI_j | \tilde{X}_j = \tilde{x}) = P(\theta_j \in CI_j | j \in \mathcal{I}_{\{\tilde{x}\},n}) = E[P(\theta_j \in CI_j | \mathcal{I}_{\{\tilde{x}\},n}) | j \in \mathcal{I}_{\{\tilde{x}\},n}] = E\left[\frac{1}{N_{\{\tilde{x}\},n}} \sum_{i \in I_{\{\tilde{x}\}}} P(\theta_i \in CI_i | \mathcal{I}_{\{\tilde{x}\}}) | j \in \mathcal{I}_{\{\tilde{x}\},n}\right].
\]

Plugging in \( P(\cdot | \theta, \nu, \tilde{X}^{(n)}) \) for \( \tilde{P} \) in the coverage condition (27), taking the expectation conditional on \( \mathcal{I}_{\{\tilde{x}\},n} \) and using uniform boundedness, it follows that the lim inf of the term
in the conditional expectation is no less than $1 - \alpha$. Then, by uniform boundedness of this term,

$$\liminf_{n \to \infty} P(\theta_j \in CI_j \mid \tilde{X}_j = \tilde{x}) \geq 1 - \alpha. \quad (29)$$

This is a conditional version of the EB coverage condition (14) from the main text.

## C.2 Results for general shrinkage estimators

We assume that $Z_i = (\hat{\theta}_i - \theta_i)/\sigma_i$ is approximately normal with variance one and mean $b_i$ under the sequence of probability measures $\tilde{P} = \tilde{P}^{(n)}$. To formalize this, we consider a triangular array of distributions satisfying the following conditions.

**Assumption C.1.** For some random variables $\tilde{b}_i$ and constants $b_{i,n}$, $Z_i - \tilde{b}_i$ satisfies

$$\lim_{n \to \infty} \max_{1 \leq i \leq n} \left| \tilde{P}(Z_i - \tilde{b}_i \leq t) - \Phi(t) \right| = 0$$

for all $t \in \mathbb{R}$ and, for all $\mathcal{X} \in \mathcal{A}$ and any $\varepsilon > 0$, $\frac{1}{N_{\mathcal{X},n}} \sum_{i \in I_{\mathcal{X},n}} \tilde{P}(|\tilde{b}_i - b_{i,n}| \geq \varepsilon) \to 0$.

Note that, when applying the results with $\tilde{P}^{(\cdot)}$ given by the sequence of measures $P(\cdot \mid \theta, \nu, \tilde{X}^{(n)})$, the constants $b_{i,n}$ will be allowed to depend on $\theta, \nu, \tilde{X}^{(n)}$.

Let $g : \mathbb{R} \to \mathbb{R}^p$ be a vector of moment functions. We consider critical values $\hat{\chi}^{(n)} = (\hat{x}_1, \ldots, \hat{x}_n)$ based on an estimate of the conditional expectation of $g(b_{i,n})$ given $\tilde{X}_i$, where the expectation is taken with respect to the empirical distribution of $\tilde{X}_i, b_{i,n}$. Due to the discreteness of this measure, we consider the behavior of this estimate on average over sets $\mathcal{X} \in \mathcal{A}$. We assume that there exists a function $m : \mathcal{X} \to \mathbb{R}^p$ that plays the role of the conditional expectation of $g(b_{i,n})$ given $\tilde{X}_i$, along with estimates $\hat{m}_i$ of $m(\tilde{X}_i)$, which satisfy the following assumptions.

**Assumption C.2.** For all $\mathcal{X} \in \mathcal{A}$, $N_{\mathcal{X},n} \to \infty$, $\frac{1}{N_{\mathcal{X},n}} \sum_{i \in I_{\mathcal{X},n}} (g(b_{i,n}) - m(\tilde{X}_i)) \to 0$, and, for all $\varepsilon > 0$, $\frac{1}{N_{\mathcal{X},n}} \sum_{i \in I_{\mathcal{X},n}} \tilde{P}(|\hat{m}_i - m(\tilde{X}_i)| \geq \varepsilon) \to 0$.

**Assumption C.3.** For every $\mathcal{X} \in \mathcal{A}$ and every $\varepsilon > 0$, there is a partition $\mathcal{X}_1, \ldots, \mathcal{X}_J \in \mathcal{A}$ of $\mathcal{X}$ and $m_1, \ldots, m_J$ such that, for each $j$ and all $x \in \mathcal{X}_j$, $m(x) \in B_\varepsilon(m_j)$, where $B_\varepsilon(m) = \{\hat{m} : \|\hat{m} - m\| \leq \varepsilon\}$.

**Assumption C.4.** For some compact set $M$ in the interior of the set of values of $\int g(b)dF(b)$ where $F$ ranges over all probability measures on $\mathbb{R}$, we have $m(x) \in M$ for all $x$.

Let $\rho_g(m, \chi)$ and $\text{cva}_{\alpha,g}(m)$ be defined as in Section 6,

$$\text{cva}_{\alpha,g}(m) = \inf\{\chi : \rho_g(m, \chi) \leq \alpha\} \quad \text{where} \quad \rho_g(m, \chi) = \sup_F E_F[r(b, \chi)] \text{ s.t. } E_F[g(b)] = m.$$
Let $\hat{\chi}_i = \text{cva}_{\alpha,g}(\tilde{m}_i)$. We will consider the average non-coverage $\text{ANC}_n(\hat{\chi}^{(n)}; \mathcal{X})$ of the collection of intervals $\{\hat{\theta}_i \pm \text{se}_i \cdot \hat{\chi}_i\}$.

**Theorem C.1.** Suppose that Assumptions C.1, C.2, C.3 and C.4 hold, and that, for some $j$, $\lim_{b \to \infty} g_j(b) = \lim_{b \to -\infty} g_j(b) = \infty$ and $\inf_b g_j(b) \geq 0$. Then, for all $\mathcal{X} \in \mathcal{A}$,

$$E_{\tilde{P}}\text{ANC}_n(\hat{\chi}^{(n)}; \mathcal{X}) \leq \alpha + o(1).$$

If, in addition, $Z_i - \tilde{b}_i$ is independent over $i$ under $\tilde{P}$, then $\text{ANC}_n(\hat{\chi}^{(n)}; \mathcal{X}) \leq \alpha + o(\tilde{P}(1))$.

### C.3 Empirical Bayes shrinkage toward regression estimate

We now apply the general results in Appendix C.2 to the EB setting. As in Section 3, we consider unshrunk estimates $Y_1, \ldots, Y_n$ of parameters $\theta = (\theta_1, \ldots, \theta_n)'$, along with regressors $X^{(n)} = (X_1, \ldots, X_n)$ and variables $\tilde{X}^{(n)} = (\tilde{X}_1, \ldots, \tilde{X}_n)'$, which include $\sigma_i$ and which play the role of the conditioning variables. (While Section 3 uses $X_i, \sigma_i$ as the conditioning variable $\tilde{X}_i,$ here we generalize the results by allowing the conditioning variables to differ from $X_i.$) The initial estimate $Y_i$ has standard deviation $\sigma_i,$ and we observe an estimate $\hat{\sigma}_i.$ We obtain average coverage results by considering a triangular array of probability distributions $\tilde{P} = \tilde{P}^{(n)}$, in which the $X_i$’s, $\sigma_i$’s and $\theta_i$’s are fixed. EB coverage can then be obtained for a distribution $P$ of the data, $\theta$ and some nuisance parameter $\tilde{\nu}$ such that these conditions hold almost surely with $P(\cdot | \theta, \tilde{\nu}, \tilde{X}^{(n)}, X^{(n)})$ playing the role of $\tilde{P}$.

We consider the following generalization of the baseline specification considered in the main text. Let

$$\hat{\theta}_i = \hat{X}_i' \hat{\delta} + w(\hat{\gamma}, \hat{\sigma}_i)(Y_i - \hat{X}_i' \hat{\delta})$$

where $\hat{X}_i$ is an estimate of $X_i$ (we allow for the possibility that some elements of $X_i$ are estimated rather than observed directly, which will be the case, for example, when $\sigma_i$ is included in $X_i$), $\hat{\delta}$ is any random vector that depends on the data (such as the OLS estimator in a regression of $Y_i$ on $X_i$), and $\hat{\gamma}$ is a tuning parameter that determines shrinkage and may depend on the data. This leads to the standard error $\text{se}_i = w(\hat{\gamma}, \hat{\sigma}_i) \hat{\sigma}_i$ so that the $t$-statistic is

$$Z_i = \frac{\hat{\theta}_i - \theta_i}{\text{se}_i} = \frac{\hat{X}_i' \hat{\delta} + w(\hat{\gamma}, \hat{\sigma}_i)(Y_i - \hat{X}_i' \hat{\delta}) - \theta_i}{w(\hat{\gamma}, \hat{\sigma}_i) \hat{\sigma}_i} = \frac{Y_i - \theta_i}{\hat{\sigma}_i} + \frac{[w(\hat{\gamma}, \hat{\sigma}_i) - 1](\theta_i - \hat{X}_i' \hat{\delta})}{w(\hat{\gamma}, \hat{\sigma}_i) \hat{\sigma}_i}.$$

We use estimates of moments of order $\ell_1 < \cdots < \ell_p$ of the bias, where $\ell_1 < \cdots < \ell_p$ are positive integers. Let $\hat{\mu}_\ell$ be an estimate of the $\ell$th moment of $(\theta_i - X_i' \hat{\delta})$, and suppose that this moment is independent of $\sigma_i$ in a sense formalized below. Then an estimate of the $\ell$th
moment of the bias is $\hat{m}_{i,j} = \frac{[w(\gamma, \delta_i) - 1]^{\ell_j}}{w(\gamma, \delta_i)^{\ell_j}} \mu_{ij}$. Let $\hat{m}_i = (\hat{m}_{1}, \ldots, \hat{m}_p)'$. The EBCI is then given by $\hat{\theta}_i = w(\gamma, \delta_i) \hat{\sigma}_i \cdot \text{cva}_{\alpha, g}(\hat{m}_i)$ where $g_j(b) = b^{\ell_j}$. We obtain the baseline specification in Section 3.2 when $p = 2$, $\ell_1 = 2$, $\ell_2 = 4$, $\gamma = \hat{\mu}_2$ and $w(\hat{\mu}_2, \sigma_i) = \hat{\mu}_2/(\hat{\mu}_2 + \sigma_i^2)$.

We make the following assumptions.

**Assumption C.5.**

$$\lim_{n \to \infty} \max_{1 \leq i \leq n} \left| \hat{P} \left( \frac{Y_i - \theta_i}{\sigma_i} \leq t \right) - \Phi(t) \right| = 0.$$ 

We give primitive conditions for Assumption C.5 in Supplemental Appendix D.1, and verify them in a linear fixed effects panel data model. The primitive conditions involve considering a triangular array of parameter values such that sampling error and empirical moments of the parameter value sequence are of the same order of magnitude, and defining $\theta_i$ to be a scaled version of the corresponding parameter.

**Assumption C.6.** The standard deviations $\sigma_i$ are bounded away from zero. In addition, for some $\delta$ and $\gamma$, $\hat{\delta}$ and $\hat{\gamma}$ converge to $\delta$ and $\gamma$ under $\hat{P}$, and, for any $\varepsilon > 0$,

$$\lim_{n \to \infty} \max_{1 \leq i \leq n} \hat{P}(|\hat{\sigma}_i - \sigma_i| \geq \varepsilon) = 0 \quad \text{and} \quad \lim_{n \to \infty} \max_{1 \leq i \leq n} \hat{P}(|\hat{X}_i - X_i| \geq \varepsilon) = 0.$$ 

**Assumption C.7.** The variable $\hat{X}_i$ takes values in $\mathcal{S}_1 \times \cdots \times \mathcal{S}_s$ where, for each $k$, either $\mathcal{S}_k = [x_k, x_k]$ (with $-\infty < x_k < x_k < \infty$) or $\mathcal{S}_k$ is a finitely discrete set with minimum element $x_k$ and maximum element $x_k$. In addition, $\hat{X}_{i1} = \sigma_i$ (the first element of the set is given by $\sigma_i$). Furthermore, for some $\mu_0$ such that $(\mu_{0, \ell_1}, \ldots, \mu_{0, \ell_p})$ is in the interior of the set of values of $\int g(b) \, dF(b)$ where $F$ ranges over probability measures on $\mathbb{R}$ where $g_j(b) = b^{\ell_j}$ and some constant $K$, the following holds. Let $\mathcal{A}$ denote the collection of sets $\tilde{S}_1 \times \cdots \times \tilde{S}_s$ where $\tilde{S}_k$ is a positive Lebesgue measure interval contained in $[x_k, x_k]$ in the case where $\mathcal{S}_k = [x_k, x_k]$, and $\tilde{S}_k$ is a nonempty subset of $\mathcal{S}_k$ in the case where $\mathcal{S}_k$ is finitely discrete. For any $\mathcal{X} \in \mathcal{A}$, $N_{X,n} \to \infty$ and

$$\frac{1}{N_{X,n}} \sum_{i \in \mathcal{I}_{X,n}} (\theta_i - X_\ell \delta^{\ell_j}) \to \mu_{0, \ell_j}, \quad \frac{1}{N_{X,n}} \sum_{i \in \mathcal{I}_{X,n}} |\theta_i|^{\ell_j} \leq K, \quad \text{and} \quad \frac{1}{N_{X,n}} \sum_{i \in \mathcal{I}_{X,n}} \|X_i\|^{\ell_j} \leq K.$$ 

In addition, the estimate $\hat{\mu}_{\ell_j}$ converges in probability to $\mu_{0, \ell_j}$ under $\hat{P}$ for each $j$.

**Theorem C.2.** Let $\hat{\theta}_i$ and $\sigma_i$ be given above and let $\hat{\chi}_i = \text{cva}_{\alpha, g}(\hat{m}_i)$ where $\hat{m}_i$ is given above and $g(b) = (b^{\ell_1}, \ldots, b^{\ell_p})$ for some positive integers $\ell_1, \ldots, \ell_p$, at least one of which is even. Suppose that Assumptions C.5, C.6 and C.7 hold, and that $w()$ is continuous in an open set containing $\{\gamma\} \times \mathcal{S}_1$ and is bounded away from zero on this set. Let $\mathcal{A}$ be as given
in Assumption C.7. Then, for all $X \in \mathcal{X}$, $E_{\tilde{P}} \text{ANC}_n(\hat{\chi}^{(n)}; X) \leq \alpha + o(1)$. If, in addition, $(Y_i, \hat{\sigma}_i)$ is independent over $i$ under $\tilde{P}$, then $\text{ANC}_n(\hat{\chi}^{(n)}; X) \leq \alpha + o_{\tilde{P}}(1)$.

As a consequence of Theorem C.2, we obtain, under the exchangeability condition (28), conditional EB coverage, as defined in Eq. (29), for any distribution $P$ of the data and $\theta, \nu$ such that the conditions of Theorem C.2 hold with probability one with the sequence of probability measures $P(\cdot | \theta, \nu; X^{(n)}, \tilde{X}^{(n)})$ playing the role of $\tilde{P}$. This follows from the arguments in Appendix C.1.

**Corollary C.1.** Let $\theta, \nu, X^{(n)}, \tilde{X}^{(n)}, Y_i$ follow a sequence of distributions $P$ such that the conditions of Theorem C.2 hold with $\tilde{X}_i$ taking on finitely many values, and $P(\cdot | \theta, \nu; X^{(n)}, \tilde{X}^{(n)})$ playing the role of $\tilde{P}$ with probability one, and such that the exchangeability condition (28) holds. Then the intervals $CI_i = \{\hat{\theta}_i \pm w(\hat{\gamma}, \hat{\sigma}_i) \hat{\sigma}_i \cdot \text{cva}_{\alpha,g} (\hat{m}_i)\}$ satisfy the conditional EB coverage condition (29).

The first part of Theorem 4.1 (average coverage) follows by applying Theorem C.2 with the conditional distribution $P(\cdot | \theta)$ playing the role of $\tilde{P}$. The second part (EB coverage) follows immediately from Corollary C.1.
